Singularities in Hermitian pluripotential theory

Working draft, October 13, 2026

Introduction

A singular potential can be studied through its growth near its poles, through the holomorphic functions that remain integrable there, or through its Monge–Ampère measure. These descriptions lead to ordinary singularity types, multiplier ideals and curvature measures. Global pluripotential theory relates them and asks which singularities can be approximated by analytic ones. This book develops that theory for Hermitian backgrounds, starting from *Singularities in global pluripotential theory* [Xia].

In a fixed Kähler class, all bounded potentials have the same Monge–Ampère mass. The non-pluripolar mass of a singular potential can therefore be compared with a fixed total mass, and this comparison connects analytic approximation, envelopes and energy. A nonclosed Hermitian background changes this relation at its first step: the mass can vary even among smooth potentials. Ordinary singularity type, which identifies potentials with bounded difference, no longer determines a single mass. Envelopes and multiplier ideals remain available, but their connection to mass requires different arguments.

This loss of closedness is distinct from the geometry of the manifold. A non-Kähler manifold can carry closed positive currents, and a Kähler manifold can be equipped with a nonclosed Hermitian form. Let X be a connected compact complex manifold of dimension $n \geq 1$, and let θ be a smooth real $(1,1)$-form on X. A function u is θ-plurisubharmonic if it is locally the sum of a plurisubharmonic function and a smooth function and the current $\theta_u = \theta + \mathrm{dd}^{\mathrm{c}} u$ is positive. If θ is closed, this current is locally a complex Hessian. For a general background, a smooth local correction still makes u plurisubharmonic, but leaves a smooth remainder in the current. Compactness, regularization and multiplier ideals thus survive locally; the new difficulties arise when these constructions are related globally.

Closedness, mass and energy

Let ω be a Hermitian form on X, that is, a smooth strictly positive $(1,1)$-form. If ω is Kähler, every smooth real potential u with $\omega + \mathrm{dd^c} u > 0$ satisfies

$$\int_X (\omega + \mathrm{dd^c} u)^n = \int_X \omega^n.$$

The identity extends to bounded ω-plurisubharmonic potentials. For singular potentials, the non-pluripolar product can have smaller total mass, and the difference measures the mass excluded at the poles.

For a general Hermitian form, integration by parts gives instead

$$\int_X (\omega + \mathrm{dd^c} u)^n - \int_X \omega^n = \sum_{k=1}^{n-1} \binom{n}{k} \int_X u (\mathrm{dd^c} u)^{k-1} \wedge \mathrm{dd^c}(\omega^{n-k})$$

for every smooth u. The derivatives of the background already affect the mass before singularities appear. Chapter 2 proves that mass invariance is equivalent to $\mathrm{dd^c}(\omega^j) = 0$ for $1 \le j \le n-1$. The usual global comparison inequality would force this invariance, so a comparison argument in an arbitrary Hermitian background must account for these derivatives.

Once mass varies, its upper and lower bounds become separate questions. The scalar Hopf manifolds of dimension at least three have unbounded masses of smooth potentials with positive perturbed form, while the standard Hopf threefold has a positive infimum of those masses. A different compact threefold carries a balanced metric with bounded masses whose infimum is zero (Chapter 8 and Section 26.18). Neither bound follows from the other. The envelope and measure constructions below accommodate this variation; Part IX develops volume comparison and equation theory under explicit mass bounds.

Mass conservation does not by itself restore the Kähler energy. At a smooth potential u with $\omega + \mathrm{dd^c} u > 0$, consider the one-form

$$\alpha_u(v) = \int_X v (\omega + \mathrm{dd^c} u)^n$$

on the space of such potentials, where v is a smooth real tangent direction. For a Kähler form, it is the differential of the Monge–Ampère energy. In dimension at least two, a primitive even near the zero potential forces $\mathrm{d}\omega = 0$ (Theorem 3.1.1). On a non-Kähler surface, a Gauduchon metric conserves mass but has no such primitive. Perron interpolation and Legendre duality can still be constructed by envelopes; an interpretation through a metric energy needs a separate justification.

A Gauduchon metric supplies a conserved linear trace in place of the varying nonlinear mass. Its form γ satisfies $\mathrm{dd^c}(\gamma^{n-1}) = 0$, and hence, for every θ-plurisubharmonic potential,

$$\int_X (\theta + \mathrm{dd^c} u) \wedge \gamma^{n-1} = \int_X \theta \wedge \gamma^{n-1}.$$

This trace measure determines u up to an additive constant. In a fixed background, for a smooth positive volume form $\mathrm{d}V$ and the normalization $\int_X u\,\mathrm{d}V = 0$, weak convergence of trace measures is equivalent to L^1 convergence of potentials (Chapter 5). The trace stays finite even when the nonlinear Monge–Ampère mass is infinite. Extended non-pluripolar products and finite damped measures make it possible to study such potentials, while passage from damped to undamped measures requires control near the poles.

Singularity types and envelopes

Multiplier ideals record the holomorphic functions locally square integrable against e^{-ku}, for every $k > 0$. This gives a second equivalence relation on potentials, coarser than ordinary singularity type. To compare the two, fix $u \in \mathrm{PSH}(X, \theta)$ and take envelopes in the same background. The ordinary envelope $P_\theta[u]$ is the upper semicontinuous regularization of the supremum of the θ-plurisubharmonic $h \leq 0$ with $h \leq u + C$ for some constant C. The multiplier-ideal envelope $P_\theta[u]_{\mathcal{I}}$ uses instead the $h \leq 0$ with the same multiplier ideals as u at every positive weight.

In a closed big class on a compact Kähler manifold, for potentials of positive mass, the equality of these two envelopes characterizes $\mathcal{I}$-good singularities and is equivalent to a mass identity and approximation by analytic singularities. In the Hermitian setting, analytic approximation still relates the envelopes even when a mass identity is unavailable. Correcting the curvature errors keeps the dyadic approximants in a positive Hermitian background, and their envelopes decrease to the multiplier-ideal envelope. In such a positive background, comparing the two envelopes defines a uniform topology on ordinary classes in which their equality characterizes the closure of the analytic classes, including classes with infinite-mass representatives (Theorem 16.6.1). This topology can identify distinct ordinary classes.

The obstacle in an envelope is part of this construction. A smooth change $\theta \mapsto \theta + \mathrm{dd}^{\mathrm{c}}\chi$ transforms potentials by $u \mapsto u - \chi$ and transforms their obstacles as well. Keeping only the obstacle zero need not give an invariant topology; allowing all smooth obstacles does. Whether equality of the envelopes at zero implies equality at every smooth obstacle is therefore a substantive question. It holds in a smooth big background with bounded mass when the multiplier-ideal envelope has positive lower volume, as well as on curves and on certain product loci without those volume conditions (Proposition 30.8.1 and Corollaries 16.6.8 and 30.13.1). The general case at zero volume remains open.

Envelopes and mass give complementary ways to compare singularities. An ordinary model is a fixed point $P_\theta[u] = u$, and the infimum and supremum of mass over an ordinary type define its lower and upper singularity volumes. These volumes need not agree. In a smooth big background with bounded mass, volume comparison gives a completely metrizable topology on the models of positive lower volume. At zero volume, the comparison can fail to distinguish models, so an extension must retain information that mass has lost.

On curves, the polar curvature—the part of $\theta + \mathrm{dd^c} u$ carried by the pole set—determines a model. Total variation of this measure gives a complete metric that includes zero-volume models, with the ideal models as the closure of the analytic models. The construction extends to certain higher-dimensional product loci without an ambient mass bound (Proposition 16.6.19). A general higher-dimensional model contains more information: residual top-degree mass may lie on a diffuse pole set although every polar curvature current on every modification vanishes. Distinct models can even have the same residual measure and both volumes, while their comparison distance is positive (Proposition 16.6.34). Thus a classification by measures already has limitations in closed Kähler backgrounds.

Restriction raises a related question. A potential may be identically $-\infty$ on a submanifold even though its generic Lelong number there is zero. In this case, the restrictions of its ambient multiplier ideals define finite divisorial data on every modification. Trace envelopes turn this data into constraints on potentials of the submanifold. Exact realization is possible on curves and in sufficiently large backgrounds on Kähler targets, and projective pullback data also admit exact realizations on Hopf manifolds of unbounded mass (Theorem 19.8.1). Thus failure of a mass bound does not itself prevent realization. Exact divisorial data nevertheless need not determine the Monge–Ampère mass, or a single ordinary type.

Equations with prescribed data

The varying mass also changes the normalization of an equation. Given a smooth real function F on X, one seeks a smooth pair (u, c) satisfying

$$(\omega + \mathrm{dd^c} u)^n = c\, \mathrm{e}^F \, \mathrm{d}V, \qquad \omega + \mathrm{dd^c} u > 0, \qquad \sup_X u = 0.$$

In a Kähler background, integration determines $c > 0$ before solving for u. In a Hermitian background the left-hand mass depends on the unknown potential, so the constant must be found together with it. Such a smooth pair exists and is unique. The linearization gives an adjoint Gauduchon probability measure describing the variation of $\log c$ with the density, and leads to a variational volume defined by Gauduchon test forms. This volume remains finite even on manifolds with unbounded upper Monge–Ampère mass.

Positive variational volume, however, need not imply that a background is big, meaning that it admits a potential ρ with $\theta + \mathrm{dd^c} \rho \geq \delta \omega$ for some $\delta > 0$. A nef nonclosed background on a projective manifold has positive variational volume and fails this condition (Theorem 26.13.1). Up to a smooth change of representative, the same example occurs at a finite maximal Chern–Ricci time (Theorem 26.20.3). An argument for geometric convergence that needs bigness therefore cannot substitute positive variational volume for it.

For a nonnegative, nonzero L^p density, $p > 1$, continuous solutions still exist and the positive constant is still unique, but uniqueness of the potential is a separate matter.

A smooth density with zeros may have distinct normalized smooth solutions. For a continuous density whose positive set is connected and dense, bounded solutions are unique up to constants (Theorem 11.4.1). Selection by approximation must also be distinguished from uniqueness. Moreover, when singularities are prescribed, distinct divisorial types can have the same normalization functional and supporting Gauduchon probabilities (Chapter 15); the scalar response does not recover the full type.

Replacing the determinant by an intermediate elementary symmetric polynomial leads to the Hessian measure $H_m(u) = (\omega + \mathrm{dd^c}u)^m \wedge \omega^{n-m}$, for $2 \leq m < n$. Its admissible cone permits negative eigenvalues of the perturbed form, so bounded products require capacity estimates beyond the plurisubharmonic calculus. Derivatives of the background again obstruct the usual comparison inequality. Rescaling one potential and working on a sufficiently small sublevel set, however, allows the torsion error to be absorbed. The resulting modified comparison gives strict domination on an arbitrary Hermitian background. For example, for every $a > 0$ and smooth real F, the equation $H_m(u) = \mathrm{e}^{au+F}\omega^n$ has exactly one bounded admissible solution, and it is smooth (Corollary 12.12.2). Thus the increasing dependence on the potential can recover uniqueness and regularity even when mass is not conserved.

To prescribe singularities as well as the measure, one fixes a reference potential and uses relative envelopes to control the solution. For general finite non-pluripolar measures, Part IX proves existence in two regimes: semipositive big backgrounds of positive lower mass, with a model reference admitting a competitor in a smaller background, and arbitrary smooth big backgrounds of bounded mass, with a model reference of positive lower volume. These solutions belong to a relative envelope class. Membership in the prescribed ordinary type requires the stronger conclusion that their difference from the reference is bounded; additional estimates give this conclusion for suitable data.

Geometric constructions

Logarithmic poles give concrete tests of the theory. On a resolution, removing a prescribed divisorial pole can leave a strictly positive residual form, where a bounded equation determines the remaining potential. A divisor forced by the background behaves differently: it belongs to the type of minimal singularities, and removing it can force the current to descend. The constructions in Sections 14.21 and 14.22 distinguish a freely prescribed pole from such a compulsory one.

The regularity of a potential also affects the geometry of its current. When that current is smooth and strictly positive off an analytic set, a Hölder potential places the analytic set at finite distance, making the regular metric incomplete if the set is nonempty (Theorem 1.18.1). Boundedness alone is insufficient: radial examples in closed Kähler classes have continuous minimal residuals and complete regular ends. The integral controlling the potential differs from the one controlling path length. This distinction comes from regularity, even before closedness is lost.

Holomorphic sections link singularities to geometry through a closed line-bundle curvature, so counting sections cannot measure an arbitrary Hermitian Monge–Ampère mass. Gauduchon degrees control section growth and flag valuations, while fibrations can concentrate equilibrium measures on a lower-dimensional base. Partial Bergman kernels connect these section spaces to envelopes of singular weights. Closed Bott–Chern classes and locally conformally Kähler structures give further settings where the differential constraints can be used more precisely.

Reading the book

We assume familiarity with complex manifolds, differential forms and currents. Chapter 1 develops the plurisubharmonic tools used throughout. On a first reading, the maximum principle, normalized compactness and exponential integrability are the starting points; the longer approximation and descent arguments can be consulted when needed. The mass and energy calculations explain the obstructions above, and Gauduchon traces, non-pluripolar products and the Hopf construction complete the foundations.

The equation chapters develop smooth and weak estimates and comparison principles; the Hessian chapter examines how these arguments change when positivity is weakened. Envelopes and analytic approximation then develop the comparison of ordinary and ideal types; interpolation, restriction and holomorphic sections connect it to geometry. Part IX gives the volume and equation theory under mass hypotheses. The appendix explains descent to compact unibranch spaces and solves equations on cones, normalized curves and cuspidal products. Open questions are collected in Chapter 33, and the sources and precise dependencies in Chapter 34; monograph references also appear where they are used.

8.2 The radial–vertical block 283
8.3 Heat potentials and the mixed derivative 284
8.4 Variation of the heat time 287
8.5 A base correction and unbounded mass 291
8.6 Higher-dimensional Hopf manifolds 292
8.7 Minimum mass and fiber averaging 294
8.8 Sharp damping under unitary rotations 296
8.8.1 Positive fiber flux 296
8.8.2 Heat concentration at large depth 299
8.8.3 Concentration at the critical weight 306
8.9 Limits of shrinking smooth potentials 308
8.9.1 Positive quadratic measures 309
8.9.2 Orbital mixtures 309
8.9.3 Fiber measures 311
8.9.4 Changing the Hermitian metric 314

Part II Monge–Ampère and Hessian equations

9 Smooth Monge–Ampère equations 319
9.1 Scalar bounds and uniqueness 320
9.2 The potential bound from weighted integration 321

9.3 The linearized equation and smooth dependence 324
9.4 Second derivatives and ellipticity 325
9.5 The continuity method 329
9.6 The smooth exponential equation 330
9.7 Variation of the normalization scalar 331
9.8 Normalization on the Hopf threefold 333
9.9 Prescribing a Gauduchon volume form 335
9.10 Bounds for the Gauduchon potential 336
9.11 The adjoint equation for Gauduchon volume 339
9.12 The matrix structure of the Gauduchon equation 341
9.13 The largest-eigenvalue estimate 344
9.14 A Liouville theorem for the limiting cone 351
9.15 The gradient bound by rescaling 355
9.16 Existence for the Gauduchon ansatz 357
9.17 Normalization for the Gauduchon equation 359

10 Continuous solutions and normalization 363
10.1 Continuous solvability 364
10.2 The modified comparison principle 364
10.3 Capacity estimates and uniform compactness 367
10.3.1 Stability under a power capacity bound 370
10.4 Construction of continuous solutions 371
10.5 Smoothness of bounded solutions 373
10.6 The vanishing exponent and scalar uniqueness 376
10.7 Normalization on the Hopf threefold 377
10.8 Stability for concave equations 381
10.9 Gradient bounds for concave equations 385

11 Uniqueness for degenerate equations 391
11.1 Extrema and density sublevels 392
11.1.1 A square-root threshold 396
11.2 Polarized cofactors and propagation 397
11.2.1 Weighted energy 398
11.2.2 The real symbol and exterior-ball propagation 398
11.2.3 The unweighted energy defect 401
11.3 Integral rigidity in dimensions two and three 402
11.4 Bounded uniqueness and connectedness 404
11.4.1 The energy of the difference 405
11.4.2 Concentrating smooth test potentials 409
11.5 Comparison and invariant mass 411
11.6 Smooth nonuniqueness for a degenerate density 414
11.6.1 Three rank-one directions 414
11.6.2 The scalar coefficients 415
11.6.3 Two forms with the same cube 416
11.6.4 Restoring strict positivity of the background 417
11.6.5 A continuum of radial solutions 418

11.7 Nonuniqueness with a zero set of empty interior 420
11.8 Quadratic density zeros 424
11.9 A real analytic density 428
11.9.1 Prescribing the determinant 429
11.9.2 Extension over the projective ends 430
11.9.3 A positive equation background 431
11.9.4 Zeros and higher dimensions 431

12 Complex Hessian equations 433
12.1 The admissible cone 434
12.2 Liouville and gradient estimates 440
12.3 A trace estimate with a prescribed potential 444
12.4 Bounded complex Hessians and elliptic extensions 451
12.5 Proper equations and admissible approximation 454
12.5.1 Decreasing approximation of bounded potentials 456
12.6 Continuous products, envelopes and domination 458
12.7 Continuous equations and regularity 462
12.8 Bounded potentials and recursive Hessian currents 465
12.9 Sobolev capacity and two Hessian factors 470
12.10 Local capacities and decreasing products 475
12.11 Locality and maxima of bounded potentials 484
12.12 Hessian mass and global comparison 488
12.12.1 Modified comparison 491
12.12.2 Domination and proper equations 494

Part III Relative singularities and equations

13 Envelopes and volumes of singularities 499
13.1 Contact sets 500
13.1.1 Affine growth and projective envelopes 504
13.2 Bounded domination in a semipositive background 519
13.3 Upper and lower volumes 521
13.4 Relative envelope classes 523
13.5 Model references and positive mass 525
13.6 Infinite mass inside the envelope class 527

14 Equations with prescribed singularities 529
14.1 Domination with a smaller background 531
14.2 Bounded equations in a semipositive big background 533
14.2.1 The exponential equation 534
14.2.2 The normalized equation 535
14.3 A quantitative stability estimate 538
14.4 Hölder continuity from bounded stability 540
14.4.1 Regularity for a measure with a Hölder reference 542
14.5 Local continuity in a semipositive big background 543
14.6 Homogeneous replacement on a coordinate ball 545

14.7 Contact support in a big background 548
14.7.1 Quasi-continuous obstacles 550
14.8 Compactness with a common lower barrier 552
14.9 A bounded subsolution theorem 555
14.10 Adding weighted Monge–Ampère measures 557
14.11 Equations in a prescribed ordinary type 559
14.11.1 Existence for a positive exponent 562
14.11.2 The normalized equation 564
14.12 Comparison above a strict singular barrier 565
14.13 Subsolutions and the Gauduchon trace 568
14.14 Stability above a strict barrier 570
14.15 Minimal singularities in an arbitrary big background 572
14.16 Local Hölder continuity in a big background 577
14.16.1 Limits of normalized exponential solutions 578
14.17 Interior smoothness on the regular locus 580
14.17.1 Local comparison 581
14.17.2 Bounded traces and smoothness 583
14.17.3 Smooth exact approximants 585
14.17.4 Localization near the nonregular set 590
14.17.5 Derivative estimates and bounded traces 593
14.17.6 Proof of the main theorem 597
14.18 Degenerating semipositive backgrounds 598
14.18.1 Small resolutions of nodes 603
14.18.2 Measures and bounded potentials at a node 605
14.18.3 Distances across finitely many contracting regions . . . 607
14.19 Symmetry and the selected projective limit 616
14.19.1 The invariant projective solution 618
14.19.2 Second derivatives at positive exponent 622
14.20 Local density and boundary control 623
14.20.1 Smooth boundary traces 624
14.20.2 A bounded discontinuous potential 625
14.20.3 Compact gluing 627
14.21 Equations with resolved logarithmic poles 629
14.21.1 Residual mass 632
14.22 Minimal singularities on blowups 632
14.23 Representing measures in an ordinary type 637
14.24 The homogeneous equation with a Hölder reference 639
14.25 Singular measures on shrinking spheres 641
14.26 Lower mass and solvability for all measures 643
14.27 Subsolutions for an individual density 647
14.27.1 The greatest normalized threshold subsolution 649
14.27.2 Smooth comparison tests 650
14.28 Gauduchon tests for integrable densities 652
14.29 Exact equations on products with zero lower mass 655
14.29.1 Closed factors and arbitrary integrable densities 659

14.30 Singular measures on products with a curve 661
14.30.1 The logarithmic potential and its measure trace 661
14.30.2 Exponential equations and uniform selection on the curve 664
14.30.3 The product equation and its maximal coefficient 666
14.31 Stability of the subsolution threshold 669
14.31.1 Finite sums of densities 670
14.31.2 Approximation by bounded density roots 672
14.31.3 Density roots from a closed factor 674
14.32 Power capacity bounds and threshold equations 675
14.32.1 A logarithmic density with critical coefficient one 677
14.33 Limits of exponential equations 679
14.33.1 A positive limiting exponent 680
14.34 Exponential equations for an individual density 681
14.34.1 An error bound for the scalar limit 683
14.34.2 Exponential equations at zero threshold 685
14.34.3 Solvable exponents and collapse at zero threshold 689
14.34.4 Positive endpoints and one-sided limits 690
14.35 Radial selection for integrable densities 694
14.35.1 Separation and the radial flux 694
14.35.2 The normalized limit 695
14.35.3 Scalar centering and its moment boundary 697
14.35.4 Order in the separated class 699

15 Normalization and weak adjoint measures 701
15.1 The scalar functional 701
15.2 Supporting probability measures 704
15.2.1 Directional derivatives 705
15.2.2 Generic uniqueness 706
15.2.3 Gauduchon adjoints 707
15.2.4 Continuous positive complex Hessians 708
15.2.5 Products with a Hermitian factor 709
15.2.6 Divisorial smoothing 711
15.3 A convex functional on probability measures 718
15.4 Bounded measurable densities and stability 720
15.5 Entropy and the closed case 721
15.6 Entropy bounds 723
15.6.1 The mass bounds as entropy differences 724
15.6.2 Entropy for a prescribed ordinary type 725
15.7 Changing the prescribed singularities 726
15.7.1 Uniform comparison of the scalar functionals 727
15.8 Varying positive backgrounds 729
15.9 Divisorial types and moving sections 731
15.9.1 One-sided divisorial classes and sharp thresholds 734
15.10 The mass determined by the functional 737

15.11 Convex-body criteria for varying references 740
15.11.1 Canonical models and their mass 741
15.11.2 Hausdorff control of the functional 743
15.11.3 A family with nonanalytic isolated poles 744
15.11.4 Positive mass with a degenerate smooth residual 746
15.12 Selection by a vanishing exponential parameter 748
15.12.1 A norm defined by the critical scalar 749
15.12.2 Norming probabilities and integral bounds 750
15.12.3 Bounds for the centered potentials 753
15.12.4 Scalar envelopes of subsolutions 754
15.13 Selection for logarithmic models on products 756
15.13.1 The ordinary model and the greatest solutions 757
15.13.2 The selected limit with varying data 759
15.13.3 The critical coefficient and separated order 762
15.13.4 Weak adjoints on a product surface 763
15.14 Residual regularity in radial singularity types 767
15.14.1 The prescribed ordinary type 767
15.14.2 Density criterion and exact inverse 769
15.14.3 Smooth residuals from flat errors 771
15.14.4 Compact examples and sharp derivative thresholds . . . 772
15.14.5 Smooth residuals with an open density-zero annulus . . 772
15.14.6 Products with a zero-lower-mass factor 773
15.15 Envelopes for singular radial obstacles 774
15.15.1 The convex minorant and its residual 774
15.15.2 Uniform bounds through moving contact 777
15.15.3 The full envelope on a Hermitian product 778

16 Multiplier-ideal envelopes and $\mathcal{I}$-goodness 781
16.1 The Kähler characterization 782
16.2 Ideal projection 782
16.2.1 Analytic and divisorial singularities 785
16.3 Changes of background and envelope mass 786
16.3.1 Envelope equality and infinite mass 787
16.4 L^1 geometry of ideal classes 787
16.4.1 Completion on a curve 788
16.4.2 Mass and capacity convergence 790
16.4.3 Comparison with scalar normalization 792
16.5 Limits of analytic envelopes 792
16.5.1 Dyadic regularization 795
16.5.2 Absorbing the curvature error 796
16.6 A topology on ordinary singularity types 797
16.6.1 Analytic closure 799
16.6.2 Separation and mass 800
16.6.3 Transport with an obstacle 801
16.6.4 All smooth obstacles 803

16.6.5 Countable poles and all obstacles . . . 807
16.6.6 Relative divisors and fiber obstacles . . . 810
16.6.7 Divisorial products and zero volume . . . 822
16.6.8 Several curve factors . . . 829
16.6.9 Varying the curve coefficients . . . 835
16.6.10 Arbitrary curve backgrounds . . . 840
16.6.11 Equality below all obstacles on separated products . . . 844
16.6.12 Auxiliary compact complex factors . . . 846
16.6.13 A polar metric in a background with unbounded mass 850
16.6.14 Models over a curve . . . 851
16.6.15 Finite curve factors . . . 855
16.6.16 Models pulled back by a finite curve map . . . 857
16.6.17 Hopf surface fibers and unbounded ambient mass . . . 860
16.6.18 Complete model topologies . . . 862
16.7 Small curvature and strict ordinary types . . . 890

Part IV Interpolation and restriction

17 Perron interpolation and the geodesic equation . . . 895
17.1 Subgeodesics and endpoint bounds . . . 896
17.2 Perron segments . . . 897
17.3 The smooth product equation . . . 899
17.4 The L^2 action and torsion . . . 900
17.5 Basic finite energy potentials on a Hopf manifold . . . 901
17.6 Negative directions of the raw action . . . 905
17.7 Explicit basic geodesics and singular potentials . . . 907
17.8 Model projection and test curves . . . 909

18 Test curves and Legendre duality . . . 911
18.1 Envelope test curves and rays . . . 911
18.2 Perron maximality . . . 912
18.3 Recovering the singularity envelopes . . . 914
18.4 A logarithmic pole on the projective line . . . 915

19 Restriction and intrinsic trace data . . . 919
19.1 Restricted ideals and trace data . . . 920
19.2 Comparison with ordinary restriction . . . 922
19.2.1 Logarithmic divisors with a small-curvature residual . 923
19.3 Realization on a compact curve . . . 924
19.4 The Poisson equation in the atomic trace type . . . 926
19.5 Singularity distance on a curve . . . 927
19.5.1 Total variation of the atomic data . . . 928
19.6 The trace envelope . . . 930
19.6.1 Limits of restricted analytic envelopes . . . 931
19.6.2 Envelopes on modifications . . . 933
19.6.3 Exact realization on a Kähler submanifold . . . 935

19.6.4 Positive mass and prescribed equations 936
19.7 Exact traces over a curve 937
19.8 Exact traces on Hopf manifolds 939
19.8.1 Divisors under a dominant map 940
19.8.2 The full trace envelope 942
19.8.3 Mass and the ideal class 943
19.8.4 Decreasing analytic models 945
19.9 Product realizations and their measures 946
19.10 Ordinary trace volumes on a nonclosed ruled surface 949
19.10.1 Ambient ideal orders and ordinary type 952
19.10.2 Pullback and strict representatives 952

Part V Holomorphic sections and geometric models

20 Holomorphic sections and Hermitian mass 957
20.1 Weighted sections and Bergman currents 958
20.2 Gauduchon degree and vanishing 960
20.3 Restricted sections and trace data 961
20.4 Bounded weighted sections 963
20.5 Section growth on a curve 964
20.6 Homogeneous sections on a Hopf manifold 965
20.7 Section counts and infinite Hermitian mass 967

21 Flags, convex bodies and section growth 969
21.1 Flag valuations and degree bounds 969
21.2 The body of a graded section algebra 971
21.3 Intrinsic dimension, lattice and growth 972
21.4 Moishezon manifolds and bounded mass 975
21.5 Flags on a point blowup 976
21.6 Curvature rank and section growth 978
21.7 The Hopf flag and its lower-dimensional body 981

22 Hopf fibrations and toric potentials 983
22.1 Weighted sections on the projective base 983
22.2 Descended measures and equations 984
22.3 Logarithmic coordinates and the gradient simplex 987

23 Divisorial currents on compact modifications 989
23.1 Divisorial trace currents 990
23.2 Compatibility between models 991
23.3 The trace envelope as a common majorant 993
23.4 Bott–Chern classes and closed currents 993
23.5 The b-divisor class of a closed positive current 996
23.6 Nef Cartier realizations 997
23.7 Continuous representatives and pullback 999
23.8 Exceptional divisors between trace models 1002

24 Classes with a nonclosed background 1007
24.1 Affine classes with prescribed derivative 1007
24.2 Residual trace classes 1008
24.3 Nef realizations and residual-current limits 1010
24.4 Divisorial classes and infinite mass 1012

25 Envelope systems over Hermitian perturbations 1013
25.1 Curves constant on a left half-line 1014
25.2 Transition maps and envelope systems 1014
25.3 The limiting curve and recovery 1016
25.4 Changes of representative and limiting mass 1019
25.5 Failure of recovery in a positive background 1020
25.6 Recovery through the Hopf fibration 1024
25.6.1 A nonanalytic family 1026
25.6.2 Exact pullback and smooth changes of background . . . 1027

Part VI Gauduchon duality and finite volumes

26 A Gauduchon variational volume 1031
26.1 The quotient and the smooth equation 1032
26.2 The equality case of concavity and the first variation 1035
26.3 Second variation on background classes 1036
26.4 Recovering a positive class from its Gauduchon derivative 1038
26.5 The Hessian metric and its completion 1039
26.5.1 Product and blowup examples 1041
26.5.2 Invariant backgrounds on compact Lie-group quotients 1042
26.5.3 Warped product cones and flat completion 1053
26.6 A compact dual problem over Gauduchon currents 1066
26.7 Supporting probabilities represented by maximizing currents . . 1069
26.8 Integrability of Gauduchon determinant measures 1071
26.8.1 Uniform bounds near a smooth density 1074
26.8.2 Uniformly controlled complex Hessians 1079
26.9 Integrable densities in the compact Gauduchon problem 1085
26.9.1 The tail condition and perturbations of the density . . . 1086
26.9.2 Supporting probabilities for an integrable density 1088
26.9.3 Trace inequalities at the subsolution threshold 1090
26.9.4 A smooth maximizing form with an analytic degeneracy set 1094
26.9.5 The limit of the exponential equations 1096
26.9.6 Envelope criteria and extension across the degeneracy set 1097
26.9.7 A full-mass point pole without a smooth maximizing test 1102
26.9.8 Quantitative convergence of the currents 1105
26.9.9 The classes of the divisorial components 1107

26.9.10 A branched projective example 1108
26.9.11 A moment condition on maximizing tests 1109
26.10 Nef limits and nonattainment 1111
26.11 Subtraction with a closed nef core 1113
26.12 Subtraction on warped products 1117
26.13 Positive volume without bigness 1121
26.13.1 Volume tests and threshold tests 1124
26.14 Varying the probability measure 1127
26.14.1 Upper and lower masses 1128
26.15 Curvature conditions for mass extrema 1131
26.16 Curvature pairs and positive lower mass 1133
26.16.1 The bounded cubic identity 1134
26.16.2 The curvature criterion 1135
26.16.3 Negative-line-bundle quotients 1137
26.16.4 A Calabi–Eckmann family without LCK metrics 1138
26.17 Geometric bounds and determinant concentration 1139
26.17.1 Intrinsic determinant measures and the complete profile 1142
26.17.2 Fixed determinant data with degenerating ellipticity . . 1144
26.17.3 The same obstruction for nonclosed pluriclosed metrics 1146
26.17.4 Concentration at exact maximizers for varying roots . . 1147
26.18 Vanishing lower mass 1149
26.18.1 The elliptic quotient 1149
26.18.2 Averaging the trace and compact curves 1151
26.18.3 The volume of the positive root 1154
26.18.4 Consequences for dimension and equations 1156
26.18.5 A balanced metric and a finite upper mass 1157
26.19 Orders of degeneration at the nef boundary 1160
26.19.1 Elliptic surface volumes and order spectra 1163
26.19.2 Comparison under an arbitrary modification 1166
26.19.3 Strict changes under one blowup 1169
26.19.4 Positive-current subtraction and divisorial residuals . . 1172
26.19.5 Integer orders in fixed projective cones 1175
26.19.6 A maximum-rank comparison criterion 1181
26.19.7 Flat anticanonical curves 1183
26.19.8 Flat divisors and Hartogs extension 1190
26.19.9 Punctured line bundles and elliptic quotients 1194
26.19.10 Cotangent torsors on split elliptic ruled surfaces 1197
26.19.11 Symmetric tensors on split elliptic ruled surfaces 1201
26.19.12 Section algebras of cotangent extensions 1205
26.19.13 Cotangent extensions with zero ruling component 1208
26.20 Current tests for smooth positivity 1211
26.20.1 Maximal time of the Chern–Ricci flow 1212
26.20.2 A positive-volume endpoint that is not big 1216
26.20.3 Twisting and distance bounds 1218
26.21 Divisorial constraints and residual volume 1220

26.21.1 Varying divisorial coefficients 1223
26.21.2 A ruled residual and its subtraction cost 1225
26.22 A divisorial threshold on the Hopf threefold 1228

Part VII Partial kernels and equilibrium

27 Partial kernels and quotient equilibrium 1233
27.1 Selected spaces and partial Bergman kernels 1235
27.2 A local Bernstein–Markov estimate 1236
27.3 Partial envelopes on a weighted compact set 1237
27.4 An upper bound for partial Fubini–Study limits 1239
27.5 The determinant functional 1242
27.5.1 Dependence on the continuous weight 1243
27.5.2 Stability of normalized kernels 1247
27.6 Partial kernels under a modification 1252
27.6.1 Convergence with a Kähler modification 1255
27.7 Kernels on a fibration 1256
27.7.1 The quotient equilibrium measure 1258
27.7.2 The Hopf equilibrium measure 1259
27.8 Isolated logarithmic poles on a fibration 1259
27.9 A point pole on the Hopf manifold 1263
27.10 Singularities along a section over a divisor 1268
27.10.1 A bounded divisorial band from fiber integrability . . . 1272
27.10.2 Several crossing base divisors 1276
27.10.3 Fiber integrability on a modified base 1281
27.10.4 Semipositive residuals with positive volume 1284
27.10.5 Fixed exceptional orders and coefficient thresholds . . . 1286
27.10.6 A semipositive residual with nonzero defect 1289
27.11 Horizontal poles over projective space 1292
27.11.1 The domination envelope 1293
27.11.2 Binomial kernels 1294
27.11.3 Changing the integration volume 1296
27.12 Degenerate curvature and growing vanishing orders 1298
27.12.1 A uniform tail estimate 1299
27.12.2 The limiting envelope and the transition scale 1300
27.13 Localization on curves 1304
27.13.1 Curvature quadrature domains 1310
27.13.2 Gaussian transitions at curvature boundaries 1312
27.13.3 Growth ranges and compact examples 1318
27.13.4 Corrections from the smooth weight 1319
27.14 A logarithmic kernel scale in two dimensions 1321
27.15 Anisotropic point jets and isolated poles on fibrations 1323
27.15.1 Corrected and homogeneous centers 1327
27.15.2 An isolated selecting potential on a submersion 1328
27.16 Newton selection and moment-shell limits 1330

27.16.1 The growth constraint and its envelope 1331
27.16.2 Norms, lattice growth and the lower bound 1333
27.16.3 The limit measure and the ambient metric 1334
27.16.4 A rank-one selection with nonclosed sampling 1335
27.17 Rounding in multiplier-ideal kernel families 1336
27.18 Three monomial bands from a multiplier-ideal selection 1339

Part VIII Closed classes and locally conformally Kähler geometry

28 Bott–Chern classes and singular loci 1349
28.1 Closed classes with Hermitian lower bounds 1350
28.2 Minimal multiplicities and the non-nef locus 1352
28.3 The non-Kähler locus 1353
28.4 Null loci and numerical restricted volumes 1355
28.5 Restricted volumes and Hermitian perturbations 1356
28.6 Finite restricted masses of closed classes 1357
28.7 Divisorial traces with bounded remainder 1361
28.8 Divisorial components at the threshold 1365
28.9 Currents on the elliptic threefold 1369
28.9.1 Potentials and envelopes from the base 1372
28.9.2 Sections selected by multiplier ideals 1373
28.9.3 The boundary volume and section growth 1374
28.9.4 Limits of the minimizing Gauduchon forms 1375
28.10 Smooth equations on the ample locus 1377
28.11 Density zeros and metric degeneration 1378
28.11.1 Determinant and normal distance 1381
28.11.2 Smoothness of exceptional residuals 1382
28.12 Radial densities and metric completeness 1384
28.13 Equations on products with a curve 1387
28.14 An incomplete metric in a big class 1389
28.14.1 A nef class with an incomplete null end 1393
28.14.2 An incomplete metric with compatible flow data 1398
28.15 Normal length near a divisor 1404
28.15.1 The critical exponent on a compact torus 1406
28.16 Rigid boundary classes on a torus 1409
28.17 Nonrigid classes on a quotient resolution 1412
28.18 Semipositive metrics in a four-point blowup family 1415
28.18.1 The image of metric restriction 1418
28.19 Oeljeklaus–Toma manifolds 1421
28.19.1 The construction 1422
28.19.2 Potentials of the transverse form 1423
28.19.3 Monge–Ampère masses on threefolds 1425
28.19.4 Hermitian metrics whose dd^c has a sign 1429

29 Locally conformally Kähler geometry 1431
29.1 The Lee form and the Kähler covering 1432
29.2 Gauduchon representatives and the Lee class 1433
29.2.1 The least eigenvalue of Lee curvature 1435
29.3 Ordinary and twisted potentials 1438
29.3.1 The Vaisman metric on the Hopf manifold 1439
29.4 Volume equations in Gauduchon gauge 1440
29.4.1 Invariant volumes on Vaisman manifolds 1441
29.4.2 Radial volumes on scalar Hopf manifolds 1444
29.5 Chern–Ricci flatness and Vaisman rigidity 1448
29.5.1 A flat conformal gauge that is not Gauduchon 1450
29.6 The Lee–Gauduchon cone 1452
29.6.1 Bimeromorphic invariance 1454
29.6.2 Balanced metrics and the Hopf cone 1456
29.7 Strongly Gauduchon metrics 1457

Part IX Theory under mass bounds

30 Volumes under bounded mass 1463
30.1 Comparison of singularity volumes 1465
30.2 Volume deficits and relative full mass 1466
30.3 Domination and ordinary envelopes 1468
30.4 Strict barriers and background variation 1473
30.5 Monotone limits 1477
30.5.1 Recovery of envelope systems 1483
30.6 Cauchy convergence of model potentials 1485
30.7 Rooftops and capacity convergence 1489
30.8 Volumes of multiplier-ideal envelopes 1493
30.8.1 A countable divisorial positivity criterion 1497
30.9 Model comparison under background changes 1500
30.10 Two-sided background perturbations 1504
30.11 A complete metric on positive-volume models 1508
30.12 Model potentials on curves 1512
30.12.1 The ordinary-type topology on a curve 1517
30.12.2 Concentration of diffuse polar curvature 1518
30.12.3 Convergence for all obstacles 1520
30.13 Background changes on curves 1523
30.14 A complete space over varying curve backgrounds 1528

31 Relative equations under positive lower mass 1533
31.1 Equations for finite measures 1535
31.2 Domination 1535
31.2.1 Domination for extended measures 1536
31.3 Common envelopes and dominated continuity 1539
31.3.1 Convergence under a fixed measure 1542

31.4 Moving bounded carrier measures 1542
31.4.1 Convergence with a common envelope 1544
31.5 General measures in the minimal envelope class 1545
31.6 Equations with a model reference 1547
31.7 Normalization at exponent zero 1550
31.7.1 Nonuniqueness in the minimal envelope class 1551

32 Big backgrounds under bounded mass 1553
32.1 Equations for finite measures 1555
32.2 Convergence under a fixed measure 1555
32.3 Relative moments 1557
32.3.1 Higher moments in the minimal singularity type 1560
32.4 General measures in the minimal class 1563
32.4.1 Exponential and normalized equations 1564
32.5 Relative projection and supersolutions 1565
32.5.1 Varying model references 1567
32.6 Weighted measure addition 1569
32.6.1 Ordinary types and bounded carriers 1572
32.7 General measures with a model reference 1576
32.7.1 Stability under changes of reference 1578
32.7.2 Arbitrary weighted sums 1580
32.8 Relative boundedness for L^p data 1582

Part X Problems and historical notes

33 Problems in Hermitian pluripotential theory 1589
33.1 Threshold equations and singular limits 1589
33.1.1 Individual density thresholds 1590
33.1.2 Dual attainment and exact equations 1593
33.1.3 Regularity of singular solutions 1595
33.1.4 Uniqueness and selection 1596
33.2 Positive Gauduchon volume and bigness 1597
33.2.1 Collapse of normalized Gauduchon tests 1598
33.3 Closed positivity and geometric equations 1600

Conventions

Unless otherwise stated, X denotes a connected compact complex manifold of dimension $n \geq 1$. A Hermitian form is a smooth real strictly positive $(1,1)$-form. The letter ω is reserved for such a form, while θ denotes an arbitrary smooth real $(1,1)$-form. Whenever θ or ω is assumed to be closed, this is stated explicitly.

We follow the normalizations of [Xia]:

$$\mathrm{d}^{\mathrm{c}} = \frac{\mathrm{i}}{4\pi}(\bar{\partial} - \partial), \qquad \mathrm{dd}^{\mathrm{c}} = \frac{\mathrm{i}}{2\pi}\partial\bar{\partial}.$$

Thus, on a disk in $\mathbb{C}$ with coordinate z, $\mathrm{dd}^{\mathrm{c}} \log |z|^2$ is the unit Dirac measure at the origin. Multiplier ideals of a quasi-plurisubharmonic function u are defined with the weight $\exp(-u)$, and Monge–Ampère masses carry no factor $1/n!$.

Frequently used notation

The following symbols are used throughout the book; the last column gives the place where each is defined. Notation that is used in only one chapter is introduced in that chapter.

Symbol	Meaning	Defined in
$\mathrm{PSH}(X,\theta)$, θ_u	θ-plurisubharmonic functions; $\theta_u = \theta + \mathrm{dd^c}u$	Definition 1.1.1
$u \preceq v$, $u \sim v$	comparison and equality of ordinary singularity types	Definition 1.12.1
$\mathcal{I}(u)$	multiplier ideal sheaf of u	Definition 1.12.2
$u \preceq_{\mathcal{I}} v$, $u \sim_{\mathcal{I}} v$	comparison and equality of multiplier ideals at all weights	Section 1.12
$\nu(u,x)$	Lelong number of u at x	Section 1.13
$P_\theta(f)$, V_θ	envelope below an obstacle f; $V_\theta = P_\theta(0)$	Section 1.19
$P_\theta[u]$	envelope of the ordinary singularity type; its fixed points are the ordinary models	Definition 1.19.1
$P_\theta[u]_{\mathcal{I}}$	multiplier-ideal envelope	Definition 16.2.1
$\mathrm{MA}_\theta(u)$	Monge–Ampère measure of a bounded potential; where a chapter says so, also the extended measure	Proposition 1.7.1
$\mathrm{MA}^{\mathrm{ext}}_\theta(u)$	extended non-pluripolar measure, also written $\langle \theta_u^n \rangle$	Theorem 6.1.1
Cap_ω	Hermitian capacity	Section 1.8
$\nu_-(\omega)$, $\nu_+(\omega)$	lower and upper mass of a Hermitian form; bounded mass property	Definition 6.5.1
Gauduchon, balanced and pluriclosed metrics	Hermitian forms γ with $\mathrm{dd^c}(\gamma^{n-1}) = 0$, $\mathrm{d}(\gamma^{n-1}) = 0$ and $\mathrm{dd^c}\gamma = 0$, respectively	Definition 4.1.1
$\mathcal{T}_\gamma$, $d_{\gamma,d}$	Gauduchon trace map and trace metric	Section 5.1
$\underline{\mathrm{vol}}_\theta$, $\overline{\mathrm{vol}}_\theta$	lower and upper volumes of a singularity type	Definition 13.3.1
$\mathcal{E}_{\mathrm{env}}(X,\theta,\varphi)$	relative envelope class of a reference φ	Definition 13.4.1
d_θ	volume comparison of ordinary models	Definition 30.6.1
$b_h(f)$	subsolution threshold of a density f	Theorem 14.27.1
$\mathcal{D}_h$, ρ_h	space of density roots and root functional	Proposition 14.31.2
$\mathcal{V}_\mu(\theta)$, $\lambda_\mu(\theta)$	Gauduchon variational volume and root volume	Definition 26.1.1

Part I
The Hermitian foundations

Chapter 1
Plurisubharmonic functions and singularities

A function whose complex Hessian is bounded below by a smooth form becomes plurisubharmonic after a local smooth correction. This brings the local theory of plurisubharmonic functions to a compact complex manifold, provided the smooth remainder left by the correction is kept when potentials are glued, when their Hessians are multiplied and when one integrates by parts. Normalization by the supremum then controls the resulting families globally, giving compactness, uniform exponential integrability and capacity estimates on the whole manifold. Products of Hessians require more care than the potentials themselves: without a common bound, convergence of potentials in L^1, or even in capacity, does not prevent their Monge–Ampère measures from concentrating.

To keep track of singularities under these operations, we compare potentials in two ways: by domination up to an additive constant, which leads to ordinary singularity types and their envelopes, and by the local integrability of holomorphic functions against exponential weights, which leads to multiplier ideals. Lelong numbers, analytic approximation and modifications are the main tools for computing the latter.

1.1 Plurisubharmonic potentials

Throughout the chapter, X is a connected compact complex manifold of dimension $n \geq 1$, θ is a smooth real $(1,1)$-form and ω is a Hermitian form on X, unless a statement specifies another setting. There are two distinct extensions of the Kähler setting: one can study a closed background on a non-Kähler manifold, or allow the background itself to be nonclosed. In both cases positivity is expressed through quasi-plurisubharmonic functions.

On an open set U in a complex manifold, a *plurisubharmonic function* is a locally integrable upper semicontinuous function satisfying the submean inequality on every complex line in local coordinates. We write $\mathrm{PSH}(U)$ for the set of these functions. A function is *quasi-plurisubharmonic* if it is locally the sum of a plurisubharmonic

function and a smooth real function; the set of such functions is denoted by $\mathrm{QPSH}(U)$. The following relative positivity condition makes sense on any such open set as well.

Definition 1.1.1 A quasi-plurisubharmonic function u on X is *θ-plurisubharmonic* if

$$\theta + \mathrm{dd^c} u \geq 0$$

as a current. We denote the set of these functions by $\mathrm{PSH}(X, \theta)$.

Since $\omega > 0$, every constant function belongs to $\mathrm{PSH}(X, \omega)$.

Proposition 1.1.1 *Every real distribution u on X with $\theta + \mathrm{dd^c} u \geq 0$ has a unique θ-plurisubharmonic representative. On each relatively compact coordinate ball with coordinates $z = (z_1, \ldots, z_n)$, there is a constant $A > 0$ such that $u + A|z|^2$ is plurisubharmonic. Conversely, every quasi-plurisubharmonic function u on X belongs to $\mathrm{PSH}(X, C\omega)$ for some constant $C > 0$.*

Proof On a coordinate ball with compact closure in a larger chart, smoothness of θ gives

$$\theta \leq A\mathrm{dd^c}|z|^2$$

for a sufficiently large A. Consequently,

$$\mathrm{dd^c}(u + A|z|^2) \geq A\mathrm{dd^c}|z|^2 - \theta \geq 0.$$

The local distributional characterization of plurisubharmonic functions, [Dem12, Chapter I, Theorem 5.8], gives a unique plurisubharmonic representative of $u + A|z|^2$. Subtracting the smooth correction gives a quasi-plurisubharmonic representative of u on the ball. These representatives agree on overlaps: after a common local smooth correction, two of them become plurisubharmonic functions that are equal almost everywhere, hence everywhere. They therefore glue to a unique θ-plurisubharmonic representative.

For the converse, cover X by finitely many open sets $V_j \Subset U_j$, where each U_j is a chart on which $u = p_j + f_j$, with p_j plurisubharmonic and f_j smooth. On the compact set $\overline{V}_j$, the smooth form $\mathrm{dd^c} f_j$ is bounded below by $-C_j\omega$ for some constant C_j, so $\mathrm{dd^c} u \geq \mathrm{dd^c} f_j \geq -C_j\omega$ on V_j. Any constant $C > 0$ larger than all the C_j gives $\mathrm{dd^c} u \geq -C\omega$ on X. □

For $u \in \mathrm{PSH}(X, \theta)$, choose coordinates z and a constant $A > 0$ as in Proposition 1.1.1, and put $p = u + A|z|^2$. Then

$$\theta + \mathrm{dd^c} u = \mathrm{dd^c} p + (\theta - A\mathrm{dd^c}|z|^2).$$

Thus local plurisubharmonic theory applies to p, while the smooth remainder $\theta - A\mathrm{dd^c}|z|^2$ records the original background; this remainder must be kept when forming products or integrating by parts.

Proposition 1.1.2 *If $\theta = \mathrm{dd}^{\mathrm{c}}\rho$ on an open set for a smooth function ρ, then $\mathrm{d}\theta = 0$ on that set. In particular, at a point where $\mathrm{d}\theta \neq 0$, no neighborhood admits such a representation.*

Proof Apply d and use $\mathrm{ddd}^{\mathrm{c}} = 0$. □

Conversely, a closed real $(1,1)$-form has smooth local dd^{c}-potentials on sufficiently small coordinate balls, by the local $\partial\bar\partial$-lemma; this local fact does not require X to admit a Kähler metric.

The exterior derivative also constrains the regularity of a potential whose current is pointwise proportional to a Hermitian form. In dimension at least two, differentiating such an identity expresses the derivative of the proportionality factor through smooth coefficients.

Lemma 1.1.1 *Let X be a complex manifold of dimension $n \geq 2$, let θ be a smooth real $(1,1)$-form and let γ be a Hermitian form on X. Suppose that real-valued $u, a \in L^1_{\mathrm{loc}}(X)$ satisfy*

$$\theta + \mathrm{dd}^{\mathrm{c}} u = a\gamma$$

as currents. Then a and u are smooth.

Proof Taking the exterior derivative and multiplying by γ^{n-2} gives

$$\mathrm{d}a \wedge \gamma^{n-1} = \mathrm{d}\theta \wedge \gamma^{n-2} - a\,\mathrm{d}\gamma \wedge \gamma^{n-2}.$$

At each point, $\xi \mapsto \xi \wedge \gamma^{n-1}$ is an isomorphism from real one-forms to real $(2n-1)$-forms, as one sees in a unitary frame. Its inverse depends smoothly on the point. Let B and C be the images of $\mathrm{d}\theta \wedge \gamma^{n-2}$ and $\mathrm{d}\gamma \wedge \gamma^{n-2}$ under this inverse. They are smooth real one-forms, and

$$\mathrm{d}a = B - aC$$

in the sense of distributions. Since $a \in L^1_{\mathrm{loc}}$, the right-hand side is locally integrable, so $a \in W^{1,1}_{\mathrm{loc}}$. Differentiating the equation and using the smoothness of its coefficients, we obtain inductively $a \in W^{k,1}_{\mathrm{loc}}$ for every integer k, and the local Sobolev embedding shows that a is smooth. Consequently $\mathrm{dd}^{\mathrm{c}} u = a\gamma - \theta$ is smooth; taking its trace in local coordinates and applying elliptic regularity shows that u is smooth as well. □

1.2 Changes of background

A positive current can be written as a smooth form plus a complex Hessian in more than one way. Changing the decomposition by a smooth dd^{c}-exact form changes the potential by a bounded function, and positive linear combinations allow us to compare potentials belonging to different backgrounds. In this section, η denotes a second smooth real $(1,1)$-form on X.

Proposition 1.2.1 *Let f be a smooth real function on X, and set $\theta' = \theta + \mathrm{dd}^{\mathrm{c}} f$. Then*

$$\mathrm{PSH}(X,\theta) \longrightarrow \mathrm{PSH}(X,\theta'), \qquad u \longmapsto u - f$$

is a bijection. It preserves the positive current and changes each potential by a bounded function. Moreover, $\mathrm{d}\theta' = \mathrm{d}\theta$.

Proof For every $u \in \mathrm{PSH}(X,\theta)$,

$$\theta' + \mathrm{dd}^{\mathrm{c}}(u - f) = \theta + \mathrm{dd}^{\mathrm{c}} u.$$

The inverse map is $v \mapsto v + f$, and f is bounded because X is compact. The last assertion follows from $\mathrm{ddd}^{\mathrm{c}} f = 0$. □

Thus the natural object is the class of θ modulo smooth dd^{c}-exact forms. This quotient of all smooth real $(1,1)$-forms contains nonclosed classes; the usual Bott–Chern cohomology group is the corresponding quotient of closed forms.

Proposition 1.2.2 *If $u \in \mathrm{PSH}(X,\theta)$ and $v \in \mathrm{PSH}(X,\eta)$, then, for $a, b \geq 0$ with $a + b > 0$,*

$$au + bv \in \mathrm{PSH}(X, a\theta + b\eta).$$

In particular, $\mathrm{PSH}(X,\theta)$ *is convex. If $\eta \geq \theta$, then* $\mathrm{PSH}(X,\theta) \subseteq \mathrm{PSH}(X,\eta)$.

Proof Omitting a term whose coefficient is zero, we see that $au + bv$ is quasi-plurisubharmonic. Moreover,

$$a\theta + b\eta + \mathrm{dd}^{\mathrm{c}}(au + bv) = a(\theta + \mathrm{dd}^{\mathrm{c}} u) + b(\eta + \mathrm{dd}^{\mathrm{c}} v) \geq 0.$$

For the inclusion, add the semipositive smooth form $\eta - \theta$ to $\theta + \mathrm{dd}^{\mathrm{c}} u$. □

By Proposition 1.1.1, any two quasi-plurisubharmonic functions on X belong to $\mathrm{PSH}(X, C\omega)$ for a common sufficiently large constant C. This allows us to compare their singularities within one positive background.

1.3 Maxima and the maximum principle

Maxima allow us to truncate potentials and to modify them on an open set without losing the lower curvature bound. For a smooth background, the local maximum and gluing principles for plurisubharmonic functions keep this bound: one freezes the coefficients of the background on small balls and then lets the resulting curvature error tend to zero.

Lemma 1.3.1 *If $u, v \in \mathrm{PSH}(X,\theta)$, then* $\max(u,v) \in \mathrm{PSH}(X,\theta)$. *Consequently, if $\theta \geq 0$ and $u \in \mathrm{PSH}(X,\theta)$, then* $\max(u,-t)$ *is θ-plurisubharmonic for every real t.*

Proof Adding a common local smooth correction to u and v shows that $\max(u, v)$ is quasi-plurisubharmonic. To obtain the sharp lower bound for its Hessian, fix a positive constant $(1, 1)$-form κ on a coordinate ball. For each $\varepsilon > 0$, every point of the ball has a neighborhood on which θ is close to a constant form θ', in the sense that $-\varepsilon\kappa \le \theta - \theta' \le \varepsilon\kappa$. Write $\theta' + \varepsilon\kappa = \mathrm{dd}^{\mathrm{c}} r$ with a quadratic polynomial r. Then $\mathrm{dd}^{\mathrm{c}}(u + r) \ge \theta + \mathrm{dd}^{\mathrm{c}} u \ge 0$, so $u + r$ and, likewise, $v + r$ are plurisubharmonic; hence so is their maximum. It follows that

$$\theta + 2\varepsilon\kappa + \mathrm{dd}^{\mathrm{c}} \max(u, v) \ge 0$$

on each such neighborhood, and letting $\varepsilon \to 0$ gives $\theta + \mathrm{dd}^{\mathrm{c}} \max(u, v) \ge 0$. The last assertion follows because constants belong to $\mathrm{PSH}(X, \theta)$ when $\theta \ge 0$. □

Lemma 1.3.2 *Let Y be a complex manifold, let β be a smooth real $(1, 1)$-form on Y, and let $D \subset Y$ be open. Suppose that u is β-plurisubharmonic on Y, that v is β-plurisubharmonic on D, and that*

$$\limsup_{D \ni y \to x} v(y) \le u(x) \qquad (x \in \partial D).$$

Then the function equal to $\max(u, v)$ on D and to u on $Y \setminus D$ is β-plurisubharmonic.

Proof Denote the glued function by w; it is upper semicontinuous by the boundary inequality. Freeze β on a small coordinate ball as in the proof of Lemma 1.3.1, and choose a quadratic correction r such that $u + r$ and $v + r$ are plurisubharmonic on their respective domains. Off ∂D, the function $w + r$ is plurisubharmonic, being locally either $u + r$ or the maximum of two plurisubharmonic functions. At a point of ∂D, it equals $u + r$ and dominates $u + r$ on the ball, so it satisfies the submean inequality on every complex line through that point. Thus $w + r$ is plurisubharmonic on the whole ball. Letting the error of the frozen coefficients tend to zero gives $\beta + \mathrm{dd}^{\mathrm{c}} w \ge 0$. □

For quasi-plurisubharmonic functions, an inequality that holds almost everywhere holds everywhere. This allows comparisons proved for Sobolev or Lebesgue classes to be applied to the potentials themselves.

Lemma 1.3.3 *Let a, b be quasi-plurisubharmonic functions on a complex manifold. If $a \le b$ almost everywhere, then $a \le b$ everywhere. In particular, equality almost everywhere implies equality everywhere.*

Proof On a coordinate ball, add the same smooth function q to both functions so that $a + q$ and $b + q$ are plurisubharmonic. By the submean inequality and upper semicontinuity, a plurisubharmonic function is, at each point, the limit of its averages over balls centered there as the radius tends to zero. The almost-everywhere inequality orders these averages, so passing to the limit gives $a + q \le b + q$. Subtracting q proves the claim. □

Lemma 1.3.4 *Let a, b be quasi-plurisubharmonic functions on a complex manifold. If $a(x) < b(x)$ at a point x where both values are finite, then $\{a < b\}$ has positive volume with respect to any smooth positive volume form.*

Proof Choose a number c with $a(x) < c < b(x)$. By upper semicontinuity, $a < c$ on a neighborhood V of x. If $\{b > c\} \cap V$ had zero volume, then $b \le c$ almost everywhere on V, and Lemma 1.3.3 would give $b(x) \le c$, a contradiction. Thus $\{b > c\} \cap V$, which is contained in $\{a < b\}$, has positive volume. □

Lemma 1.3.5 *A plurisubharmonic function on $\mathbb{C}^m$, $m \ge 1$, that is bounded above is constant.*

Proof First let f be a smooth subharmonic function on $\mathbb{C}$ with $f \le M$. Write $\sigma = (\Delta f)\, dA$ for its nonnegative Laplacian measure, where Δ and dA are Euclidean. Green's formula for circular means gives, for $R > 0$,

$$\frac{1}{2\pi}\int_0^{2\pi} f(Re^{it})\, dt - f(0) = \frac{1}{2\pi}\int_0^R \frac{\sigma(B(0,r))}{r}\, dr.$$

For fixed $r_0 > 0$ and $R > r_0$, the right-hand side is at least $\sigma(B(0,r_0))\log(R/r_0)/(2\pi)$, while the left-hand side is at most $M - f(0)$. Letting $R \to \infty$ gives $\sigma(B(0,r_0)) = 0$. Thus f is harmonic, and the Liouville theorem for the positive harmonic function $M + 1 - f$ shows that f is constant.

Now let p be plurisubharmonic on $\mathbb{C}^m$ and bounded above. Its convolutions with a smooth nonnegative radial probability kernel are smooth plurisubharmonic functions with the same upper bound. By the planar case, their restrictions to every affine complex line are constant, so each convolution is constant on $\mathbb{C}^m$. Since the convolutions converge to p in L^1_{loc}, the function p is almost everywhere equal to a constant, and hence constant by Lemma 1.3.3. □

For a function f, we write $f^*(x) = \limsup_{y\to x} f(y)$ for its upper semicontinuous regularization. A subset of a complex manifold is *pluripolar* if each of its points has a neighborhood U such that the part of the subset in U is contained in $\{p = -\infty\}$ for some $p \in \mathrm{PSH}(U)$. The local upper-envelope theorem recalled in [Xia] states that if a nonempty family of plurisubharmonic functions is locally uniformly bounded above, then the regularization of its supremum is plurisubharmonic and differs from the supremum only on a pluripolar set.

Periodicity also forces rigidity when an entire subharmonic function has only logarithmic upper growth.

Lemma 1.3.6 *Let h be subharmonic on $\mathbb{C}$, with $h(\zeta + 1) = h(\zeta)$. If there are real constants $A \ge 0$ and B such that*

$$h(\zeta) \le A\log(1 + |\zeta|) + B \qquad (\zeta \in \mathbb{C}),$$

then h is constant.

Proof By the growth bound, the real translates $h(\cdot + s)$, $s \in [0,1]$, form a family of subharmonic functions that is locally uniformly bounded above. The local upper-envelope theorem therefore shows that

$$H(\zeta) = \Big(\sup_{s\in[0,1]} h(\zeta + s)\Big)^*$$

is subharmonic. By periodicity, H is invariant under every real translation, so it depends only on $\operatorname{Im}\zeta$, and its subharmonicity means that it is a convex function of $\operatorname{Im}\zeta$. On the imaginary axis it satisfies $H(\mathrm{i}y) \le A\log(2+|y|) + B$. Since a nonconstant convex function on $\mathbb{R}$ grows at least linearly at one end, this bound shows that H is constant. Thus $h \le H$ is bounded above, and Lemma 1.3.5 shows that h is constant. □

Lemma 1.3.7 *Let U be a complex manifold, let θ be a smooth real $(1,1)$-form on U, and let $Z \subset U$ be closed and locally pluripolar. Let u be θ-plurisubharmonic on $U \setminus Z$ and locally bounded above near Z. Then its upper-limit extension, defined at $x \in Z$ by $u(x) = \limsup_{U\setminus Z \ni y\to x} u(y)$, is θ-plurisubharmonic on U. In particular, this applies when Z is a proper analytic subset of U.*

Proof First suppose that u is plurisubharmonic. Near a point of Z, choose a plurisubharmonic function $\psi \le 0$ with $\psi = -\infty$ on Z. For $t > 0$, extend $u + t\psi$ by $-\infty$ on Z. The local upper bound for u makes this extension upper semicontinuous. It is plurisubharmonic off Z, and its submean inequality on complex lines is automatic at points of Z, where its value is $-\infty$. It is therefore plurisubharmonic on the whole neighborhood. As $t \downarrow 0$, these functions increase, with a common local upper bound. By the local upper-envelope theorem, the regularization of their limit is a plurisubharmonic function that agrees with u almost everywhere off Z, hence everywhere off Z by Lemma 1.3.3. By upper semicontinuity and the submean inequality, its value at a point of Z is the upper limit of u off Z, so it is the upper-limit extension of u.

For a smooth background, fix a positive constant form κ on a coordinate chart and let $\epsilon > 0$. On a sufficiently small ball, freeze θ to a constant form θ' with $-\epsilon\kappa \le \theta - \theta' \le \epsilon\kappa$, and choose a quadratic potential q for $\theta' + \epsilon\kappa$. Applying the preceding argument to the plurisubharmonic function $u + q$ shows that the upper-limit extension satisfies $\theta + \mathrm{dd}^{\mathrm{c}}u \ge -2\epsilon\kappa$ on the ball. Since the extension is defined by upper limits, it does not depend on the ball, and letting $\epsilon \downarrow 0$ gives $\theta + \mathrm{dd}^{\mathrm{c}}u \ge 0$. Finally, analytic subsets are locally pluripolar: locally, a proper analytic subset is contained in the $-\infty$ locus of the logarithm of the sum of the squared moduli of local defining functions. □

Lemma 1.3.8 *Let X be a complex manifold of dimension $n \geq 2$, let θ be a smooth real $(1,1)$-form on X, and let $p \in X$. Every θ-plurisubharmonic function on $X \setminus \{p\}$ is locally bounded above near p and extends uniquely to a member of $\mathrm{PSH}(X, \theta)$. If X is compact, it is bounded above on $X \setminus \{p\}$.*

Proof Choose coordinates centered at p and write $\Delta_R = \{z \in \mathbb{C} : |z| < R\}$. On the coordinate polydisk Δ_R^n, add a smooth quadratic function to the given function to obtain a plurisubharmonic function h on $\Delta_R^n \setminus \{0\}$. Write the coordinates as (z_1, z_2, z'), with z' absent when $n = 2$, and choose $0 < r < R$. The compact set

$$K = \{|z_1| \leq r,\ |z_2| = r,\ |z_j'| \leq r\}$$

avoids the puncture, so $h \leq M$ on K for some finite M. Consider a point of the punctured closed polydisk of radius r. If $z_1 \neq 0$, the disk in the z_2-direction through the point avoids the puncture and has its boundary in K, so the maximum principle gives $h \leq M$ at the point. If $z_1 = 0$ and $(z_2, z') \neq 0$, the disk in the z_1-direction through the point avoids the puncture, and its boundary consists of points with $z_1 \neq 0$, where the bound has already been proved; the maximum principle again gives $h \leq M$. Subtracting the smooth correction proves the local upper bound.

By Lemma 1.3.7, applied with $Z = \{p\}$, the upper-limit extension belongs to $\mathrm{PSH}(X, \theta)$. It is unique by Lemma 1.3.3. If X is compact, the extension is an upper semicontinuous function on a compact space and is therefore bounded above. □

Lemma 1.3.9 *Let u be θ-plurisubharmonic near a point x. If a C^2 function a touches u from above at x, that is, $a \geq u$ near x and $a(x) = u(x)$, then $\theta(x) + \mathrm{dd^c} a(x) \geq 0$.*

Proof In coordinates centered at x, let q be a quadratic polynomial with $\mathrm{dd^c} q = \theta(x)$, and let $\varepsilon > 0$. On a sufficiently small ball about x, we have $\theta \leq \theta(x) + \varepsilon \mathrm{dd^c}|z|^2$, so $u + q + \varepsilon|z|^2$ is plurisubharmonic, and $a + q + \varepsilon|z|^2$ touches it from above at x. By the submean inequality on complex lines through x, a C^2 function touching a plurisubharmonic function from above at x has nonnegative complex Hessian at x. Hence $\theta(x) + \mathrm{dd^c} a(x) + \varepsilon \mathrm{dd^c}|z|^2 \geq 0$, and letting $\varepsilon \to 0$ proves the lemma. □

1.4 Normalized compactness

Fix a smooth positive probability volume form $\mathrm{d}V$ on X, used for L^1 norms. Consider a sequence of plurisubharmonic functions on a connected domain that is locally uniformly bounded above. By the local compactness theorem recalled in [Xia], it has a subsequence that either converges in L^1_{loc} or converges locally uniformly to $-\infty$. For normalized θ-plurisubharmonic functions on X, a point at which the maximum is attained excludes the second alternative, and connectedness of X propagates the first one across X.

The submean inequality also controls upper limits at moving points.

Lemma 1.4.1 *Let u_j, u be quasi-plurisubharmonic functions on an open set U in a complex manifold. Suppose that $u_j \to u$ in $L^1_{\mathrm{loc}}(U)$ and that $\mathrm{dd}^c u_j \geq -\beta$ for a fixed smooth real $(1,1)$-form β on U. If $x_j \to x$ in U, then*

$$\limsup_{j\to\infty} u_j(x_j) \leq u(x).$$

Moreover, the tail envelopes $h_j = (\sup_{k\geq j} u_k)^*$ decrease to u.

Proof On a coordinate ball about x, add a common smooth correction q so that $u_j + q$ and $u + q$ are plurisubharmonic. For a fixed small radius, the submean inequality bounds $(u_j + q)(x_j)$ by the average of $u_j + q$ over the ball of that radius centered at x_j. As $j \to \infty$, these averages converge to the average of $u + q$ over the ball of the same radius centered at x: the contribution of $u_j - u$ tends to zero in L^1, and the integral of the fixed locally integrable function $u + q$ over a ball depends continuously on its center. Letting the radius decrease to zero proves the inequality.

The same estimate gives local uniform upper bounds for the u_j with j large. By coefficient freezing and the local upper-envelope theorem, the tail envelopes are therefore quasi-plurisubharmonic, with the same lower Hessian bound. They decrease with j. If their limit exceeded $u(x)$ at some point x, the definition of the regularization would give indices $k_j \geq j$ and points $x_j \to x$ contradicting the first assertion for the subsequence (u_{k_j}). On the other hand, an almost everywhere convergent subsequence of (u_j) shows that $h_j \geq u$ almost everywhere, hence everywhere by Lemma 1.3.3. Thus $h_j \downarrow u$. □

Theorem 1.4.1 *For every smooth real $(1,1)$-form θ on X, the family*

$$\mathcal{K}_\theta = \{u \in \mathrm{PSH}(X,\theta) : \sup_X u = 0\}$$

is compact in $L^1(X, \mathrm{d}V)$. In particular, there is a constant C_θ such that

$$\int_X |u|\,\mathrm{d}V \leq C_\theta \quad (u \in \mathcal{K}_\theta).$$

Proof Let (u_j) be a sequence in $\mathcal{K}_\theta$. By upper semicontinuity, there are points x_j with $u_j(x_j) = 0$; passing to a subsequence, we may assume that $x_j \to x$. Cover X by finitely many connected coordinate balls, and on a slightly larger ball around each of them choose a fixed smooth function r_i such that every $u_j + r_i$ is plurisubharmonic; such corrections exist because θ is smooth. Since $u_j \leq 0$, these local functions are uniformly bounded above.

On a ball containing x in its interior, locally uniform convergence to $-\infty$ is impossible, because the values $(u_j + r_i)(x_j) = r_i(x_j)$ stay bounded below. Local compactness therefore gives a subsequence converging in L^1 on this ball. If a second ball meets the first, local compactness on the second ball cannot yield convergence to $-\infty$ on compact subsets of the intersection, since the first limit is finite almost everywhere there. Thus a further subsequence converges in L^1 on the second ball. Since X is connected, the intersection graph of the finite cover by connected balls is

connected. Proceeding along this graph and passing to subsequences finitely many times, we obtain local L^1 convergence on every ball, and a partition of unity then gives convergence in $L^1(X)$ to a function u.

The inequalities $\theta + \mathrm{dd}^{\mathrm{c}} u_j \geq 0$ pass to the limit in the sense of distributions. By Proposition 1.1.1, u has a θ-plurisubharmonic representative, still denoted by u. Since $u_j \leq 0$, we have $u \leq 0$ almost everywhere, hence everywhere by Lemma 1.3.3.

By Lemma 1.4.1, $0 = \lim_j u_j(x_j) \leq u(x)$. Thus $u(x) = 0$, and the limit belongs to $\mathcal{K}_\theta$. This proves sequential compactness, which is compactness in the metric space $L^1(X)$. The norm bound follows, since a compact subset of $L^1(X)$ is bounded. □

Corollary 1.4.1 *Let (u_j) be a decreasing sequence in $\mathrm{PSH}(X, \theta)$ with uniformly bounded L^1 norms. Then its pointwise limit u belongs to $\mathrm{PSH}(X, \theta)$; in particular, u is not identically $-\infty$. Moreover, $u_j \to u$ in L^1.*

Proof On each connected coordinate ball, after a common smooth correction, the limit of a decreasing sequence of plurisubharmonic functions is either plurisubharmonic or identically $-\infty$. Fatou's lemma, applied to the negative parts, excludes the second alternative because of the L^1 bound. Hence u is quasi-plurisubharmonic, and the inequality $\theta + \mathrm{dd}^{\mathrm{c}} u \geq 0$ passes to the decreasing limit. Finally, the nonnegative functions $u_1 - u_j$ increase to $u_1 - u$, so monotone convergence gives $u_j \to u$ in L^1.□

1.5 Uniform exponential integrability

For a single quasi-plurisubharmonic function v on X, Skoda's local integrability theorem, recalled in [Xia], applies after local smooth corrections. Taking the smallest exponent over a finite cover gives $\mathrm{e}^{-a(v)v} \in L^1(X)$ for some $a(v) > 0$. Normalized compactness makes the exponent and the bound for the integral uniform: otherwise, a convergent weighted sum of counterexamples would violate this qualitative statement.

Let K_ω be the constant of Theorem 1.4.1 for the background ω, so that every $v \in \mathrm{PSH}(X, \omega)$ with $\sup_X v = 0$ satisfies

$$\int_X |v| \, \mathrm{d}V \leq K_\omega. \tag{1.1}$$

Lemma 1.5.1 *There are constants $\alpha > 0$ and $C < +\infty$, depending only on $(X, \omega, \mathrm{d}V)$, such that*

$$\int_X \mathrm{e}^{-\alpha v} \, \mathrm{d}V \leq C \quad \textit{for all } v \in \mathrm{PSH}(X, \omega) \textit{ with } \sup_X v = 0.$$

Proof Suppose that no such pair exists. Set $a_j = 2^{-j}$ and choose normalized potentials $v_j \in \mathrm{PSH}(X, \omega)$ with

$$\int_X \exp\left(-\frac{a_j}{j} v_j\right) \mathrm{d}V \geq 2^j.$$

The partial sums $V_N = \sum_{j \le N} a_j v_j$ decrease, since every $v_j \le 0$. They belong to $\mathrm{PSH}(X, \omega)$ by Proposition 1.2.2, because $\sum_j a_j \le 1$, and their L^1 norms are uniformly bounded by (1.1). By Corollary 1.4.1, their limit V is therefore ω-plurisubharmonic. Since all summands are nonpositive, $V \le a_j v_j$ for every j.

Fix $p > 0$. For every $j \ge 1/p$,

$$\int_X \mathrm{e}^{-pV} \, \mathrm{d}V \ge \int_X \mathrm{e}^{-p a_j v_j} \, \mathrm{d}V \ge \int_X \mathrm{e}^{-(a_j/j) v_j} \, \mathrm{d}V \ge 2^j .$$

Thus e^{-pV} is not integrable for any $p > 0$, which contradicts the integrability of $\mathrm{e}^{-a(V)V}$ obtained above from Skoda's theorem. □

1.6 Local products and capacity

Bedford–Taylor products of bounded plurisubharmonic functions, and the capacity defined through them, measure the exceptional sets of plurisubharmonic functions and control bounded approximation. We recall these classical facts of local pluripotential theory from [Xia, GZ17]. The *plurifine topology* is the coarsest topology that makes all local plurisubharmonic functions continuous. It is finer than the ordinary topology; in particular, strict superlevel sets of quasi-plurisubharmonic functions are plurifine open.

Theorem 1.6.1 (Bedford–Taylor) *Let $1 \le k \le n$. If $p_1, \dots, p_k$ are locally bounded plurisubharmonic functions on a domain in $\mathbb{C}^n$, their mixed product $\mathrm{dd^c} p_1 \wedge \cdots \wedge \mathrm{dd^c} p_k$ is a positive closed current of order zero. It is symmetric, multilinear in its current factors, and continuous under simultaneous locally bounded decreasing approximation. It does not charge pluripolar sets and is local in the plurifine topology.*

Here plurifine locality means that if two families of such functions agree on a plurifine open Borel set, then their products have the same restriction to that set.

Products multiplied by a bounded potential need more than the weak convergence of the unweighted products in Theorem 1.6.1. An auxiliary complex variable recovers the weight from an ordinary mixed product in one more dimension, including at top degree.

Lemma 1.6.1 *Let $a_j \downarrow a$ and $b_{i,j} \downarrow b_i$, $1 \le i \le r \le n$, be locally uniformly bounded plurisubharmonic functions on a domain in $\mathbb{C}^n$. Then*

$$a_j \, \mathrm{dd^c} b_{1,j} \wedge \cdots \wedge \mathrm{dd^c} b_{r,j} \longrightarrow a \, \mathrm{dd^c} b_1 \wedge \cdots \wedge \mathrm{dd^c} b_r$$

weakly as currents. The same holds for quasi-plurisubharmonic functions that become plurisubharmonic after fixed smooth corrections, and after wedging with smooth forms that converge locally in C^∞.

Proof First let $r = n$, and write $\mu_j = \bigwedge_i \mathrm{dd^c} b_{i,j}$ and $\mu = \bigwedge_i \mathrm{dd^c} b_i$. Work over a relatively compact ball on which $-M \le a_j, a \le M$. On the product of this ball with a disk of radius R in an auxiliary variable w, where $\log R^2 > M + 1$, set

$$v_j(z,w) = \max\{a_j(z), \log|w|^2\}, \qquad v(z,w) = \max\{a(z), \log|w|^2\}.$$

These are locally bounded plurisubharmonic functions, also at $w = 0$, and $v_j \downarrow v$. Pulling back the functions $b_{i,j}$ and b_i to the product and applying Theorem 1.6.1 in dimension $n + 1$, we obtain

$$T_j = \mu_j \wedge \mathrm{dd^c} v_j \longrightarrow T = \mu \wedge \mathrm{dd^c} v.$$

Since μ is closed, $T = \mathrm{dd^c}(v\mu)$. As μ has top degree in the base variables, only derivatives in w contribute. Testing against product test functions and applying Fubini's theorem therefore identifies T with $\mu(\mathrm{d}z)$ times the circle measure

$$\mathrm{dd^c_w} \max\{a(z), \log|w|^2\} = \sigma_{\exp(a(z)/2)}.$$

Here σ_t is the uniform probability measure on the circle $|w| = t$: the radial derivative jumps from zero to $2/t$ there, so the Euclidean Laplacian has total mass 4π, and our normalization of $\mathrm{dd^c}$ divides that mass by 4π. This distributional computation is valid for every bounded Borel function a; no continuity in z is needed. The same description holds for T_j.

Choose a smooth radial compactly supported function $\vartheta(w)$, supported away from zero and from the circle $|w| = R$, that equals $\log|w|^2$ on all circles with $-M \le \log|w|^2 \le M$. For every smooth compactly supported test function ξ on the base,

$$\langle T_j, \xi\vartheta\rangle = \int \xi a_j \, \mathrm{d}\mu_j, \qquad \langle T, \xi\vartheta\rangle = \int \xi a \, \mathrm{d}\mu.$$

The convergence $T_j \to T$ therefore proves the top-degree assertion.

For $r < n$, wedge with $n - r$ constant positive $(1,1)$-forms, each the Hessian of a positive quadratic function, and apply the top-degree case. By polarization, the products of positive constant $(1,1)$-forms span the real constant forms of bidegree $(n - r, n - r)$, and multiplying them by smooth test functions recovers every coefficient of the currents. For quasi-plurisubharmonic functions, add the fixed smooth corrections to the decreasing sequences, apply the result to the corrected functions, and expand; the term involving the correction to a_j converges by the ordinary decreasing continuity of the products. Finally, the local Chern–Levine–Nirenberg bounds show that these finitely many products have uniformly bounded variation on compact sets. This allows smooth forms converging locally in C^∞ to replace fixed forms in the tests. □

For concentric coordinate balls $B' \Subset B$ and a Borel set $E \subset B'$, the *relative Bedford–Taylor capacity* is

$$\operatorname{cap}(E, B) = \sup\Big\{\int_E (\mathrm{dd^c} v)^n : v \in \mathrm{PSH}(B),\ 0 \le v \le 1\Big\}.$$

If v is bounded, nonconstant and plurisubharmonic on B, applying the definition to $(v - \inf_B v)/(\sup_B v - \inf_B v)$ gives

$$(\mathrm{dd^c} v)^n(E) \le (\sup_B v - \inf_B v)^n \operatorname{cap}(E, B);$$

for constant v both sides vanish. Write $\mathrm{Vol}(E) = \int_E \mathrm{d}V$, where $\mathrm{d}V$ is a fixed smooth positive volume form. We use two standard local estimates on these balls, with constants $C, a > 0$ depending only on the nested balls and on $\mathrm{d}V$:

(1) If $w \le 0$ is plurisubharmonic on B and v is bounded and plurisubharmonic on B, then
$$\int_{B'} |w|(\mathrm{dd^c} v)^n \le C\|w\|_{L^1(B)}\|v\|^n_{L^\infty(B)}.$$
Since adding a constant to v does not change $(\mathrm{dd^c} v)^n$, one may first normalize v by such a constant. This is the weighted Chern–Levine–Nirenberg inequality.

(2) For every Borel set $E \subset B'$,
$$\mathrm{Vol}(E) \le C \exp\big(-a \operatorname{cap}(E, B)^{-1/n}\big),$$
where the right-hand side is zero when the capacity is zero. This is the classical local volume–capacity estimate.

Both are classical results of local pluripotential theory [GZ17, Chapters 3 and 4]; the conventions for bounded products and capacity in [Xia, Chapter 2] agree with these up to fixed constants.

The dependence on the range of the potential can be read off from the usual cutoff argument. Let $M > 0$ and let p be plurisubharmonic on B with $0 \le p \le M$. Let $\kappa = \mathrm{dd^c}|z|^2$ be the Euclidean form, and choose a cutoff function χ supported in B, with $0 \le \chi \le 1$, equal to one on a smaller ball and satisfying $-C\kappa \le \mathrm{dd^c}\chi \le C\kappa$. Integration by parts gives, for $1 \le j \le n$,

$$\begin{aligned}\int \chi(\mathrm{dd^c} p)^j \wedge \kappa^{n-j} &= \int p\, \mathrm{dd^c}\chi \wedge (\mathrm{dd^c} p)^{j-1} \wedge \kappa^{n-j} \\ &\le CM \int_{\operatorname{supp}\chi} (\mathrm{dd^c} p)^{j-1} \wedge \kappa^{n-j+1}.\end{aligned}$$

Iterating this estimate with nested cutoffs between B' and B, and stopping at degree one or at degree zero, we obtain respectively

$$\begin{aligned} \int_{B'} (\mathrm{dd^c} p)^j \wedge \kappa^{n-j} &\le C_j M^{j-1} \int_B \mathrm{dd^c} p \wedge \kappa^{n-1}, \\ \int_{B'} (\mathrm{dd^c} p)^j \wedge \kappa^{n-j} &\le C_j M^j. \end{aligned} \tag{1.2}$$

The constants depend only on the nested balls and on j. For bounded p, the integrations by parts are justified by local decreasing regularization.

Definition 1.6.1 For a compact set E in an open Euclidean ball $B \subset \mathbb{C}^n$, the *relative extremal function* is

$$h_{E,B} = \sup\{u \in \mathrm{PSH}(B) : -1 \le u \le 0,\ u|_E \le -1\}.$$

The constant -1 is a competitor, and the family is bounded above by zero. The local upper-envelope theorem therefore gives $h^*_{E,B} \in \mathrm{PSH}(B)$ with $-1 \le h^*_{E,B} \le 0$. Allowing all competitors $u \le 0$ with $u|_E \le -1$ gives the same supremum, because the truncation $\max(u, -1)$ of such a competitor is a competitor in the original family.

A sequence of functions f_j converges to f *in local capacity* if $\mathrm{cap}(K \cap \{|f_j - f| > \epsilon\}, B) \to 0$ for every $\epsilon > 0$, every coordinate ball B and every compact set $K \subset B$. An assertion holds *quasi-everywhere*, abbreviated q.e., if it holds outside a pluripolar set; in particular, differences of functions that may both be $-\infty$ are considered only off such a set. A positive measure is *non-pluripolar* if it gives zero mass to every pluripolar set.

A function is *quasi-continuous* if, for every $\epsilon > 0$, it is continuous outside an open set of capacity less than ϵ. Plurisubharmonic functions have this property for the local Bedford–Taylor capacity, and a Borel set has zero capacity if and only if it is pluripolar. A locally uniformly bounded monotone sequence of plurisubharmonic functions converges in capacity: to its limit if it decreases, and to the upper semicontinuous regularization of its limit if it increases. If uniformly bounded plurisubharmonic functions converge in capacity, their local products converge weakly, and this remains true after the products are multiplied by uniformly bounded quasi-continuous coefficients converging in capacity. These local results, recalled in [Xia, GZ17], also apply to quasi-plurisubharmonic functions after a common smooth correction.

Theorem 1.6.2 (Mixed Monge–Ampère inequality) *Let $U \subset \mathbb{C}^n$ be a domain, and let β be its Euclidean Hermitian form. Let a, b be locally bounded plurisubharmonic functions on U, and let f, g be nonnegative measurable functions on U with*

$$(\mathrm{dd^c} a)^n \ge f\beta^n, \qquad (\mathrm{dd^c} b)^n \ge g\beta^n.$$

Then, for $0 \le k \le n$,

$$(\mathrm{dd^c} a)^k \wedge (\mathrm{dd^c} b)^{n-k} \ge f^{k/n} g^{(n-k)/n} \beta^n.$$

The comparison principle of Bedford and Taylor also has mixed forms, recalled in [Xia]. Let a, b be locally bounded plurisubharmonic functions on U such that $E = \{a < b\} \Subset U$, and let S be a positive closed $(n-1, n-1)$-current that is

a product of Hessians of bounded plurisubharmonic functions and smooth closed positive forms. Then

$$\int_E \mathrm{dd^c} b \wedge S \le \int_E \mathrm{dd^c} a \wedge S. \tag{1.3}$$

Indeed, apply the Bedford–Taylor integration by parts formula to $b_\epsilon = \max\{a, b-\epsilon\}$, and let $\epsilon \downarrow 0$, using monotone continuity to pass to the limit. Replacing one factor at a time, we obtain, with $P = \mathrm{dd^c} a$ and $Q = \mathrm{dd^c} b$,

$$\int_E P^{n-j} \wedge Q^j \le \int_E P^n, \qquad 0 \le j \le n. \tag{1.4}$$

The local envelope theorem for bounded obstacles, recalled in [Xia, GZ17], shows where an envelope can carry Monge–Ampère mass. Let B be a ball with a smooth strictly plurisubharmonic defining function $h < 0$, and let f be a bounded quasi-continuous obstacle with $Ah \le f \le 0$ for some $A > 0$. Then the envelope

$$q = \big(\sup\{v \in \mathrm{PSH}(B) : v \le f \text{ q.e.}\}\big)^*$$

satisfies $Ah \le q \le 0$, tends to zero at the boundary, and

$$\mathbf{1}_{\{q<f\}} (\mathrm{dd^c} q)^n = 0. \tag{1.5}$$

For a locally bounded quasi-plurisubharmonic function v and a smooth convex increasing function F on a neighborhood of the range of v, the bounded Bedford–Taylor chain rule reads

$$\mathrm{dd^c} F(v) = F'(v)\mathrm{dd^c} v + F''(v)\, \mathrm{d}v \wedge \mathrm{d^c} v. \tag{1.6}$$

The gradient term, and its products with positive Bedford–Taylor factors of bounded potentials, are nonnegative. These identities belong to the bounded local calculus recalled in [Xia, GZ17]; they follow by decreasing regularization, and bounded potentials have the local Sobolev regularity needed to define the gradient term. In particular, inequalities derived from this formula survive local smoothing with a lower curvature error tending to zero.

Lemma 1.6.2 *Let B be a coordinate ball and let τ be a finite non-pluripolar measure with compact support in B. Then there is a bounded plurisubharmonic function v on B such that $\tau \ll (\mathrm{dd^c} v)^n$.*

Proof For $n \ge 2$, we use Cegrell's decomposition theorem. On a bounded hyperconvex domain in $\mathbb{C}^n$, $n \ge 2$, let $\mathcal{E}_0$ consist of the bounded negative plurisubharmonic functions with zero boundary values and finite total Monge–Ampère mass. The theorem states that every positive compactly supported measure τ has a decomposition

$$\tau = g(\mathrm{dd^c} v)^n + \tau_s, \qquad v \in \mathcal{E}_0, \qquad 0 \le g \in L^1((\mathrm{dd^c} v)^n),$$

where τ_s is a positive measure carried by a pluripolar set. If τ is non-pluripolar, then $\tau_s = 0$, so $\tau \ll (\mathrm{dd^c} v)^n$.

In dimension one, the assertion follows directly from the Green potential. Let $a \le 0$ be the Green potential of τ on the disk, normalized by $\mathrm{dd^c} a = \tau$. Then $v = \mathrm{e}^a$ is bounded and subharmonic, and

$$\mathrm{dd^c} v \ge \mathrm{e}^a \tau.$$

To justify this inequality, set $a_M = \max(a, -M)$. The chain rule (1.6) in dimension one gives $\mathrm{dd^c} \mathrm{e}^{a_M} \ge \mathrm{e}^{a_M} \mathrm{dd^c} a_M$, and the right-hand side is at least $\mathrm{e}^a \tau$ on $\{a > -M\}$. Let $M \to \infty$, using the decreasing convergence of the bounded subharmonic functions e^{a_M} on the left and monotone convergence on the right. Since $\{a = -\infty\}$ is polar and τ charges no polar set, $\mathrm{e}^a > 0$ almost everywhere for τ. Thus $\tau \ll \mathrm{dd^c} v$. □

For a signed measure ν, write $|\nu|$ for its total variation measure and $\|\nu\|_{\mathrm{TV}(B)} = |\nu|(B)$. On a curve, the Green representation controls capacity by the total variation of the Laplacian, together with an L^1 term for the harmonic remainder.

Lemma 1.6.3 *Let $B' \Subset B$ be concentric disks in $\mathbb{C}$. There is a constant C, depending only on these disks, such that for all quasi-subharmonic functions u, v on a neighborhood of $\overline{B}$ and all $t > 0$,*

$$\mathrm{cap}(B' \cap \{|u - v| > t\}, B) \le \frac{C}{t} \left(\|u - v\|_{L^1(B)} + \|\mathrm{dd^c}(u - v)\|_{\mathrm{TV}(B)} \right). \tag{1.7}$$

Here the difference $u - v$ is formed off the pole sets of u and v.

Proof Put $f = u - v$ and write the Jordan decomposition on B as $\mathrm{dd^c} f = \alpha^+ - \alpha^-$. Let $g^\pm \le 0$ be the Green potentials of $\alpha^\pm$ on B with zero boundary values. The $L^1(B)$ norm of the Green kernel of the disk is bounded uniformly in its pole, so

$$\|g^+\|_{L^1(B)} + \|g^-\|_{L^1(B)} \le C \|\mathrm{dd^c} f\|_{\mathrm{TV}(B)}.$$

Indeed, on the unit disk the kernel is $\log |(z-\zeta)/(1-\overline{\zeta} z)|^2$; its logarithmic singularity is uniformly integrable, and $|1 - \overline{\zeta} z| \le 2$. Scaling gives the bound on B.

The distribution $h = f - g^+ + g^-$ is harmonic, and the interior mean-value estimate gives

$$\|h\|_{L^\infty(B')} \le C \left(\|f\|_{L^1(B)} + \|\mathrm{dd^c} f\|_{\mathrm{TV}(B)} \right).$$

The identity $u + g^- = v + g^+ + h$ holds almost everywhere, hence everywhere by Lemma 1.3.3. Thus $|u - v| \le -g^+ - g^- + |h|$ off the polar sets of u and v. Let $0 \le a \le 1$ be a subharmonic test function on B. Since the measure $\mathrm{dd^c} a$ charges no polar set, this pointwise bound, the weighted Chern–Levine–Nirenberg estimate and (1.2) yield

$$\int_{B'} |u - v| \, \mathrm{dd^c} a \le C \left(\|f\|_{L^1(B)} + \|\mathrm{dd^c} f\|_{\mathrm{TV}(B)} \right).$$

Restricting the integral to $B' \cap \{|u - v| > t\}$, dividing by t and taking the supremum over a proves (1.7). □

1.6.1 Polar parts on curves

Every locally finite signed measure ν on a Riemann surface splits uniquely as the sum of its *polar part* ν^{pol}, which is carried by a polar Borel set, and a measure that charges no polar set. To construct the splitting locally, choose countably many polar Borel sets whose $|\nu|$-masses approach the supremum over all polar Borel sets, and restrict ν to their union, which is again polar. Uniqueness allows these local decompositions to be patched together and shows that $\nu \mapsto \nu^{\mathrm{pol}}$ is linear.

For a locally quasi-subharmonic function u, the *polar curvature* of u is the positive measure $\mu_u = (\mathrm{dd^c} u)^{\mathrm{pol}} = \mathbf{1}_{\{u=-\infty\}} \mathrm{dd^c} u$. The second equality holds because smooth corrections do not change polar parts, while bounded truncations and plurifine locality show that $\mathbf{1}_{\{u>-j\}} \mathrm{dd^c} u$ charges no polar set. The following inverse maximum principle shows that an upper bound for the difference of two potentials orders their polar curvatures.

Lemma 1.6.4 *Let $B \subset \mathbb{C}$ be a disk and let $f \in L^1_{\mathrm{loc}}(B)$ have a distributional Laplacian that is a signed Radon measure. If $f \le 0$ almost everywhere, then $(\Delta f)^{\mathrm{pol}} \ge 0$.*

Proof It suffices to prove $\Delta f(K) \ge 0$ for every compact polar set $K \subset B$; restriction to smaller disks and inner regularity then give the assertion. Choose open neighborhoods O_j of K with smooth boundaries such that $\overline{O}_{j+1} \subset O_j \Subset B$ and $\bigcap_j \overline{O}_j = K$. Let h_j be the function that equals one on $\overline{O}_j$, is harmonic on $B \setminus \overline{O}_j$, and vanishes on ∂B. The Dirichlet problem on this smooth domain shows that h_j is continuous with $0 \le h_j \le 1$. Its outward normal derivative on ∂O_j is nonpositive, so the jump of the derivative across ∂O_j gives $\Delta h_j \le 0$ on B in the sense of distributions. The maximum principle gives $h_{j+1} \le h_j$.

Since $0 \le h_j \le 1$, the sequence converges in $L^1_{\mathrm{loc}}(B)$. Let h be the superharmonic representative of this limit; it may differ from the pointwise limit on K. It is harmonic off K, so its Laplacian is supported on the polar set K. On the other hand, $-h$ is bounded and subharmonic, so its Laplacian charges no polar set, by Theorem 1.6.1. Hence h is harmonic on B. Since $0 \le h \le h_1$ and h_1 tends to zero at ∂B, the maximum principle gives $h = 0$. It follows that $h_j \to 0$ smoothly on compact subsets of $B \setminus K$, while $h_j = 1$ on K.

Choose $0 \le \chi \in C_c^\infty(B)$ equal to one near K. For large j, regularize h_j by convolution on a neighborhood of $\operatorname{supp} \chi$, obtaining smooth functions $h_{j,\epsilon}$ with $\Delta h_{j,\epsilon} \le 0$. Since $f \le 0$,

$$\begin{aligned} \int_B \chi h_{j,\epsilon} \, \mathrm{d}(\Delta f) &= \int_B f \, \Delta(\chi h_{j,\epsilon}) \, \mathrm{d}x \, \mathrm{d}y \\ &\ge \int_B f \left(2 \nabla \chi \cdot \nabla h_{j,\epsilon} + h_{j,\epsilon} \Delta \chi\right) \mathrm{d}x \, \mathrm{d}y. \end{aligned}$$

For fixed j, the convolutions converge uniformly to h_j on $\operatorname{supp} \chi$, because h_j is continuous. On the support of the derivatives of χ, the function h_j is harmonic for all large j. We may therefore first let $\epsilon \downarrow 0$ and then let $j \to \infty$. The smooth convergence away from K makes the right-hand side tend to zero, and dominated convergence

for the signed measure Δf makes the left-hand side tend to $\Delta f(K)$. This proves $\Delta f(K) \geq 0$. □

Corollary 1.6.1 *Let u, v be locally quasi-subharmonic functions on a Riemann surface. If $u \leq v + C$ on an open set for some constant C, then $\mu_u \geq \mu_v$ there. Moreover,*

$$\mu_{\max(u,v)} = \mu_u \wedge \mu_v, \tag{1.8}$$

where the right-hand side is the greatest measure dominated by both μ_u and μ_v.

Proof Apply Lemma 1.6.4 to $u - v - C$ in local coordinates. Since smooth functions have zero polar part, linearity of the polar part gives the first assertion. Applying it to $u - \max(u, v)$ and to $v - \max(u, v)$ gives the inequality $\leq$ in (1.8).

For the reverse inequality, add a common smooth correction to make u and v subharmonic on a coordinate disk. On a smaller disk, let g be the Green potential of the restriction of $\lambda = \mu_u \wedge \mu_v$ to that disk, so that $\mathrm{dd^c} g = \lambda$. The distributions $u - g$ and $v - g$ have positive Hessians and hence subharmonic representatives a and b. Since $\max(u, v) = g + \max(a, b)$ almost everywhere, the Hessian of $\max(u, v)$ dominates λ. Restricting this inequality to a polar Borel set carrying λ proves the reverse inequality on the smaller disk, and these local statements give it on the whole surface. □

1.6.2 Products at small pole sets

A top-degree product can carry mass on a pole set, and the non-pluripolar product discards this mass. When the unbounded locus is sufficiently small, the full local current product is well defined. Singularity order then compares its residual measures on the pole set, and bounded perturbations leave these measures unchanged.

Theorem 1.6.3 *Let $\Omega \subset \mathbb{C}^n$ be a domain and $S \subset \Omega$ a closed set of Hausdorff dimension zero. Suppose that $u_1, \ldots, u_q$, $1 \leq q \leq n$, are plurisubharmonic on Ω and locally bounded on $\Omega \setminus S$. Then their inductively defined full current product*

$$\left(\mathrm{dd^c} u_1 \wedge \cdots \wedge \mathrm{dd^c} u_q\right)_{\mathrm{full}}$$

is a closed positive current of order zero. It is symmetric, multilinear, local in the ordinary topology, and continuous under simultaneous decreasing approximation by plurisubharmonic functions. The weighted current $u_1 \left(\mathrm{dd^c} u_2 \wedge \cdots \wedge \mathrm{dd^c} u_q\right)_{\mathrm{full}}$ has coefficients of locally finite variation. These full products may charge S.

Proof Apply the classical theorem on products with unbounded potentials, together with its monotone continuity statement, in [Dem12, Chapter III, Theorem 4.5 and Proposition 4.9, pp. 152–156], with the underlying current $T = 1$. For every choice of m of the functions, that theorem requires the intersection of their unbounded loci to have zero Hausdorff measure of dimension $2n - 2m + 1$. This intersection lies in

S, and $2n - 2m + 1 \geq 1$, so the measure is zero. The same hypothesis gives local integrability of the weighted current. Symmetry, multilinearity and locality on open sets follow from the local construction of the currents and decreasing regularization.□

The subscript distinguishes this product from the non-pluripolar product used later; the two coincide for locally bounded functions.

Lemma 1.6.5 *Let $\Omega \subset \mathbb{C}^n$ be a domain and $S \subset \Omega$ a closed set of Hausdorff dimension zero. Let a, b be plurisubharmonic on Ω and locally bounded off S, with $\{a = -\infty\} = S$. If $a \leq b + C$ near S for some finite constant C, then, as positive Radon measures,*

$$\mathbf{1}_S (\mathrm{dd^c} b)^n_{\mathrm{full}} \leq \mathbf{1}_S (\mathrm{dd^c} a)^n_{\mathrm{full}}.$$

If $a - b$ is bounded near S, equality holds.

Proof Fix a compact set $E \subset S$ and $\varepsilon > 0$, and put $w_c = \max\{b - c, (1 + \varepsilon)a\}$ for $c > 0$. Since $a = -\infty$ on the compact set E, upper semicontinuity gives a neighborhood of E on which $a < -(C + c)/\varepsilon$ and $a \leq b + C$. Off S, on this neighborhood, $b - c - (1 + \varepsilon)a \geq -C - c - \varepsilon a > 0$, while on S the second branch of the maximum equals $-\infty$. Thus $w_c = b - c$ near E, and locality on open sets gives $(\mathrm{dd^c} w_c)^n_{\mathrm{full}}(E) = (\mathrm{dd^c} b)^n_{\mathrm{full}}(E)$.

As $c \to \infty$, the functions w_c decrease to $(1 + \varepsilon)a$. Theorem 1.6.3 applies to every w_c with the same set S, so their full measures converge weakly to $(1 + \varepsilon)^n (\mathrm{dd^c} a)^n_{\mathrm{full}}$. Since the mass of a compact set is upper semicontinuous under weak convergence of positive measures, we obtain

$$(\mathrm{dd^c} b)^n_{\mathrm{full}}(E) \leq (1 + \varepsilon)^n (\mathrm{dd^c} a)^n_{\mathrm{full}}(E).$$

Here we apply the semicontinuity after multiplying the measures by a fixed nonnegative cutoff function with compact support, equal to one near E; both masses on E are finite by the theorem. Letting $\varepsilon \downarrow 0$ and applying inner regularity to all compact sets $E \subset S$ gives the asserted inequality of measures. If $a - b$ is bounded near S, then also $\{b = -\infty\} = S$, so the roles of a and b can be interchanged, and equality follows. □

1.6.3 Sobolev regularity at divisorial poles

For a potential that is a convex function of $\log |f|$, with f holomorphic, the growth of the convex function at $-\infty$ determines which derivatives are integrable near the divisor of f. The gradient and the classical Laplacian have different thresholds. Moreover, the distributional Laplacian keeps a measure on the divisor unless the slope of the convex function tends to zero.

Let $U \subset \mathbb{C}^n$ be a sufficiently small neighborhood of 0, and let $f \not\equiv 0$ be a holomorphic function on U with $f(0) = 0$. Write

$$f = g \prod_{j=1}^{N} h_j^{m_j}, \qquad m_0 = \min_j m_j,$$

where g is a holomorphic unit and the h_j are distinct irreducible germs represented on U. Fix a convex nondecreasing function $\chi \in C^2((-\infty, A])$ and shrink U so that $\log|f| < A-1$. Set $v = \chi(\log|f|)$ off $Z = \{f = 0\}$; this function is plurisubharmonic and bounded above, and we extend it across Z by Lemma 1.3.7. In this subsection, gradients, Laplacians, Sobolev spaces and the volume form $\mathrm{d}V$ are the real Euclidean ones. Write $|\partial f|^2 = \sum_j |\partial f/\partial z_j|^2$, so that $|\nabla|f|| = |\partial f|$ off Z.

Lemma 1.6.6 *After shrinking U, there is a constant $C > 0$ such that*

$$|\partial f| \le C|f|^{1-1/m_0} \quad \text{on } U \setminus Z.$$

For each compact set $K \subset U$, there are $C_K, r_K > 0$ with

$$\int_{K\cap\{|f|=r\}} |\partial f|\,\mathrm{d}S \le C_K r \qquad (0 < r < r_K),$$

where $\mathrm{d}S$ is the Euclidean surface measure on the real hypersurface $\{|f| = r\}$. In particular, for every nonnegative measurable function Ψ,

$$\int_{K\cap\{0<|f|<r_K\}} \Psi(|f|)|\partial f|^2\,\mathrm{d}V \le C_K \int_0^{r_K} \Psi(r) r\,\mathrm{d}r.$$

Proof Shrink U so that $|h_j| \le 1$ and the unit g, its inverse and the first derivatives of g and of all h_j are bounded. For each j, $|f|^{1/m_0} \le C|h_j|^{m_j/m_0} \le C|h_j|$. Logarithmic differentiation of the factorization therefore gives

$$\frac{|\partial f|}{|f|} \le C\left(1 + \sum_j |h_j|^{-1}\right) \le C|f|^{-1/m_0},$$

which proves the first bound.

For small $\zeta \in \mathbb{C}$, let μ_ζ be the Euclidean volume measure of the fiber divisor $\{f = \zeta\}$, counted with multiplicity. As $\zeta \to 0$, we have $\log|f-\zeta| \to \log|f|$ in L^1_{loc}: by the local compactness theorem recalled at the beginning of Section 1.4, it suffices to identify subsequential limits, and the convergence is locally uniform off Z, which identifies every such limit and excludes convergence to $-\infty$. The Poincaré–Lelong formula therefore gives weak convergence of the fiber currents, and hence of their Euclidean trace measures. Pairing with a fixed nonnegative cutoff function equal to one near K shows that $\sup_{|\zeta|<r_K} \mu_\zeta(K) < \infty$ for some $r_K > 0$.

The critical locus of f has finitely many local components, and f is constant on each of them. After shrinking U, every remaining critical component passes through 0, where f vanishes. Thus the small nonzero fibers are smooth. On $\{|f| = r\}$, the coarea formula for the map f to the circle of radius r gives

$$\int_{K\cap\{|f|=r\}} |\partial f|\,\mathrm{d}S = \int_{|\zeta|=r} \mu_\zeta(K)\,\mathrm{d}S(\zeta) \le C_K r.$$

The coarea formula for the function $|f|$, together with $|\nabla|f|| = |\partial f|$, proves the last inequality. The same formulas hold in dimension one, where the fiber volume is the counting measure. □

Proposition 1.6.1 *For each* $2 \le p < \infty$,

$$v \in W^{1,p}_{\mathrm{loc}}(U) \quad\Longleftrightarrow\quad \int_{-\infty}^{A} |\chi'(s)|^p \mathrm{e}^{(2-p)s/m_0}\,\mathrm{d}s < \infty.$$

In this case, the weak gradient of v *is the zero extension of* $\chi'(\log|f|)\nabla\log|f|$ *from* $U\setminus Z$.

Proof At a smooth point of a component of multiplicity m_0, outside the other components, multiplying the defining function of the component by a holomorphic m_0-th root of the remaining unit gives a normal coordinate w_1 with $f = w_1^{m_0}$. Coordinate changes with bounded derivatives and Jacobians preserve local first-order Sobolev integrability. With $r = |w_1|$ and $s = m_0\log r$, polar integration of the classical gradient gives, up to fixed positive factors,

$$\int_0^{r_0} |\chi'(m_0\log r)|^p r^{1-p}\,\mathrm{d}r = \frac{1}{m_0}\int_{-\infty}^{m_0\log r_0} |\chi'(s)|^p \mathrm{e}^{(2-p)s/m_0}\,\mathrm{d}s.$$

Such smooth points occur in every neighborhood of 0. This proves necessity, since changing the finite upper endpoint does not affect convergence.

For sufficiency, put

$$s_\varepsilon = \tfrac{1}{2}\log(|f|^2+\varepsilon^2), \qquad v_\varepsilon = \chi(s_\varepsilon).$$

For small $\varepsilon > 0$, these are C^2 plurisubharmonic functions decreasing to v. By convexity, $|\chi(s)| \le C(1+|s|)$ for $s \le A$, so the local exponential integrability of $\log|f|$, recalled in [Xia], gives convergence in every local L^p space with $p < \infty$. By the chain rule,

$$|\nabla v_\varepsilon| = \chi'(s_\varepsilon)\frac{|f|}{|f|^2+\varepsilon^2}|\partial f|.$$

Apply Lemma 1.6.6 with the coarea formula, keeping two powers of $|\partial f|$ for the level estimate and bounding the other $p-2$ powers by the first inequality of the lemma. The local integral of $|\nabla v_\varepsilon|^p$ over $K\cap\{0<|f|<r_K\}$ is then bounded by

$$C\int_0^{r_K} |\chi'(\tfrac{1}{2}\log(r^2+\varepsilon^2))|^p \frac{r^{p+(p-2)(1-1/m_0)+1}}{(r^2+\varepsilon^2)^p}\,\mathrm{d}r.$$

With $s = \frac{1}{2}\log(r^2+\varepsilon^2)$, we have $\mathrm{d}s = r\,\mathrm{d}r/(r^2+\varepsilon^2)$ and $r \le (r^2+\varepsilon^2)^{1/2}$, so this is at most

$$C \int_{-\infty}^{A} |\chi'(s)|^p \mathrm{e}^{(2-p)s/m_0}\, \mathrm{d}s.$$

The integral over the part where $|f| \geq r_K$ is uniformly bounded as well. Weak compactness in Sobolev spaces and the local L^p convergence therefore show that $v \in W^{1,p}_{\mathrm{loc}}$. Its weak gradient agrees with the classical one off Z, and Z has Lebesgue measure zero, which proves the final assertion. □

Proposition 1.6.2 *Let G be the zero extension of $\chi''(\log|f|)|\nabla \log|f||^2$ from $U \setminus Z$, and put $\ell = \lim_{s\to-\infty} \chi'(s)$. For each $1 \leq p < \infty$,*

$$G \in L^p_{\mathrm{loc}}(U) \quad \Longleftrightarrow \quad \int_{-\infty}^{A} |\chi''(s)|^p \mathrm{e}^{2(1-p)s/m_0}\, \mathrm{d}s < \infty.$$

In the sense of distributions,

$$\Delta v = G + \ell\, \Delta \log|f|,$$

where $\Delta \log|f|$ is a positive measure carried by the divisor of f. In particular, Δv is represented by a locally L^p function exactly when $\ell = 0$ and the integral above is finite.

Proof The limit $\ell \geq 0$ exists because χ' is nonnegative and nondecreasing. Near a smooth point of a component of multiplicity m_0, outside the other components, the coordinate reduction to $f = w_1^{m_0}$ makes the positive complex Hessian of v off Z a single factor in the normal direction. Its Euclidean traces in the two coordinate systems are uniformly comparable, so polar integration gives necessity. In general, $G = \chi''(\log|f|)|\partial f|^2/|f|^2$ off Z. The coarea formula and Lemma 1.6.6, now bounding the remaining $2p-2$ powers of $|\partial f|$ by the first inequality of the lemma, give

$$\int_{K\cap\{0<|f|<r_K\}} G^p\, \mathrm{d}V \leq C \int_0^{r_K} |\chi''(\log r)|^p r^{-1-2(p-1)/m_0}\, \mathrm{d}r.$$

The substitution $s = \log r$ proves sufficiency. For $p = 1$ the integral is always finite, since $\int_{-\infty}^{A} \chi'' = \chi'(A) - \ell$.

For the distributional identity, use s_ε and v_ε from the preceding proof. Direct differentiation gives

$$\Delta v_\varepsilon = \chi''(s_\varepsilon) \frac{|f|^2|\partial f|^2}{(|f|^2+\varepsilon^2)^2} + \chi'(s_\varepsilon)\Delta s_\varepsilon,$$
$$\Delta s_\varepsilon = \frac{2\varepsilon^2|\partial f|^2}{(|f|^2+\varepsilon^2)^2}.$$

Off Z, the first term tends locally uniformly to G. By the level estimate of Lemma 1.6.6 and the same substitution, its integral over $K \cap \{|f| < r_0\}$ is at most

$$C \int_{-\infty}^{\frac{1}{2}\log(r_0^2+\varepsilon^2)} \chi''(s)\,\mathrm{d}s.$$

This bound tends to zero if we first let $\varepsilon \to 0$ and then $r_0 \to 0$, so the first term converges to G in L^1_{loc}.

The positive measures Δs_ε converge weakly to $\Delta \log|f|$, with locally bounded masses, and the Poincaré–Lelong formula shows that this limit is a measure supported on Z. On $\{|f| < r_0\}$,

$$0 \le \chi'(s_\varepsilon) - \ell \le \chi'(\tfrac{1}{2}\log(r_0^2+\varepsilon^2)) - \ell,$$

while $\Delta s_\varepsilon \to 0$ uniformly on compact subsets of $\{|f| \ge r_0\}$. Taking the same successive limits shows that $(\chi'(s_\varepsilon) - \ell)\Delta s_\varepsilon \to 0$ weakly. Since $v_\varepsilon \to v$ in L^1_{loc}, passing to the limit in the formula for Δv_ε gives the identity. If $\ell > 0$, the measure $\ell\,\Delta\log|f|$ is nonzero and singular with respect to Lebesgue measure; uniqueness of the Lebesgue decomposition therefore proves the final criterion. □

Example 1.6.1 Shrink U so that $\log|f| < -2$, and let $0 < a < 1$. Then the plurisubharmonic function

$$v_a = -(-\log|f|)^a$$

has $\Delta v_a \in L^1_{\mathrm{loc}}$, while

$$v_a \in W^{1,2}_{\mathrm{loc}} \quad\Longleftrightarrow\quad a < \tfrac{1}{2}.$$

It belongs to no $W^{1,p}_{\mathrm{loc}}$ with $p > 2$ and to no $W^{2,1}_{\mathrm{loc}}$.

Proof Here $\chi(s) = -(-s)^a$ is of class C^2 on $(-\infty, -1]$, so the preceding propositions apply with $A = -1$. Moreover, $\chi'(s) = a(-s)^{a-1}$ and $\chi''(s) = a(1-a)(-s)^{a-2}$, so $\ell = 0$. The two propositions give the assertion about the Laplacian and the first-order thresholds. At $a = 1/2$, the first-order integral diverges logarithmically; for $p > 2$, its exponential factor forces divergence.

For second derivatives, take a smooth point of a component of multiplicity m, outside the other components, with a normal coordinate w_1 such that $f = w_1^m$. Write $F(r) = \chi(m\log r)$ with $r = |w_1|$. The real second derivative of v_a in the unit direction tangent to the circles $|w_1| = r$ equals $F'(r)/r = m\chi'(m\log r)/r^2$. Thus the integral of its absolute value over the normal disk is bounded below, up to a fixed positive factor, by

$$\int_0^{r_0} \chi'(m\log r)\frac{\mathrm{d}r}{r} = \frac{1}{m}\int_{-\infty}^{m\log r_0} \chi'(s)\,\mathrm{d}s = +\infty.$$

Hence the classical Hessian of v_a off the divisor is not locally integrable, whereas local integrability is necessary for $W^{2,1}_{\mathrm{loc}}$. Since smooth coordinate changes preserve this Sobolev class, the argument is complete. □

1.6.4 Spherical Monge–Ampère measures

A bounded radial maximum gives a measure concentrated on a real hypersurface. This supplies singular measures that still give zero mass to pluripolar sets.

Lemma 1.6.7 *For $r > 0$, let σ_r be the normalized Euclidean surface measure on $\{|z| = r\} \subset \mathbb{C}^n$. Then*

$$\left(\mathrm{dd^c} \log \max\{|z|^2, r^2\}\right)^n = \sigma_r .$$

In particular, σ_r does not charge pluripolar sets.

Proof Write $t = \log |z|^2$ and approximate $\max\{t, \log r^2\}$ uniformly by smooth convex increasing functions $F_\epsilon(t)$ whose derivatives equal zero below $\log r^2 - \epsilon$ and one above $\log r^2 + \epsilon$. Their compositions with t extend smoothly across zero. Since $\mathrm{dd^c} t$ has rank $n - 1$ off zero, the chain rule gives

$$(\mathrm{dd^c} F_\epsilon(t))^n = n(F_\epsilon')^{n-1} F_\epsilon'' \, \mathrm{d}t \wedge \mathrm{d^c} t \wedge (\mathrm{dd^c} t)^{n-1}.$$

The integral of $\mathrm{d^c} t \wedge (\mathrm{dd^c} t)^{n-1}$ over each sphere is one. Indeed, $\mathrm{d^c} t$ integrates to one on the Hopf circle, and the induced form on $\mathbb{P}^{n-1}$ is $\mathrm{dd^c} \log(1 + |w|^2)$; its top power has density $(n-1)!\pi^{-(n-1)}(1 + |w|^2)^{-n}$ on the affine chart, whose integral is one. Thus each displayed radial measure has total mass $\int ((F_\epsilon')^n)' \, \mathrm{d}t = 1$. Its support shrinks to the sphere, and its rotation invariance identifies the limit as σ_r. Uniform bounded-potential convergence identifies that limit with the product in the statement. Non-pluripolarity follows from Theorem 1.6.1. □

1.6.5 Measure concentration under integrable convergence

Decreasing approximation controls Bedford–Taylor products, but convergence of the potentials in L^1 alone does not. If plurisubharmonic functions tend to zero in L^1_{loc} and are locally uniformly bounded, the range estimate (1.2) shows that their Monge–Ampère measures tend to zero. Without a common bound, smooth bounded potentials that tend to zero, even in capacity, can have Monge–Ampère measures converging to a point mass.

Lemma 1.6.8 *Let $\Omega \subset \mathbb{C}^n$ be a domain. Suppose that $u_j \in \mathrm{PSH}(\Omega) \cap L^\infty_{\mathrm{loc}}(\Omega)$ tend to zero in $L^1_{\mathrm{loc}}(\Omega)$ and satisfy $\sup_j \|u_j\|_{L^\infty(K)} < \infty$ for every compact set $K \subset \Omega$. Then $(\mathrm{dd^c} u_j)^n(K) \to 0$ for every such K.*

Proof Fix concentric balls $B' \Subset B \Subset B_1 \Subset \Omega$, and put $\beta = \mathrm{dd^c}|z|^2$. If ψ is a nonnegative smooth cutoff function supported in B_1 and equal to one near $\overline{B}$, integration by parts gives

$$0 \le \int_B \mathrm{dd^c} u_j \wedge \beta^{n-1} \le \int_{B_1} u_j \mathrm{dd^c}\psi \wedge \beta^{n-1} \le C\|u_j\|_{L^1(B_1)} \longrightarrow 0.$$

Choose $M > 0$ with $|u_j| \le M$ on B for all j, and apply the first estimate in (1.2) to $u_j + M$, whose values lie in $[0, 2M]$. It bounds the top-degree mass of B' by $C(2M)^{n-1}$ times the trace integral over B, which tends to zero; for $n = 1$ the trace estimate itself suffices. Covering K by finitely many such balls proves the lemma. □

The construction uses a regularized maximum of a small multiple of a logarithm in one variable and a potential in the remaining variables. Its Monge–Ampère measure can be computed exactly by integration over circles in the first variable, and this will keep its top-degree mass fixed while the logarithmic coefficient tends to zero.

Lemma 1.6.9 *Let $n \ge 2$, let $U \subset \mathbb{C}^{n-1}$ be a domain, and let v be a smooth plurisubharmonic function on U. Fix $\varepsilon, R, \eta > 0$ and $A \in \mathbb{R}$. Let χ_η be the convolution of $t \mapsto \max(t, 0)$ with a smooth even probability density supported in $[-\eta, \eta]$, and put*

$$q(\zeta) = \varepsilon \log(|\zeta|^2/R^2), \qquad T(\zeta, z') = v(z') - A - q(\zeta),$$
$$h(\zeta, z') = q(\zeta) + \chi_\eta(T(\zeta, z'))$$

for $\zeta \neq 0$. Then h extends to a smooth plurisubharmonic function on $\mathbb{C} \times U$. Set

$$w_\eta(t) = n\chi_\eta'(t)^{n-1}\chi_\eta''(t), \qquad r_t(z') = R\exp\big((v(z') - A - t)/(2\varepsilon)\big).$$

The function w_η is nonnegative, supported in $[-\eta, \eta]$, and has integral one. For every $f \in C_c(\mathbb{C} \times U)$,

$$\int f(\mathrm{dd^c} h)^n = \varepsilon \int_U \left[\int_{-\eta}^{\eta} w_\eta(t) \int_0^{2\pi} f(r_t(z')\mathrm{e}^{\mathrm{i}\vartheta}, z') \frac{\mathrm{d}\vartheta}{2\pi}\, \mathrm{d}t\right] (\mathrm{dd^c} v)^{n-1}. \tag{1.9}$$

Proof By convexity, $0 \le \chi_\eta' \le 1$ and $\chi_\eta'' \ge 0$. The function χ_η vanishes on $(-\infty, -\eta]$ and equals t on $[\eta, \infty)$. Since $T \to +\infty$ as $\zeta \to 0$, we have $h = v - A$ near each point with $\zeta = 0$, which gives the smooth extension. Off the hyperplane $\{\zeta = 0\}$, the function q is pluriharmonic and

$$\mathrm{dd^c} h = \chi_\eta'(T)\mathrm{dd^c} v + \chi_\eta''(T)\, \mathrm{d}T \wedge \mathrm{d^c} T \ge 0.$$

The second summand has rank at most one, and the first has rank at most $n - 1$. Hence

$$(\mathrm{dd^c} h)^n = n\chi_\eta'(T)^{n-1}\chi_\eta''(T)\, \mathrm{d}T \wedge \mathrm{d^c} T \wedge (\mathrm{dd^c} v)^{n-1}.$$

The last factor has top degree in the variables z', so the derivatives of v in $\mathrm{d}T \wedge \mathrm{d^c} T$ contribute nothing. Write $s = \log(|\zeta|^2/R^2)$. In polar coordinates, $\mathrm{d}q = \varepsilon\, \mathrm{d}s$ and $\mathrm{d^c} q = \varepsilon\, \mathrm{d}\vartheta/(2\pi)$. At fixed z', the change of variables from s to $t = v - A - \varepsilon s$ gives (1.9). There is no contribution near $\zeta = 0$, where $h = v - A$ and the form $\mathrm{dd^c} h$ has rank at most $n - 1$. Finally, w_η is the derivative of $(\chi_\eta')^n$, whose values at $-\eta$ and η are zero and one. □

Proposition 1.6.3 *Let $\Omega \subset \mathbb{C}^n$, $n \ge 2$, be a bounded domain and $a \in \Omega$. For every $c > 0$, there are smooth bounded plurisubharmonic functions $u_j \le 0$ on Ω such that*

$$\|u_j\|_{L^p(\Omega)} \longrightarrow 0 \quad (1 \le p < \infty), \qquad (\mathrm{dd^c} u_j)^n \longrightarrow c\delta_a \quad \textit{vaguely}.$$

The same sequence tends to zero in local capacity. Here the norms are taken with respect to Lebesgue measure, and vague convergence means convergence against every compactly supported continuous test function.

Proof Translate a to the origin and write $z = (\zeta, z') \in \mathbb{C} \times \mathbb{C}^m$, $m = n - 1$. It suffices to construct measures of mass one and then multiply the potentials by $c^{1/n}$. For $\delta > 0$, put $H_\delta(z') = \log(|z'|^2 + \delta^2)$. With $s = |z'|^2$, the complex Hessian of H_δ has the eigenvalue $(s + \delta^2)^{-1}$ with multiplicity $m - 1$ in the directions orthogonal to z' and the eigenvalue $\delta^2(s + \delta^2)^{-2}$ in the radial direction. Taking the determinant and integrating in polar coordinates gives

$$(\mathrm{dd^c} H_\delta)^m = \frac{m!}{\pi^m} \frac{\delta^2}{(|z'|^2 + \delta^2)^{m+1}} \, \mathrm{d}\lambda_{2m}, \qquad \int_{|z'|<b} (\mathrm{dd^c} H_\delta)^m = \left(\frac{b^2}{b^2 + \delta^2} \right)^m,$$

where λ_{2m} is Lebesgue measure. These probability measures tend to δ_0 as $\delta \downarrow 0$, since their mass outside each ball about the origin tends to zero.

Choose $R > \max(1, \sup_\Omega |\zeta|)$ and a ball $P \subset \mathbb{C}^m$ containing the projection of Ω to the z' variables. Set

$$\delta_j = \varepsilon_j = j^{-1}, \qquad \eta_j = j^{-2}, \qquad v_j = \varepsilon_j^{-1/m} H_{\delta_j},$$
$$A_j = \sup_P v_j + 2\varepsilon_j \log(Rj).$$

Apply Lemma 1.6.9 on $\mathbb{C} \times \mathbb{C}^m$ to these data, and let $u_j = h_j - \eta_j$, where h_j is the resulting function. The convolution satisfies $0 \le \chi_{\eta_j}(t) - \max(t, 0) \le \eta_j$, and $q + \max(T, 0) = \max(q, v_j - A_j)$. Both branches of this maximum are negative on Ω, so

$$\varepsilon_j \log(|\zeta|^2/R^2) - \eta_j \le u_j \le 0.$$

Each u_j is smooth and bounded on Ω, since the second branch $v_j - A_j$ is bounded below on the bounded set P. The logarithm has finite $L^p(\Omega)$ norm for every finite p, by polar integration on a fixed polydisk containing Ω. Hence $u_j \to 0$ in all these norms.

Let $B' \Subset B \Subset \Omega$ be concentric balls, and let $w \in \mathrm{PSH}(B)$ with $0 \le w \le 1$. Since $|u_j| \le \varepsilon_j |\log(|\zeta|^2/R^2)| + \eta_j$, the weighted Chern–Levine–Nirenberg estimate applied to $\log(|\zeta|^2/R^2)$, together with the range estimate (1.2) for the constant term, gives

$$\int_{B'} |u_j| (\mathrm{dd^c} w)^n \le C_B(\varepsilon_j + \eta_j),$$

where C_B depends on the fixed balls and the logarithm but not on j or w. Restricting the integral to $B' \cap \{|u_j| > t\}$, dividing by $t > 0$ and taking the supremum over w shows that the capacity of $B' \cap \{|u_j| > t\}$ relative to B tends to zero.

In (1.9), the factor $\varepsilon_j (\mathrm{dd^c} v_j)^m$ equals $(\mathrm{dd^c} H_{\delta_j})^m$. For $z' \in P$ and $|t| \le \eta_j$, the radii satisfy

$$r_t(z') \le j^{-1} \exp(\eta_j/(2\varepsilon_j)) \le \mathrm{e}^{1/2}/j.$$

Extend $f \in C_c(\Omega)$ by zero to $\mathbb{C}^n$. Outside the projection of $\operatorname{supp} f$ to the z' variables, both $f(r_t e^{i\vartheta}, z')$ and $f(0, z')$ vanish. On this projection, the uniform continuity of f and the bound on the radii make their difference tend to zero uniformly. Since the weights $w_{\eta_j}(t)\,dt$ and $d\vartheta/(2\pi)$ and the measures $(dd^c H_{\delta_j})^m$ all have total mass one, it follows that

$$\int_\Omega f(dd^c u_j)^n - \int_{\mathbb{C}^m} f(0,z')(dd^c H_{\delta_j})^m \longrightarrow 0.$$

The second integral tends to $f(0)$, which proves the asserted vague limit. □

Each approximating measure has a smooth density and charges no pluripolar set, whereas the limit is a point mass. By Lemma 1.6.8, the potentials therefore have no common lower bound on some compact set. Thus convergence in capacity is compatible with concentration of the Monge–Ampère measures once common local bounds are lost.

1.6.6 Adding a prescribed local measure

The concentration in Proposition 1.6.3 can be produced on top of a given bounded potential b and repeated, so as to add an arbitrary prescribed measure to $(dd^c b)^n$. Adding a perturbation h to b creates the mixed terms $(dd^c b)^{n-r} \wedge (dd^c h)^r$. A mixed Chern–Levine–Nirenberg estimate controls them, provided that the lower-degree currents of h are kept small.

Lemma 1.6.10 *Fix the data $n, U, v, \varepsilon, R, \eta, \chi_\eta$ of Lemma 1.6.9, and write h_A for the smooth plurisubharmonic function h of that lemma, regarded as a function of A. Put $D = \{0\} \times U$, and write $[D]$ for the current of integration over this hypersurface. Then, for every $1 \le r \le n$,*

$$(dd^c h_A)^r \longrightarrow \varepsilon [D] \wedge (dd^c v)^{r-1} \quad \text{as currents on } \mathbb{C} \times U,\ A \to \infty.$$

The product on the right is integration of the restriction of the smooth form $(dd^c v)^{r-1}$ over D.

Proof Write $S = dd^c v$, $q = \varepsilon \log(|\zeta|^2/R^2)$ and $T_A = v - A - q$. The rank-one calculation in the proof of Lemma 1.6.9 gives

$$(dd^c h_A)^r = \chi_\eta'(T_A)^r S^r + r\chi_\eta'(T_A)^{r-1}\chi_\eta''(T_A)\, dT_A \wedge d^c T_A \wedge S^{r-1}$$

off D; since h_A is smooth and D has measure zero, this formula determines the current. Fix a smooth compactly supported test form. On the projection of its support to U, the function v and its derivatives are bounded. Hence the support of $\chi_\eta'(T_A)$ lies in $\{|\zeta| \le s_A\}$, where $s_A = C\exp(-A/(2\varepsilon))$ and C depends only on this compact set and the fixed data. The coefficients involving v and χ_η are bounded at the fixed parameters, so the first summand has pairing $O(s_A^2)$. In the second summand, the

term with two derivatives of v also has pairing $O(s_A^2)$, and the two cross terms have pairing $O(s_A)$: the derivative of q in the ζ direction has size $O(|\zeta|^{-1})$, and its area integral over the disk $\{|\zeta| \le s_A\}$ is $O(s_A)$.

It remains to integrate the term containing $\mathrm{d}q \wedge \mathrm{d}^{\mathrm{c}} q$. The logarithmic change of the radial variable used for (1.9) leaves the factor ε and the probability weight

$$r\chi_\eta'(t)^{r-1}\chi_\eta''(t)\,\mathrm{d}t, \qquad -\eta \le t \le \eta.$$

Only the component of the test form in the z' directions enters this term, and on the shrinking circles its coefficients tend uniformly to their values at $\zeta = 0$. Integration in the angle therefore gives, in the limit, exactly the pairing with $\varepsilon[D] \wedge S^{r-1}$. This proves the convergence in every degree. □

Lemma 1.6.11 *Let $\Omega \subset \mathbb{C}^n$ be a domain, let K and L be compact subsets of Ω with K contained in the interior L° of L, and put $\beta = \mathrm{dd}^{\mathrm{c}}|z|^2$. Let b be a locally bounded plurisubharmonic function on Ω, and let T be a smooth positive closed (r,r)-form, $1 \le r < n$. Then*

$$\int_K (\mathrm{dd}^{\mathrm{c}} b)^{n-r} \wedge T \le C_{K,L,n}(1 + \|b\|_{L^\infty(L)})^{n-r} \int_L T \wedge \beta^{n-r}.$$

Proof Put $M = 1 + \|b\|_{L^\infty(L)}$. Cover K by finitely many balls whose larger concentric balls have closures in L°. Replacing b by $b + M$, which has the same Hessian and takes values in $[0, 2M]$ on L, we may assume $0 \le b \le 2M$ there. For nested cutoff functions ψ, integration by parts against closed forms gives

$$\int \psi \mathrm{dd}^{\mathrm{c}} b \wedge W = \int b \mathrm{dd}^{\mathrm{c}} \psi \wedge W \le CM \int_{\operatorname{supp}\psi} \beta \wedge W,$$

where W is T multiplied by the remaining positive closed factors. Apply this successively to the $n - r$ Hessians of b. For bounded b, the integrations by parts are justified by local decreasing regularization and Theorem 1.6.1, with one common bound on the range. Summing over the finite cover gives the asserted constant. □

Proposition 1.6.4 *Let $\Omega \subset \mathbb{C}^n$, $n \geq 2$, be a bounded domain, let $b \in \mathrm{PSH}(\Omega) \cap L^\infty(\Omega)$, $a \in \Omega$ and $c > 0$. Given finitely many $f_i \in C_c(\Omega)$ and numbers $\tau, t > 0$, there is a smooth bounded plurisubharmonic function $h \leq 0$ on Ω such that*

$$\|h\|_{L^p(\Omega)} \leq C_{\Omega,p}\, t \quad (1 \leq p < \infty),$$
$$\left| \int_\Omega f_i \big((\mathrm{dd^c}(b+h))^n - (\mathrm{dd^c} b)^n \big) - c\, f_i(a) \right| < \tau \quad \textit{for every } i.$$

For concentric balls $B' \Subset B \Subset \Omega$ and every $w \in \mathrm{PSH}(B)$ with $0 \leq w \leq 1$, it also satisfies

$$\int_{B'} |h| (\mathrm{dd^c} w)^n \leq C_{B',B,\Omega}\, t.$$

These constants are independent of b, a, c, the test functions and the tolerances.

Proof We take for h a function from Lemma 1.6.9 whose top-degree measure approximates $c\delta_a$ and whose lower-degree currents are small; Lemma 1.6.11 then controls the mixed terms.

Write $a = (a_1, a')$ and $m = n - 1$, and fix $R = 2 \sup_\Omega |z_1| + 2$. For $\delta > 0$, put $H_\delta(z') = \log(|z' - a'|^2 + \delta^2)$. By the radial calculation in the proof of Proposition 1.6.3, $(\mathrm{dd^c} H_\delta)^m$ is a probability measure tending to $\delta_{a'}$ as $\delta \downarrow 0$. Extend every f_i by zero outside Ω, and choose δ such that

$$\left| c \int_{\mathbb{C}^m} f_i(a_1, z') (\mathrm{dd^c} H_\delta)^m - c\, f_i(a) \right| < \tau/3 \quad \text{for all } i.$$

Choose compact sets $K, L \subset \Omega$ with $K \subset L^\circ$ and K containing the supports of all f_i, and a nonnegative smooth cutoff function ψ with compact support in Ω, equal to one near L. Put $\beta = \mathrm{dd^c}|z|^2$. Expanding the top power of $\mathrm{dd^c}(b+h)$, summing the bounds of Lemma 1.6.11 with their binomial coefficients and the norms $\|f_i\|_\infty$, we find $\gamma > 0$ such that the mixed terms contribute less than $\tau/3$ to every test integral whenever h is smooth and plurisubharmonic and

$$\int_L (\mathrm{dd^c} h)^r \wedge \beta^{n-r} < \gamma, \qquad 1 \leq r < n.$$

Fix $0 < \eta \leq t/2$. Apply Lemma 1.6.9 on $\mathbb{C} \times \mathbb{C}^m$ with transverse variable $\zeta = z_1 - a_1$ and $v = c^{1/m} \varepsilon^{-1/m} H_\delta$. For $r < n$, Lemma 1.6.10 gives

$$(\mathrm{dd^c} h_A)^r \longrightarrow \varepsilon^{(n-r)/(n-1)} c^{(r-1)/(n-1)} [\{z_1 = a_1\}] \wedge (\mathrm{dd^c} H_\delta)^{r-1}$$

as $A \to \infty$. For the fixed δ, the integrals of these limits against $\psi \beta^{n-r}$ are finite, and their exponents of ε are positive. Choose $0 < \varepsilon \leq t/2$ so that each of them is less than $\gamma/2$. With these parameters fixed, choose A so large that the integrals $\int_L (\mathrm{dd^c} h_A)^r \wedge \beta^{n-r}$ are less than γ, that $v - A \leq 0$ on the projection of Ω to the z' variables, and that

$$\left| \int_\Omega f_i (\mathrm{dd^c} h_A)^n - c \int_{\mathbb{C}^m} f_i(a_1, z')(\mathrm{dd^c} H_\delta)^m \right| < \tau/3 \quad \text{for all } i.$$

The last choice follows directly from (1.9), because the circles there shrink uniformly over the projected supports of the tests and $\varepsilon(\mathrm{dd^c} v)^m = c(\mathrm{dd^c} H_\delta)^m$.

Set $h = h_A - \eta$. As in the proof of Proposition 1.6.3, h is smooth, bounded and nonpositive on Ω, with

$$\varepsilon \log(|z_1 - a_1|^2/R^2) - \eta \le h \le 0.$$

The logarithm has $L^p(\Omega)$ norm bounded uniformly for a_1 in the projection of Ω to the first coordinate: after translation, its one-variable integral is bounded by polar integration on one fixed disk. This uniform bound, the weighted Chern–Levine–Nirenberg estimate and the range estimate (1.2) give the asserted bound for the integrals over B'. Since $\varepsilon + \eta \le t$, both estimates hold with constants depending only on Ω, p, B' and B.

Finally, multilinearity of bounded products gives

$$(\mathrm{dd^c}(b+h))^n = (\mathrm{dd^c} b)^n + (\mathrm{dd^c} h)^n + \sum_{r=1}^{n-1} \binom{n}{r} (\mathrm{dd^c} b)^{n-r} \wedge (\mathrm{dd^c} h)^r.$$

The choice of δ, the choice of A for the top-degree term and the estimate of the mixed terms each contribute less than $\tau/3$ to every test integral. This proves the required inequalities, with one choice of h for all finite p. □

Theorem 1.6.4 *Let $\Omega \subset \mathbb{C}^n$, $n \ge 2$, be a bounded domain, let $b \in \mathrm{PSH}(\Omega) \cap L^\infty(\Omega)$, and let ν be a positive Radon measure on Ω. There are bounded plurisubharmonic functions $u_j \le b$ on Ω such that*

$$\|u_j - b\|_{L^p(\Omega)} \longrightarrow 0 \quad (1 \le p < \infty),$$
$$(\mathrm{dd^c} u_j)^n \longrightarrow (\mathrm{dd^c} b)^n + \nu \quad \textit{vaguely}.$$

The same sequence converges to b in local capacity. If b is smooth, every u_j can be chosen smooth. The measure ν may have infinite total mass.

Proof Choose relatively compact open sets exhausting Ω, each with closure contained in the next one. On each of these sets, take a countable family of smooth compactly supported functions that is uniformly dense in the space of continuous functions vanishing at its boundary, and add a nonnegative smooth compactly supported cutoff function equal to one on its closure. Enumerate the union of these families as (f_i). If positive measures converge against every f_i to a fixed positive Radon measure, they converge vaguely: the cutoff functions give common local mass bounds, and uniform approximation then handles every continuous compactly supported test function.

For each j, approximate ν against $f_1, \dots, f_j$ by a finite positive atomic measure

$$\nu_j = \sum_{s=1}^{N_j} c_{j,s}\delta_{a_{j,s}}, \qquad \left|\int_\Omega f_i(\nu_j - \nu)\right| < j^{-1} \quad (i \le j).$$

Such an approximation uses only the finite mass of ν on a compact neighborhood of the supports of these tests: a finite partition on which all the tests have small oscillation provides the atoms and their positive weights. Atoms of weight zero are omitted. If $N_j = 0$, set $u_j = b$. Otherwise start with $b_{j,0} = b$ and apply Proposition 1.6.4 successively to $b_{j,s-1}$, $a_{j,s}$ and $c_{j,s}$, with the tests $f_1, \dots, f_j$ and $\tau = t = (jN_j)^{-1}$. This gives perturbations $h_{j,s}$, and we define

$$b_{j,s} = b_{j,s-1} + h_{j,s}, \qquad u_j = b_{j,N_j}.$$

Every intermediate potential is bounded and plurisubharmonic, so the proposition applies at each step; the choice at the next step may depend on the bound of the current potential, and each perturbation serves all finite p at once. Summing the norm estimates yields $\|u_j - b\|_{L^p(\Omega)} \le C_{\Omega,p}/j$, and since every $h_{j,s} \le 0$, we have $u_j \le b$. Summing the measure errors gives

$$\left|\int_\Omega f_i\big((\mathrm{dd^c}u_j)^n - (\mathrm{dd^c}b)^n - \nu\big)\right| < 2/j \quad (i \le j).$$

By the choice of the family (f_i), this proves the asserted vague limit, also when $\nu(\Omega) = \infty$.

For fixed concentric balls $B' \Subset B \Subset \Omega$, the perturbations are nonpositive, so $|u_j - b| = \sum_s |h_{j,s}|$. The last estimate of Proposition 1.6.4 bounds the integral of this function against $(\mathrm{dd^c}w)^n$ over B' by $C_{B',B,\Omega}/j$, for every $w \in \mathrm{PSH}(B)$ with $0 \le w \le 1$. Restricting to the set where $|u_j - b|$ exceeds a fixed threshold, dividing by the threshold and taking the supremum over w proves convergence in local capacity. If b is smooth, the finite sums defining u_j are smooth as well. □

The construction takes place in a bounded Euclidean domain, without prescribed boundary values and without a common bound on the approximating potentials. These freedoms allow concentration even under convergence in local capacity; a fixed global Hermitian background imposes further constraints.

1.6.7 Full cluster sets at the zero potential

Theorem 1.6.4 prescribes one limit of the Monge–Ampère measures, but a single sequence of potentials can have many subsequential limits. In fact, every vaguely closed set of measures is the set of all subsequential limits for a suitable sequence of potentials tending to zero. For a domain $\Omega \subset \mathbb{C}^n$, write $\mathcal{M}_+(\Omega)$ for the set of positive Radon measures on Ω, including zero and measures of infinite total mass, with the vague topology defined by integration against $C_c(\Omega)$.

Lemma 1.6.12 *There are real functions $f_i \in C_c^\infty(\Omega)$ such that*

$$d_v(\alpha,\beta) = \sum_{i\ge 1} 2^{-i} \frac{\left|\int_\Omega f_i(\alpha-\beta)\right|}{1+\left|\int_\Omega f_i(\alpha-\beta)\right|}$$

is a metric inducing the vague topology on $\mathcal{M}_+(\Omega)$. This metric space is separable.

Proof Choose relatively compact open sets U_ℓ exhausting Ω, with $\overline{U}_\ell \subset U_{\ell+1}$. For each ℓ, choose a countable uniformly dense subset of $C_0(U_{\ell+1};\mathbb{R})$ consisting of smooth compactly supported functions, extended by zero to Ω; such families exist because $C_0(U_{\ell+1};\mathbb{R})$ is separable and its elements can be approximated uniformly by smooth functions. Add a nonnegative smooth compactly supported cutoff function equal to one near $\overline{U}_{\ell+1}$, and enumerate the union of all these functions as (f_i).

Call the maps $\alpha \mapsto \int_\Omega f_i \, d\alpha$ the coordinates. If positive measures converge to a fixed measure in every coordinate, the cutoff coordinates give common mass bounds on each $\overline{U}_{\ell+1}$, and uniform approximation then gives convergence against every $g \in C_c(\Omega)$. The same argument, applied near a fixed measure, shows that $\alpha \mapsto \int_\Omega g \, d\alpha$ is continuous for the topology generated by the coordinates: bound the relevant cutoff coordinate on a neighborhood, choose one smooth test that is uniformly close to g, and shrink the neighborhood using the coordinate of that test. Thus the coordinates generate exactly the vague topology, and they separate measures.

The function $s \mapsto s/(1+s)$ is increasing and subadditive on $[0,\infty)$. Applying it to the triangle inequalities for the coordinates gives the triangle inequality for d_v, and d_v is positive on distinct measures because the coordinates separate them. Each coordinate is continuous for this metric, and the tails of the series are uniformly small, so the metric induces exactly the topology generated by the coordinates.

Finally, the finite atomic measures with nonnegative rational weights at points of a fixed countable dense subset of Ω form a countable dense family. To approximate a measure in finitely many coordinates, partition a compact neighborhood of the supports of the corresponding tests into sets on which all these tests have small oscillation, place an atom in each set of nonzero mass, and then perturb its location and weight. Only the finite mass of that compact neighborhood is used, and the remaining tail of the metric is arbitrarily small. □

The metric controls limits along corresponding subsequences: if $d_v(\alpha_j,\beta_j) \to 0$ and one of the sequences converges vaguely to a fixed measure along a subsequence, then, by the triangle inequality, so does the other. Without common local mass bounds, however, $d_v(\alpha_j,\beta_j) \to 0$ need not imply that $\int g(\alpha_j-\beta_j) \to 0$ for every $g \in C_c(\Omega)$. For example, fix $a \in \Omega$, a unit vector e, and numbers $r_j \downarrow 0$ with $a + r_j e \in \Omega$, and put

$$\alpha_j = r_j^{-1/2}\delta_{a+r_j e}, \qquad \beta_j = r_j^{-1/2}\delta_a.$$

For every smooth compactly supported test, the difference of the two integrals is $O(r_j^{1/2})$, so $d_v(\alpha_j,\beta_j) \to 0$ because the tails of the series are small. On the other hand, if $\chi \in C_c^\infty(\Omega)$ equals one near a, the continuous test function $g(z) = \chi(z)|z-a|^{1/2}$ gives $\int g(\alpha_j - \beta_j) = 1$ for all large j.

Theorem 1.6.5 *Let $\Omega \subset \mathbb{C}^n$, $n \geq 2$, be a bounded domain. A set $F \subset \mathcal{M}_+(\Omega)$ is vaguely closed if and only if there are smooth bounded plurisubharmonic functions $u_j \leq 0$ on Ω, tending to zero in $L^p(\Omega)$ for every $1 \leq p < \infty$ and in local capacity, whose full vague cluster set is F:*

$$F = \left\{\mu \in \mathcal{M}_+(\Omega) : \ (\mathrm{dd}^c u_{j_k})^n \longrightarrow \mu \text{ vaguely for some } j_1 < j_2 < \cdots \right\}.$$

The empty set is allowed.

Proof In a metric space, the full cluster set of a sequence is the intersection of the closures of its tails: a point of this intersection can be approximated within $1/k$ at an index larger than the preceding one, successively for $k = 1, 2, \ldots$. The full cluster set is therefore closed, and Lemma 1.6.12 proves necessity.

For sufficiency, suppose first that F is nonempty and closed. A subset of a separable metric space is separable, so we may choose a dense sequence $\mu_1, \mu_2, \ldots$ in F, repetitions allowed. Concatenating the finite lists (μ_1), (μ_1, μ_2), (μ_1, μ_2, μ_3), and so on, we obtain a sequence (ν_j) in which every μ_k appears arbitrarily late. Hence every point of F is the limit of a subsequence, and since F is closed, no other subsequential limit occurs. If F is empty, take $\nu_j = j\delta_a$ for a fixed $a \in \Omega$. A nonnegative compactly supported test function equal to one at a has integral j against ν_j, so this sequence has no vaguely convergent subsequence.

In either case, let (f_i) and d_v be as in Lemma 1.6.12, and perform the finite atomic construction from the proof of Theorem 1.6.4 separately for each j, with background zero, target ν_j and tests $f_1, \ldots, f_j$. Thus we approximate ν_j in these coordinates by a finite atomic measure with error less than $1/j$. If this measure has $N_j > 0$ atoms, apply Proposition 1.6.4 successively with $t = \tau = (jN_j)^{-1}$; if it has none, take $u_j = 0$. The resulting smooth bounded plurisubharmonic functions $u_j \leq 0$ satisfy

$$\|u_j\|_{L^p(\Omega)} \leq C_{\Omega,p}/j, \qquad \left| \int_\Omega f_i \big((\mathrm{dd}^c u_j)^n - \nu_j \big) \right| < 2/j \quad (i \leq j).$$

On every fixed pair of concentric balls $B' \Subset B \Subset \Omega$, the bounds of that proposition for test measures $(\mathrm{dd}^c w)^n$, with $w \in \mathrm{PSH}(B)$ and $0 \leq w \leq 1$, also sum to $C_{B',B,\Omega}/j$. Dividing by a positive threshold and taking the supremum over w gives convergence in local capacity. These estimates require neither convergence of the targets ν_j nor a common local mass bound for them.

Splitting the series defining the metric after its first j terms gives

$$d_v\big((\mathrm{dd}^c u_j)^n, \nu_j\big) \leq 2/j + 2^{-j} \longrightarrow 0.$$

Consequently, the two sequences of measures have the same limits along corresponding subsequences, and hence the same full cluster set F. □

For subharmonic functions on a planar domain, by contrast, L^1_{loc} convergence to zero forces $\mathrm{dd}^c u_j \to 0$ in the sense of distributions, and positivity, tested against compactly supported cutoff functions, then gives vague convergence to zero. The freedom in the theorem therefore begins in dimension two.

1.6.8 Cluster sets at a bounded background

Let $\Omega \subset \mathbb{C}^n$ be a domain, $n \geq 1$, and let b be a locally bounded plurisubharmonic function on Ω. If potentials approach b from below in local capacity, every limit of their Monge–Ampère measures must dominate $(\mathrm{dd}^c b)^n$. Truncation at a fixed distance below b provides a common bound, and plurifine locality keeps the measure outside the small set where the truncation changes the potential.

Lemma 1.6.13 *Let b, u_j be locally bounded plurisubharmonic functions on Ω with $u_j \leq b$ and $u_j \to b$ in local capacity. Then, for every nonnegative $f \in C_c(\Omega)$,*

$$\liminf_{j\to\infty} \int_\Omega f(\mathrm{dd}^c u_j)^n \geq \int_\Omega f(\mathrm{dd}^c b)^n.$$

In particular, every vague subsequential limit of $(\mathrm{dd}^c u_j)^n$ dominates $(\mathrm{dd}^c b)^n$.

Proof First suppose that f is supported in B', where $B' \Subset B \Subset \Omega$ are concentric balls. Put $v_j = \max(u_j, b-1)$ and $E_j = \{u_j \leq b-1\}$. The functions v_j lie between $b-1$ and b and tend to b in local capacity. Because of their common bounds, the continuity of bounded products recalled in Section 1.6 gives $(\mathrm{dd}^c v_j)^n \to (\mathrm{dd}^c b)^n$ vaguely on B. With $R = \sup_B b - \inf_B b + 1$, the capacity bound for bounded potentials gives

$$(\mathrm{dd}^c v_j)^n(E_j \cap \operatorname{supp} f) \leq R^n \operatorname{cap}(E_j \cap \operatorname{supp} f, B) \longrightarrow 0,$$

where the limit holds because $E_j \subset \{|u_j - b| > 1/2\}$. On the plurifine open Borel set $\{u_j > b-1\}$ we have $v_j = u_j$, so Theorem 1.6.1 shows that the two measures agree there. By positivity,

$$\int f(\mathrm{dd}^c u_j)^n \geq \int f(\mathrm{dd}^c v_j)^n - \|f\|_\infty (\mathrm{dd}^c v_j)^n(E_j \cap \operatorname{supp} f).$$

Taking the lower limit proves the assertion for such f. For a general f, use a finite nonnegative partition of unity subordinate to a cover of its support by such balls. Applying the inequality along a vaguely convergent subsequence proves the final assertion. □

Theorem 1.6.6 *Assume that Ω is bounded, $n \geq 2$, and $b \in \mathrm{PSH}(\Omega) \cap L^\infty(\Omega)$. For a set $F \subset \mathcal{M}_+(\Omega)$, the following are equivalent:*

(1) *F is vaguely closed and every $\mu \in F$ satisfies $\mu \geq (\mathrm{dd}^c b)^n$;*
(2) *there are bounded plurisubharmonic functions $u_j \leq b$ on Ω, converging to b in $L^p(\Omega)$ for every $1 \leq p < \infty$ and in local capacity, whose full vague cluster set is F.*

The empty set is allowed. If b is smooth, every u_j in the second condition can be chosen smooth.

Proof If the second condition holds, Lemma 1.6.13 gives the measure inequality, and the full cluster set is closed in the metrizable vague topology by the argument at the beginning of the proof of Theorem 1.6.5.

Conversely, assume the first condition. If F is nonempty, the concatenation of a dense sequence used in the proof of Theorem 1.6.5 gives measures $\nu_j \in F$ whose full vague cluster set is F. If F is empty, take $\nu_j = (\mathrm{dd}^c b)^n + j\delta_a$ for a fixed $a \in \Omega$. A nonnegative compactly supported test function equal to one at a has integral at least j against ν_j, so this sequence has no vaguely convergent subsequence. In either case, $\nu_j - (\mathrm{dd}^c b)^n$ is a positive Radon measure.

Let (f_i) and d_v be as in Lemma 1.6.12. For each j, approximate the excess $\nu_j - (\mathrm{dd}^c b)^n$ against $f_1, \dots, f_j$ by a positive finite atomic measure, with each error less than $1/j$. If this measure has $N_j > 0$ atoms, perform the construction from the proof of Theorem 1.6.4, starting at b and using $\tau = t = (jN_j)^{-1}$ for each atom; if it has none, take $u_j = b$. Summing the estimates of Proposition 1.6.4 gives

$$\|u_j - b\|_{L^p(\Omega)} \leq C_{\Omega,p}/j, \qquad \left| \int_\Omega f_i \big((\mathrm{dd}^c u_j)^n - \nu_j \big) \right| < 2/j \quad (i \leq j).$$

For every fixed pair of concentric balls $B' \Subset B \Subset \Omega$, the same construction bounds the integral of $|u_j - b|$ over B' against $(\mathrm{dd}^c w)^n$ by $C_{B',B,\Omega}/j$, for every $w \in \mathrm{PSH}(B)$ with $0 \leq w \leq 1$. Dividing by a fixed positive threshold and taking the supremum over w gives convergence in local capacity. Each u_j is bounded and lies below b, and it is smooth when b is smooth. One sequence serves all finite p, and no common local mass bound on the ν_j is needed.

The error in the first j coordinates and the tail of the series yield

$$d_v\big((\mathrm{dd}^c u_j)^n, \nu_j \big) \leq 2/j + 2^{-j} \longrightarrow 0.$$

By the remark following Lemma 1.6.12, the two sequences of measures have the same limits along corresponding subsequences. Hence their full vague cluster sets coincide. □

For example, on the unit ball the function $b = |z|^2 - 1$ has nonzero Monge–Ampère measure. For every point a of the ball, the theorem allows the cluster sets $\{(\mathrm{dd}^c b)^n\}$, $\{(\mathrm{dd}^c b)^n + \delta_a\}$ and the empty set, but it excludes $\{0\}$; this exclusion relies on the convergence in local capacity. In dimension one, L^1 convergence alone forces $\mathrm{dd}^c u_j \to \mathrm{dd}^c b$ vaguely, so the full cluster set is always $\{\mathrm{dd}^c b\}$.

1.7 Products with smooth backgrounds

The Bedford–Taylor construction also defines products of currents of the form $\theta+\mathrm{dd^c}u$ with u locally bounded: one expands them into Hessians of plurisubharmonic functions and smooth forms. Since the result does not depend on the local correction, these products are defined globally. Their positivity is not visible term by term; it follows from the lower curvature bound by freezing the coefficients of the background. For a smooth real $(1,1)$-form θ and a function v, we write $\theta_v = \theta + \mathrm{dd^c}v$, and similarly $\omega_v = \omega + \mathrm{dd^c}v$ for other backgrounds. Fix $1 \le k \le n$.

Let u be locally bounded and θ-plurisubharmonic. On a relatively compact coordinate ball with coordinates z, choose $A > 0$ such that $p = u + q$ is plurisubharmonic, where $q = A|z|^2$. Set $\beta = \theta - \mathrm{dd^c}q$ and define

$$(\theta + \mathrm{dd^c}u)^k := \sum_{j=0}^{k} \binom{k}{j} (\mathrm{dd^c}p)^j \wedge \beta^{k-j}. \tag{1.10}$$

Each summand is a product from Theorem 1.6.1 multiplied by a smooth form. The individual terms of this expansion need not be positive.

Proposition 1.7.1 *The construction* (1.10) *and its mixed version are independent of the local correction q and of the decomposition of each current into a smooth form and the Hessian of a potential. They define global products of currents with locally bounded quasi-plurisubharmonic potentials. These products are symmetric, multilinear and plurifinely local, and they do not charge pluripolar sets. If every factor is positive, their mixed product is positive.*

Proof On the intersection of two coordinate balls, the two corrected potentials differ by a smooth function. The rule $\mathrm{dd^c}(p + f) = \mathrm{dd^c}p + \mathrm{dd^c}f$, for bounded p and smooth f in bounded local products, follows by smooth approximation; together with the binomial formula, it shows that the two expansions agree. The same argument handles a smooth change in the decomposition of a current. Moreover, any two decompositions of the same $(1,1)$-current differ by a smooth function: the difference of the potentials has a smooth Hessian, and taking its local Euclidean trace and applying elliptic regularity shows that it is smooth. Symmetry, multilinearity and locality then follow term by term. Bounded Bedford–Taylor products wedged with smooth forms have locally finite variation and do not charge pluripolar sets, so these properties pass to the finite expansion as well.

It remains to prove positivity, which does not follow from the signs of the summands. Write the factors as $T_i = \theta_i + \mathrm{dd^c}u_i$, $1 \le i \le k$, where each θ_i is a smooth real $(1,1)$-form and each u_i is locally bounded and quasi-plurisubharmonic, and assume $T_i \ge 0$. Fix $\varepsilon > 0$, a point of the coordinate ball and a positive constant form κ. On a sufficiently small neighborhood of the point, each θ_i is close to a constant, hence closed, form θ_i':

$$-\varepsilon\kappa \le \theta_i - \theta_i' \le \varepsilon\kappa.$$

Then $S_i = \theta_i' + \varepsilon\kappa + \mathrm{dd^c} u_i \geq T_i$ is a positive closed current there, with a bounded local plurisubharmonic potential, and

$$T_i + 2\varepsilon\kappa = S_i + (\theta_i - \theta_i' + \varepsilon\kappa),$$

where the last term is a smooth semipositive form. Expanding the product of the currents $T_i + 2\varepsilon\kappa$ therefore gives a sum of positive currents, so this product is positive near the chosen point. Such neighborhoods, although they depend on ε, cover the coordinate ball, so the product of the $T_i + 2\varepsilon\kappa$ is positive on the whole ball. By multilinearity, it converges weakly to the product of the T_i as $\varepsilon \to 0$, which proves positivity. □

The local expansion also gives continuity along decreasing sequences of uniformly locally bounded potentials: apply Theorem 1.6.1 to the corrected potentials and sum the finitely many terms. Since X is compact, every bounded top-degree product has finite total mass. For bounded $u \in \mathrm{PSH}(X, \theta)$ we write $\mathrm{MA}_\theta(u) = (\theta + \mathrm{dd^c} u)^n$.

Decreasing maxima compare the products of two ordered potentials on the set where they are equal. The comparison also holds in the presence of fixed positive factors, which will be useful in integration by parts.

Lemma 1.7.1 *Let $a \leq b$ be locally bounded quasi-plurisubharmonic functions on an n-dimensional complex manifold, and let θ be a smooth real $(1,1)$-form such that $\theta_a, \theta_b \geq 0$. For $1 \leq k \leq n$, let W be a product of $n-k$ positive currents with smooth backgrounds and locally bounded potentials, with $W = 1$ when $k = n$. Then*

$$\mathbf{1}_{\{a=b\}} \theta_a^k \wedge W \leq \mathbf{1}_{\{a=b\}} \theta_b^k \wedge W.$$

Proof The functions $m_\delta = \max(a + \delta, b)$ satisfy $b \leq m_\delta \leq b + \delta$ and decrease to b as $\delta \downarrow 0$. By Lemma 1.3.1 and Proposition 1.7.1, the products $\theta_{m_\delta}^k \wedge W$ are positive, and by bounded decreasing continuity they converge weakly to $\theta_b^k \wedge W$. On the plurifine open set $\{a + \delta > b\}$, which contains $\{a = b\}$, we have $m_\delta = a + \delta$, so plurifine locality identifies the restriction of $\theta_{m_\delta}^k \wedge W$ to this set with that of $\theta_a^k \wedge W$. Hence, for every compact set $K \subset \{a = b\}$ in a coordinate chart, the upper semicontinuity of the mass of compact sets under weak convergence gives

$$\int_K \theta_a^k \wedge W = \lim_{\delta \downarrow 0} \int_K \theta_{m_\delta}^k \wedge W \leq \int_K \theta_b^k \wedge W.$$

Since the measures are locally finite, inner regularity extends this inequality to all Borel subsets of the contact set, and a countable cover by charts proves the assertion.□

The products commute with pullback by holomorphic submersions. Here the pullback of a current is defined in local product coordinates by pulling back its distributional coefficients.

Lemma 1.7.2 *Let $\pi : Z \to Y$ be a holomorphic submersion of complex manifolds. For $1 \le r \le \dim Z$, let $u_1, \dots, u_r$ be locally bounded quasi-plurisubharmonic functions on Y, and let $\theta_1, \dots, \theta_r$ be smooth real $(1,1)$-forms on Y. Then*

$$\bigwedge_{i=1}^{r} \bigl(\pi^*\theta_i + \mathrm{dd^c}(u_i \circ \pi)\bigr) = \pi^*\left(\bigwedge_{i=1}^{r} (\theta_i + \mathrm{dd^c} u_i)\right).$$

For $r > \dim Y$, the product on the left vanishes, and the right-hand side is interpreted as zero.

Proof Work in product coordinates in which π is a coordinate projection. On a smaller chart of Y, choose smooth quadratic functions q_i such that $p_i = u_i + q_i$ is plurisubharmonic, and approximate each p_i by a decreasing sequence of smooth plurisubharmonic functions. Their pullbacks have the same properties on the product chart, and for smooth forms pullback commutes with wedge products. Applying bounded decreasing continuity to the local expansions (1.10) on both charts gives the asserted identity, because pullback of currents by the projection is weakly continuous: pairing the pullback with a compactly supported test form amounts to pairing the original current with the integral of the test form over the fiber variables. If $r > \dim Y$, every smooth approximating product vanishes for degree reasons, and so does its limit. □

For $C^{1,1}$ potentials, these products of currents agree with the products of their measurable Hessian coefficients.

Proposition 1.7.2 *Let $u_1, \dots, u_k$ be locally $C^{1,1}$ quasi-plurisubharmonic functions, and let $\theta_1, \dots, \theta_k$ be smooth real $(1,1)$-forms. Then the bounded product*

$$(\theta_1 + \mathrm{dd^c} u_1) \wedge \cdots \wedge (\theta_k + \mathrm{dd^c} u_k)$$

is the form with locally bounded measurable coefficients obtained by taking the wedge product of the factors pointwise almost everywhere.

Proof On a smaller coordinate ball, add a common smooth quadratic function q such that each $u_i + q$ is plurisubharmonic, and convolve with a smooth radial probability kernel. The Hessians of the convolutions are uniformly locally bounded and converge to the weak Hessians in every L^s space with $s < \infty$, so their finite products converge in L^1 on smaller balls. Since the potentials converge uniformly, the continuity of bounded Bedford–Taylor products identifies this limit with the pluripotential product. Expanding with respect to the smooth correction, as in (1.10), proves the assertion for the original factors. □

When the Hessian coefficients are bounded, a positive lower bound for the top-degree product gives a lower bound for the current itself.

Proposition 1.7.3 *Let θ be a smooth real $(1,1)$-form, let h be a Hermitian form on X, and let $u \in \mathrm{PSH}(X,\theta) \cap C^{1,1}(X)$. If*

$$(\theta + \mathrm{dd^c} u)^n \geq a h^n$$

for a constant $a > 0$, then $\theta + \mathrm{dd^c} u \geq \delta h$ as a current for some $\delta > 0$.

Proof Put $T = \theta + \mathrm{dd^c} u$. Its measurable coefficients are bounded on the compact manifold X, so there is $K > 0$ such that, almost everywhere, the eigenvalues of T relative to h lie in $[0, K]$. By Proposition 1.7.2, their product is the density of T^n with respect to h^n, and hence it is at least a. Each eigenvalue is therefore at least a/K^{n-1} almost everywhere. This inequality of matrices almost everywhere gives the asserted inequality of currents with $\delta = a/K^{n-1}$. □

The mixed Monge–Ampère inequality of Theorem 1.6.2 also holds after a smooth background is added. In the following three lemmas, $U \subset \mathbb{C}^n$ is an open set and $\beta = \mathrm{dd^c}|z|^2$.

Lemma 1.7.3 *Let $T_i = \vartheta_i + \mathrm{dd^c} u_i \geq 0$, $i = 1, 2$, where the ϑ_i are smooth real $(1,1)$-forms on U and the u_i are locally bounded quasi-plurisubharmonic functions on U. If*

$$T_i^n \geq F_i \beta^n, \qquad F_i \geq 0 \text{ measurable},$$

then, for every integer $0 \leq k \leq n$,

$$T_1^k \wedge T_2^{n-k} \geq F_1^{k/n} F_2^{(n-k)/n} \beta^n. \tag{1.11}$$

Consequently, for $a, b \geq 0$,

$$(aT_1 + bT_2)^n \geq \left(a F_1^{1/n} + b F_2^{1/n}\right)^n \beta^n. \tag{1.12}$$

Proof Fix $W \Subset U$. Since the forms ϑ_i are smooth, there is a constant C such that, for every $x \in W$ and every small ball $B_r(x)$, the constant forms

$$A_i = \vartheta_i(x) + Cr\beta$$

satisfy $0 \leq S_i \leq 2Cr\beta$ on $B_r(x)$, where $S_i = A_i - \vartheta_i$. If q_i is a quadratic potential for A_i, then $u_i + q_i$ is plurisubharmonic on $B_r(x)$ and

$$\left(\mathrm{dd^c}(u_i + q_i)\right)^n = (T_i + S_i)^n \geq F_i \beta^n.$$

Apply Theorem 1.6.2 to these two closed Hessians. After expansion, every term other than $T_1^k \wedge T_2^{n-k}$ contains some S_i and is therefore bounded by $C' r \mu$, where

$$\mu = \sum_{\ell+m \le n-1} T_1^{\ell} \wedge T_2^{m} \wedge \beta^{n-\ell-m}$$

is a locally finite measure.

A finite cover and a partition of unity give, on W,

$$T_1^k \wedge T_2^{n-k} \ge F_1^{k/n} F_2^{(n-k)/n} \beta^n - C' r \mu.$$

Letting $r \downarrow 0$ proves (1.11), and the binomial expansion then gives (1.12). □

Lemma 1.7.4 *Let ϑ be a smooth real $(1,1)$-form on U. Suppose that u is continuous, $T = \vartheta + \mathrm{dd^c} u \ge 0$, and $T^n \ge g^n \beta^n$ with $g \ge 0$ continuous. For a nonnegative convolution kernel χ_δ of mass one,*

$$(T * \chi_\delta)^n \ge (g * \chi_\delta)^n \beta^n \tag{1.13}$$

on every smaller domain on which the convolution is defined.

Proof Approximate the convolution by finite convex combinations of translates, and apply (1.12), extended by induction to finitely many terms. Along these approximations, the background forms converge smoothly and the potentials converge uniformly on compact sets. To pass to the limit, add a common quadratic function and write the difference of two n-th powers as a telescoping sum. After pairing with a test form, integration by parts bounds each term by the uniform distance between the potentials times the mass of a mixed current, and successive integration against nested cutoff functions bounds these masses uniformly. Thus the products of the bounded potentials converge, and (1.13) follows. □

For a positive $(1,1)$-current T on U, write T_{ac} for the measurable $(1,1)$-form whose coefficients are the absolutely continuous parts of the coefficients of T, and define $\det_\beta T_{\mathrm{ac}}$ by $(T_{\mathrm{ac}})^n = (\det_\beta T_{\mathrm{ac}}) \beta^n$. When the top-degree product has a continuous density, the convolution estimate identifies this determinant.

Lemma 1.7.5 *Let u be continuous and $T = \vartheta + \mathrm{dd^c} u \ge 0$, with ϑ a smooth real $(1,1)$-form on U. If $T^n = F \beta^n$ for a continuous function $F \ge 0$, then*

$$\det_\beta T_{\mathrm{ac}} = F \qquad \textit{almost everywhere.}$$

Proof Take a nonnegative smooth radial mollifier χ_δ supported in the ball of radius δ. Then $T * \chi_\delta \to T_{\mathrm{ac}}$ almost everywhere. Indeed, the convolutions of the absolutely continuous parts converge at Lebesgue points of their densities, while the convolution of the singular part λ_s of a coefficient measure is bounded by $C\delta^{-2n} |\lambda_s|(B_\delta)$, which tends to zero almost everywhere by the differentiation theorem for measures. Applying Lemma 1.7.4 with $g = F^{1/n}$ and letting $\delta \downarrow 0$ gives $\det_\beta T_{\mathrm{ac}} \ge F$.

For the reverse inequality, write the convolved current as the Hessian of a decreasing regularization of a locally bounded plurisubharmonic function plus a convergent smooth correction. The continuity of bounded products gives $(T * \chi_\delta)^n \rightharpoonup T^n$. Fatou's lemma, applied against a nonnegative compactly supported test function, then gives $\det_\beta T_{\mathrm{ac}}\, \beta^n \le T^n = F\beta^n$. □

Lemma 1.7.6 *Let $h \le a$ be locally bounded θ-plurisubharmonic functions, and let χ be a smooth function on a neighborhood of $(-\infty, 0]$ with $0 \le \chi' \le 1$ and $\chi'' \ge 0$. Then $w = a + \chi(h - a)$ is θ-plurisubharmonic and*

$$\theta_w = (1 - \chi'(h-a))\theta_a + \chi'(h-a)\theta_h + \chi''(h-a)\,\mathrm{d}(h-a) \wedge \mathrm{d}^{\mathrm{c}}(h-a).$$

In particular, $\theta_w^n \ge \chi'(h-a)^n \theta_h^n$. The positivity of θ_w and this inequality also hold for convex functions χ of class $C^{1,1}$ on compact intervals with $0 \le \chi' \le 1$.

Proof The function $G(x, y) = x + \chi(y - x)$, for $y \le x$, is convex and nondecreasing in each variable: its first derivatives are $1 - \chi'$ and χ', and its Hessian is

$$\chi'' \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \ge 0.$$

For smooth potentials, the chain rule gives the identity. For bounded potentials, add a common quadratic correction and convolve. Convolution preserves the order of the potentials, and since $G(x + r, y + r) = r + G(x, y)$, adding the same correction to both arguments adds it to G. The bounded chain rule (1.6) and its products with the gradient term give the identity in the limit. Freezing the smooth background as in the proof of Proposition 1.7.1 preserves the exact lower bound. Every term on the right is positive, and the positivity of bounded mixed products gives the last assertion.

For a convex weight of class $C^{1,1}$, extend it convexly across zero with derivative in $[0, 1]$, and smooth it in one variable. The smooth convex weights and their first derivatives converge uniformly on compact intervals, and the derivatives stay in $[0, 1]$. On each smaller coordinate ball, the corresponding potentials converge uniformly to w. The continuity of bounded products gives convergence of their top powers, while the weights on the right-hand side converge uniformly against the fixed measure θ_h^n. Passing to the limit proves the positivity and the product inequality with the original smooth background. □

1.8 Hermitian capacity

After a fixed rescaling, a local capacity test can be glued to a constant function and so becomes a global potential on X. This compares the local Bedford–Taylor capacity with a capacity defined by global potentials, and it transfers to X both the volume–capacity estimate and an estimate for the sublevel sets of normalized potentials.

For a Borel set $E \subset X$, the *Hermitian capacity* of E is

$$\mathrm{Cap}_\omega(E) = \sup_{v \in \mathrm{PSH}(X,\omega),\ 0 \le v \le 1} \int_E (\omega + \mathrm{dd^c} v)^n,$$

where the products are those of Proposition 1.7.1. Their local expansion and (1.2) show that $\mathrm{Cap}_\omega(X) < +\infty$. On relatively compact coordinate balls, a fixed smooth correction bounds the measures of global tests by a constant times the corresponding local capacity. Conversely, the gluing construction in the proof of Lemma 1.8.1 below bounds local capacity by global capacity. Consequently, the quasi-continuity of quasi-plurisubharmonic functions and the characterization of sets of capacity zero recalled in Section 1.6 hold for Cap_ω. A sequence u_j converges to u *in capacity* if

$$\mathrm{Cap}_\omega(\{|u_j - u| > \delta\}) \longrightarrow 0 \quad \text{for every } \delta > 0,$$

where pole sets may be omitted. To compare with another Hermitian form ω', choose $C \ge 1$ with $\omega' \le C\omega$. Every test $0 \le v \le 1$ for $\mathrm{Cap}_{\omega'}$ gives a test v/C for Cap_ω, and the positivity of mixed products gives

$$(\omega' + \mathrm{dd^c} v)^n \le C^n (\omega + \mathrm{dd^c}(v/C))^n.$$

Thus $\mathrm{Cap}_{\omega'} \le C^n \mathrm{Cap}_\omega$. Interchanging the two forms shows that the capacities are equivalent up to fixed multiplicative constants, so convergence in capacity does not depend on the choice of ω. Finally, the continuity statements for bounded products in Section 1.6 pass to the products with smooth backgrounds, by their local expansion and a finite cover.

1.8.1 Capacity estimates

In this subsection we abbreviate $\mathrm{Cap} = \mathrm{Cap}_\omega$, and, as before, $\omega_v = \omega + \mathrm{dd^c} v$.

Lemma 1.8.1 *There are constants $a, C > 0$ such that*

$$\mathrm{Vol}(E) \le C \exp\bigl(-a\,\mathrm{Cap}(E)^{-1/n}\bigr) \tag{1.14}$$

for every Borel set $E \subset X$. Moreover, for every $u \in \mathrm{PSH}(X,\omega)$ with $\sup_X u = 0$ and every $t > 1$,

$$\mathrm{Cap}(\{u < -t\}) \le C/t. \tag{1.15}$$

Proof Cover X by finitely many coordinate balls B'_j, with larger concentric balls B_j, $B'_j \Subset B_j$. A local capacity test $0 \le v \le 1$ on B_j can be turned into a global test as follows. Choose a smooth function χ_j with $-2 \le \chi_j \le 0$, equal to zero near $\overline{B'_j}$ and to -2 near ∂B_j. Choose $\delta > 0$ so small that

$$\omega + \delta \mathrm{dd^c} \chi_j \ge 0, \qquad 3\delta/2 \le 1.$$

The function

$$V = \max\{\delta(v + \chi_j), -\delta/2\} + \delta/2 \quad \text{on } B_j, \qquad V = 0 \quad \text{outside } B_j,$$

is ω-plurisubharmonic on X, because near ∂B_j the constant branch is the larger one, and it takes values between zero and one. On B'_j we have $\omega_V \geq \delta \mathrm{dd}^{\mathrm{c}} v$. By the positivity of bounded products,

$$\operatorname{cap}(E \cap B'_j, B_j) \leq \delta^{-n} \operatorname{Cap}(E).$$

The local volume–capacity estimate, summed over the finite cover, proves (1.14).

For the second estimate, choose on each B_j a smooth negative quadratic function r_j with $\mathrm{dd}^{\mathrm{c}} r_j \geq \omega$. For every global test $0 \leq v \leq 1$, the functions $u + r_j \leq 0$ and $v + r_j$ are plurisubharmonic on B_j. Thus

$$\begin{aligned}
\int_{\{u<-t\}} \omega_v^n &\leq t^{-1} \int_X (-u)\omega_v^n \\
&\leq t^{-1} \sum_j \int_{B'_j} (-u - r_j)\bigl(\mathrm{dd}^{\mathrm{c}}(v + r_j)\bigr)^n \\
&\leq \frac{C}{t}\left(1 + \int_X |u| \, \mathrm{d}V\right).
\end{aligned}$$

Here the second inequality uses $\omega_v \leq \mathrm{dd}^{\mathrm{c}}(v + r_j)$, and the third is the weighted Chern–Levine–Nirenberg inequality, applied to local test functions with a common bound. The L^1 bound for normalized potentials in Theorem 1.4.1 completes the proof after taking the supremum over v. □

Corollary 1.8.1 *Fix $p > 1$. There is a constant C_p such that every nonnegative $F \in L^p(X, \mathrm{d}V)$ satisfies*

$$\int_E F \, \mathrm{d}V \leq C_p \|F\|_p \operatorname{Cap}(E)^2$$

for every Borel set $E \subset X$.

Proof By Hölder's inequality and (1.14), the integral is at most

$$C\|F\|_p \exp(-a \operatorname{Cap}(E)^{-1/n}/p'), \qquad p' = p/(p-1).$$

The function $x \mapsto x^{-2}\exp(-ax^{-1/n}/p')$ is bounded on $0 < x \leq \operatorname{Cap}(X) < \infty$, and sets of capacity zero have zero volume. □

The same proof bounds the integral of an L^p density by any fixed positive power of the capacity. The exponent two will be convenient for the iteration over sublevel sets in Lemma 10.3.2.

1.8.2 Integration against a Hölder reference

A Hölder modulus for a bounded potential gives a modulus for integration against its Monge–Ampère measure. The proof uses a smooth approximation of the reference, with integration by parts controlling the change in its measure.

Lemma 1.8.2 *Let $B' \Subset B$ be concentric balls in $\mathbb{C}^n$, and let $0 < \alpha \le 1$. Suppose $p \in \mathrm{PSH}(B) \cap C^{0,\alpha}(B)$ has $C^{0,\alpha}$ norm at most N. For every $M \ge 1$ there is a constant C_M such that bounded $a, b \in \mathrm{PSH}(B)$ with $|a|, |b| \le M$ satisfy*

$$\int_{B'} |a-b|(\mathrm{dd^c} p)^n \le C_M \|a-b\|_{L^1(B)}^{\alpha/(\alpha+2n)}.$$

The constants are uniform for references with the stated bound N.

Proof Choose intermediate concentric balls and a smooth cutoff $0 \le \chi \le 1$ supported in the innermost of them and equal to one on B'. All integrations below take place away from ∂B. Let p_ε be a nonnegative radial convolution of p on a larger intermediate ball. It is plurisubharmonic, and, for small $\varepsilon > 0$,

$$\|p - p_\varepsilon\|_\infty \le C\varepsilon^\alpha, \qquad 0 \le \mathrm{dd^c} p_\varepsilon \le C\varepsilon^{-2}\mathrm{dd^c}|z|^2.$$

Both references have a common bounded range. Set $f = |a-b| = 2\max(a,b) - a - b$, and put

$$T = \sum_{j=0}^{n-1} (\mathrm{dd^c} p)^j \wedge (\mathrm{dd^c} p_\varepsilon)^{n-1-j}.$$

This is a closed positive current. Factorization and integration by parts give

$$\int \chi f \left((\mathrm{dd^c} p)^n - (\mathrm{dd^c} p_\varepsilon)^n \right) = \int (p - p_\varepsilon) \mathrm{dd^c}(\chi f) \wedge T.$$

We check that the last signed measure has variation at most $C(1+M)^2$, uniformly in ε. The term $\chi \mathrm{dd^c} f \wedge T$ is a linear combination of the positive measures formed with $\max(a,b), a, b$, whose masses are at most CM by local Chern–Levine–Nirenberg estimates. The term $f\mathrm{dd^c}\chi \wedge T$ has variation at most CM.

For the two terms involving $\mathrm{d}f$, use a cutoff η equal to one near $\operatorname{supp}\chi$. If q is any of $a, b, \max(a,b)$, translate it so that $0 \le q \le 2M$. The bounded chain rule and closedness of T give

$$\int \eta\, \mathrm{d}q \wedge \mathrm{d^c} q \wedge T = \frac{1}{2} \int q^2 \mathrm{dd^c}\eta \wedge T - \int \eta q \mathrm{dd^c} q \wedge T \le CM^2.$$

The last term is nonnegative before subtraction, and the first is bounded using the local mass of T. Since $f = 2\max(a,b) - a - b$, its gradient energy is also bounded by CM^2. Cauchy–Schwarz against the positive current T now bounds the variation of $\mathrm{d}\chi \wedge \mathrm{d^c} f \wedge T$ and $\mathrm{d^c}\chi \wedge \mathrm{d}f \wedge T$ by CM. These are all the terms of $\mathrm{dd^c}(\chi f) \wedge T$.

The bounded formulas follow first for local smooth regularizations. To pass to bounded potentials, regularize a, b, p decreasingly on the intermediate balls, write f as the displayed linear combination, and apply Lemma 1.6.1 to the expanded identities. The energy bounds are uniform; thus the integration by parts and its estimate survive this limit.

Writing $L = \|a - b\|_{L^1(B)}$, we have proved

$$\int \chi f (\mathrm{dd^c} p)^n \le C(1 + M)^2 \varepsilon^\alpha + C\varepsilon^{-2n} L. \tag{1.16}$$

For small positive L, take $\varepsilon = L^{1/(\alpha+2n)}$. A fixed admissible radius and the bounded local mass handle the remaining L. For $L = 0$, let $\varepsilon \downarrow 0$ in the same inequality. □

Corollary 1.8.2 *Let (X, ω) be compact Hermitian, and let $u \in \mathrm{PSH}(X, \omega) \cap C^{0,\alpha}(X)$, $0 < \alpha \le 1$. If uniformly bounded quasi-plurisubharmonic functions a, b have a fixed common smooth lower curvature bound, then*

$$\int_X |a - b|\, \omega_u^n \le C \|a - b\|_{L^1(\mathrm{d}V)}^{\alpha/(\alpha+2n)}.$$

The constant depends on the bounds for a, b, their lower curvature bound and the $C^{0,\alpha}$ norm of u.

Proof On each of finitely many coordinate balls, choose a fixed smooth strictly plurisubharmonic quadratic Q such that $a + Q, b + Q, u + Q$ are plurisubharmonic and $\mathrm{dd^c} Q \ge \omega$. There $0 \le \omega_u \le \mathrm{dd^c}(u + Q)$, so positivity of bounded products gives $\omega_u^n \le (\mathrm{dd^c}(u + Q))^n$. Apply Lemma 1.8.2 on smaller balls covering X. The quadratic cancels in the difference, and the local volumes are equivalent to $\mathrm{d}V$. Summing proves the assertion. □

The estimate before optimization also controls the tails of unbounded potentials. We need the following local form with a compact ambient space, so that the exponential bound for smooth volume is uniform.

Lemma 1.8.3 *Let (Y, Ω) be compact Hermitian, let $B' \Subset B \subset Y$ be coordinate balls, and let $p \in \mathrm{PSH}(B) \cap C^{0,\alpha}(B)$ have norm at most N, with $0 < \alpha \le 1$. There are $c, C > 0$, uniform for these references, such that*

$$(\mathrm{dd^c} p)^n \big(B' \cap \{v < -t\}\big) \le C\mathrm{e}^{-ct} \quad (t \ge 0)$$

for every $v \in \mathrm{PSH}(Y, \Omega)$ with $\sup_Y v = 0$.

Proof Choose a smooth quadratic Q with $\mathrm{dd^c} Q \ge \Omega$ on B and a fixed constant D such that $w = v + Q - D \le 0$. For integers $m \ge 1$, set

$$a_m = \max(w, -m), \qquad b_m = \max(w, -m - 1), \qquad f_m = a_m - b_m.$$

These are bounded plurisubharmonic truncations; $0 \le f_m \le 1$, it vanishes on $\{w \ge -m\}$, and it equals one on $\{w < -m - 1\}$. By Lemma 1.5.1 on (Y, Ω) and the

bounded correction $Q - D$,

$$\|f_m\|_{L^1(B)} \le Ce^{-am}$$

for a fixed $a > 0$. Use the proof of Lemma 1.8.2, with $M = m + 1$, keeping its estimate (1.16) before optimization. Taking $\varepsilon = e^{-am/(\alpha+2n)}$ gives

$$\int \chi f_m (dd^c p)^n \le C(1+m)^2 \exp\left(-\frac{a\alpha m}{\alpha + 2n}\right) \le Ce^{-cm}$$

for some $c > 0$. Large m ensure that the convolution radius is admissible; the common local mass handles the other integers. The bounded difference between w and v, and then choosing an integer just below the given height, prove the estimate for every real $t \ge 0$. □

1.8.3 Capacity bounds for Hölder references

To pass from the exponential tail estimate to a capacity estimate, we use a closed background on an auxiliary projective space. The local capacity comparison then returns the result to the original Hermitian manifold.

For the Fubini–Study form ω_{FS} on $\mathbb{P}^n$, normalized by $\int \omega_{FS}^n = 1$, define for a compact set K

$$T(K) = \inf_{v \in PSH(\mathbb{P}^n, \omega_{FS}),\ \sup v = 0} \exp(\sup_K v).$$

We recall the classical global extremal-function theorem in this closed setting [GZ17]. If K is non-pluripolar, the upper semicontinuous regularization of

$$V_K = \sup\{v \in PSH(\mathbb{P}^n, \omega_{FS}) : v|_K \le 0\}$$

is bounded, nonnegative and ω_{FS}-plurisubharmonic. Its Monge–Ampère probability is supported on K. If K is pluripolar, $\sup V_K = +\infty$ and $T(K) = 0$.

Lemma 1.8.4 *For every compact $K \subset \mathbb{P}^n$,*

$$T(K) \le e \exp\big(-\operatorname{Cap}_{\omega_{FS}}(K)^{-1/n}\big).$$

The right-hand side is zero for capacity zero.

Proof The pluripolar case follows from the recalled theorem and the characterization of capacity-zero sets. Otherwise let $M = \sup V_K^* < \infty$. Subtracting $\sup_K v$ from a normalized competitor, and conversely normalizing competitors for V_K, shows directly that $T(K) = e^{-M}$.

If $M \ge 1$, the function $q = V_K^*/M$ satisfies $0 \le q \le 1$ and is an admissible capacity test. Since the background is closed,

$$1 = \int_K \omega_{V_K^*}^n \le M^n \int_K \omega_q^n \le M^n \operatorname{Cap}_{\omega_{\mathrm{FS}}}(K).$$

Here $\omega_{V_K^*} \le M\omega_q$ follows from $M \ge 1$. Thus $M \ge \operatorname{Cap}_{\omega_{\mathrm{FS}}}(K)^{-1/n}$. If $M < 1$, V_K^* itself is a capacity test, so the same supported probability gives $\operatorname{Cap}_{\omega_{\mathrm{FS}}}(K) = 1$. Since $T(K) \le 1$, the stated factor e covers this case. □

Proposition 1.8.1 *Let (X, ω) be compact Hermitian. Fix $0 < \alpha \le 1$ and $N > 0$. There are $a, C > 0$ such that every $u \in \mathrm{PSH}(X, \omega) \cap C^{0,\alpha}(X)$ with $\|u\|_{C^{0,\alpha}} \le N$ satisfies*

$$\omega_u^n(E) \le C \exp\bigl(-a \operatorname{Cap}_\omega(E)^{-1/n}\bigr) \quad (E \subset X \text{ Borel}).$$

Consequently, for each $s > 0$ there is a uniform C_s with $\omega_u^n(E) \le C_s \operatorname{Cap}_\omega(E)^s$.

Proof Fix nested coordinate balls $B' \Subset B$ and a smooth quadratic Q with $\mathrm{dd^c} Q \ge \omega$ on B. The function $p = u + Q$ is plurisubharmonic with a common Hölder bound, and $\omega_u^n \le (\mathrm{dd^c} p)^n$ there. Regard B as a ball in the affine chart $\mathbb{C}^n \subset \mathbb{P}^n$ and restrict this local measure to B', extending it by zero. By Lemma 1.8.3 on $(\mathbb{P}^n, \omega_{\mathrm{FS}})$, it has a uniform exponential tail on every normalized global Fubini–Study potential. Its total mass is uniformly bounded by local Chern–Levine–Nirenberg estimates.

For a non-pluripolar compact $K \subset B'$, choose a normalized potential v with $\sup_K v \le \log T(K) + 1$. For small $T(K)$ the tail estimate gives

$$(\mathrm{dd^c} p)^n(K) \le C T(K)^c \le C \exp\bigl(-c \operatorname{Cap}_{\omega_{\mathrm{FS}}}(K)^{-1/n}\bigr).$$

The common mass bound handles the remaining $T(K)$, and pluripolar sets have zero local product mass. A bounded local potential for ω_{FS} turns every global test $0 \le v \le 1$ into a plurisubharmonic function of a fixed bounded range on B. Hence

$$\operatorname{Cap}_{\omega_{\mathrm{FS}}}(K) \le C_1 \operatorname{cap}(K, B) \le C_2 \operatorname{Cap}_\omega(K),$$

where the last inequality is the gluing construction of Lemma 1.8.1 on the original manifold. These inequalities have the required direction after taking negative inverse powers. Inner regularity of the finite local product extends the bound from compact to Borel subsets of B'. Summing over a fixed finite cover proves the first assertion. The second follows by bounding $x^{-s} \exp(-ax^{-1/n})$ on $0 < x \le \operatorname{Cap}_\omega(X)$. □

1.8.4 Convergence of potentials and measures

For quasi-continuous obstacles, a decreasing lower semicontinuous approximation keeps the original bounds and confines the error to sets of vanishing capacity.

Lemma 1.8.5 *Every bounded quasi-continuous function f on X admits bounded lower semicontinuous functions f_j with common bounds such that $f_j \downarrow f$ quasi-everywhere and $f_j \to f$ in capacity.*

Proof Choose open sets O_j of capacity at most 2^{-j} such that the restriction of f to $X \setminus O_j$ is continuous, and set $G_j = \bigcup_{k \geq j} O_k$. Then the sets G_j decrease, their capacities tend to zero, and f is continuous on the closed complement of each G_j. Choose $M \geq \sup_X f$ and define

$$f_j = f \text{ on } X \setminus G_j, \qquad f_j = M \text{ on } G_j.$$

At a boundary point of G_j, the values of f_j on the closed complement tend to the value of f there, while the values inside G_j are at least that value. Thus f_j is lower semicontinuous. The functions f_j decrease to f outside $\bigcap_j G_j$, a set of capacity zero. Since $f_j - f$ is supported in G_j, they also converge to f in capacity. □

Uniform bounds on potentials give a common capacity bound for their mixed measures.

Lemma 1.8.6 *Let $A \geq 0$ and let $0 \leq k \leq n$ be an integer. There is a constant C_A such that all the positive mixed measures*

$$\omega_{v_1} \wedge \cdots \wedge \omega_{v_k} \wedge \omega^{n-k}, \qquad v_i \in \mathrm{PSH}(X, \omega), \quad \|v_i\|_\infty \leq A,$$

are bounded above on Borel sets by $C_A \operatorname{Cap}_\omega$. In particular, their total masses are uniformly bounded. If uniformly bounded functions tend to zero in capacity, then their integrals against these measures tend to zero uniformly in the v_i.

Proof Translate the v_i so that $0 \leq v_i \leq 2A$, and put $q = (v_1 + \cdots + v_k)/B$, where $B \geq \max\{2k, 2kA, 1\}$. Then $0 \leq q \leq 1$ and

$$\omega_q = B^{-1} \sum_{i=1}^{k} \omega_{v_i} + (1 - k/B)\omega,$$

where all coefficients are positive. Expanding ω_q^n shows that the given mixed product is bounded by a constant multiple of ω_q^n, and the definition of capacity proves the first claim. The case $k = 0$ follows by testing with $v = 0$. For a bounded function z, split its integral into the parts over $\{|z| > t\}$ and over its complement; first use convergence in capacity for fixed $t > 0$, and then let $t \downarrow 0$. □

The same control applies to the total variation of a product formed with a different smooth background.

Lemma 1.8.7 *Let Ω be a Hermitian form and θ a smooth real $(1,1)$-form on X. Suppose that Ω-plurisubharmonic functions v_j have common finite upper and lower bounds and decrease to v. Then the signed measures*

$$\nu_j = (\theta + \mathrm{dd}^{\mathrm{c}} v_j)^n$$

converge to $(\theta + \mathrm{dd}^{\mathrm{c}} v)^n$ against every fixed bounded quasi-continuous function. Their total variations are bounded, uniformly in j, by a constant multiple of the local capacity on the balls of a fixed finite cover.

Proof On a relatively compact coordinate ball, choose a fixed quadratic function q such that the functions $v_j + q$ are plurisubharmonic; they still have common bounds. Expand

$$(\theta + \mathrm{dd^c} v_j)^n = \sum_{\ell=0}^{n} \binom{n}{\ell} \left(\mathrm{dd^c}(v_j + q)\right)^\ell \wedge (\theta - \mathrm{dd^c} q)^{n-\ell}.$$

The absolute value of the ℓ-th summand is bounded by a fixed constant times

$$\left(\mathrm{dd^c}(v_j + q)\right)^\ell \wedge \kappa_0^{n-\ell},$$

where κ_0 is a fixed positive Euclidean form. This positive mixed measure is bounded, uniformly in j, by a constant times the local capacity: add a fixed strictly plurisubharmonic quadratic function to $v_j + q$, expand the top power of its Hessian, and rescale its uniformly bounded range into $[0, 1]$ to apply the definition of capacity. This also covers $\ell = 0$. Summing over a finite cover gives the asserted control of the total variations. The ordinary decreasing continuity of Bedford–Taylor products gives weak convergence term by term. For a bounded quasi-continuous coefficient, remove an open set of small capacity and extend the restriction of the coefficient to the compact complement to a continuous function on X. The variation bound controls the resulting error uniformly for the sequence and its limit, and letting the capacity of the removed set tend to zero proves the assertion. □

A finite non-pluripolar measure is uniformly absolutely continuous with respect to capacity, although it need not be bounded by a power of the capacity.

Lemma 1.8.8 *Let μ be a finite non-pluripolar Borel measure on X. Then*

$$\lim_{\delta \downarrow 0} \sup\{\mu(E) : E \text{ Borel}, \ \mathrm{Cap}_\omega(E) \le \delta\} = 0.$$

Consequently, convergence in capacity implies convergence in μ-measure.

Proof If the first assertion failed, there would be $\epsilon > 0$ and Borel sets E_j of capacity at most 2^{-j} with $\mu(E_j) \ge \epsilon$. By countable subadditivity of capacity,

$$\mathrm{Cap}_\omega \left(\limsup_j E_j \right) = 0.$$

Hence $\limsup_j E_j$ is pluripolar and has μ-measure zero. On the other hand, since μ is finite, continuity from above applied to the sets $\bigcup_{k \ge j} E_k$ shows that $\limsup_j E_j$ has measure at least ϵ, a contradiction. If $u_j \to u$ in capacity, applying the first assertion to the sets $\{|u_j - u| > \delta\}$ gives the consequence. □

Lemma 1.8.9 *Let $u_j \in \mathrm{PSH}(X, \theta)$. Suppose either that u_j decreases to a function $u \not\equiv -\infty$, or that u_j increases, the sequence is uniformly bounded above, and $u = (\lim_j u_j)^*$. Then $u_j \to u$ in capacity.*

Proof In the decreasing case u is a common lower bound for the sequence and its limit; in the increasing case u_1 is one. Choose a Hermitian form $\Omega \geq \theta$ and truncate all functions at $-T$. The truncations are bounded, monotone and Ω-plurisubharmonic, so the convergence in capacity of locally bounded monotone sequences, recalled in Section 1.6, applies to them on the balls of a finite cover. By quasi-continuity of the common lower bound, there is an open set of arbitrarily small capacity containing its pole set such that the restriction of the lower bound to the compact complement is continuous. There it is finite and hence bounded below, so the capacity of the sublevel set of the lower bound at height $-T$ tends to zero as $T \to \infty$. Since the functions agree with their truncations outside this sublevel set, letting $T \to \infty$ proves the lemma. □

A fixed bounded reference potential also controls a mixed trace in which one normalized potential varies.

Lemma 1.8.10 *Let $\theta \geq 0$, and fix a bounded $\psi \in \mathrm{PSH}(X, \theta)$. There is a constant C_ψ such that*

$$\int_X \theta_v \wedge \theta_\psi^{n-1} \leq C_\psi$$

for every bounded $v \in \mathrm{PSH}(X, \theta)$ with $\sup_X v = 0$.

Proof For $n = 1$, Stokes' theorem gives $\int_X \theta_v = \int_X \theta$, so assume $n \geq 2$. Choose a fixed Hermitian form $\Omega \geq \theta$. All currents on the left-hand side are positive, and $\Omega_\psi \geq \theta_\psi$. Hence Stokes' theorem for bounded potentials gives

$$\int_X \theta_v \wedge \theta_\psi^{n-1} \leq \int_X \theta \wedge \Omega_\psi^{n-1} + \int_X v \, \mathrm{dd^c}(\Omega_\psi^{n-1}).$$

The first term on the right is bounded independently of v. To estimate the second, differentiate:

$$\mathrm{dd^c}(\Omega_\psi^{n-1}) = (n-1)\mathrm{dd^c}\Omega \wedge \Omega_\psi^{n-2} + (n-1)(n-2)\mathrm{d}\Omega \wedge \mathrm{d^c}\Omega \wedge \Omega_\psi^{n-3},$$

where the second term is absent for $n = 2$. Since $\mathrm{dd^c}\Omega$ and $\mathrm{d}\Omega \wedge \mathrm{d^c}\Omega$ are smooth forms, the absolute values of these terms are bounded by fixed multiples of the positive measures $\Omega^2 \wedge \Omega_\psi^{n-2}$ and $\Omega^3 \wedge \Omega_\psi^{n-3}$. The weighted local Chern–Levine–Nirenberg inequality of Section 1.6 bounds the integrals of $|v|$ against these measures. Indeed, on each larger coordinate ball, add fixed smooth corrections to v and ψ, shift the corrected v so that it becomes negative, expand in the corrected positive Hessian of ψ, and apply that inequality on a smaller ball. The resulting bound is

$$C(1 + \|\psi\|_\infty)^n (1 + \|v\|_{L^1(X)}).$$

By Theorem 1.4.1, normalized θ-plurisubharmonic functions have uniformly bounded L^1 norms, and summing the local bounds proves the assertion. □

1.8.5 Vanishing area on curves

On a compact curve, the integral of the background is the total mass of every curvature current. When this integral vanishes, positivity forces the current to vanish. Normalized compactness and the local estimate of capacity by total variation make this uniqueness stable as the area tends to zero.

Throughout this subsection, Y is a compact connected Riemann surface and η is a smooth positive $(1,1)$-form on Y with $\int_Y \eta = 1$, which we use for L^1 norms and for the capacity Cap_η on Y.

Lemma 1.8.11 *For a smooth real $(1,1)$-form σ on Y, put $A = \int_Y \sigma$. There is a smooth real function h with $\sigma = A\eta + \mathrm{dd^c} h$. The class $\mathrm{PSH}(Y,\sigma)$ is nonempty if and only if $A \geq 0$. If $A = 0$, it consists of the functions $-h + c$, $c \in \mathbb{R}$, and its unique member with supremum zero is $u_\sigma = -h + \min_Y h$.*

Proof The smooth form $\sigma - A\eta$ has integral zero, so the Poisson equation on the compact connected surface Y has a smooth solution h, unique up to an additive constant. If $u \in \mathrm{PSH}(Y,\sigma)$, positivity and Stokes' theorem give

$$0 \leq (\sigma + \mathrm{dd^c} u)(Y) = A.$$

Conversely, $\sigma + \mathrm{dd^c}(-h) = A\eta$, so $-h \in \mathrm{PSH}(Y,\sigma)$ when $A \geq 0$. If $A = 0$, every positive curvature measure has total mass zero and therefore vanishes. Thus $\mathrm{dd^c}(u + h) = 0$ for every $u \in \mathrm{PSH}(Y,\sigma)$, and elliptic regularity and the uniqueness of harmonic functions on Y show that $u + h$ is constant. Normalizing the supremum gives the stated formula. □

Theorem 1.8.1 *Let σ_j be smooth real $(1,1)$-forms on Y that converge uniformly to a smooth form σ_0, and suppose that*

$$A_j = \int_Y \sigma_j \geq 0, \qquad \int_Y \sigma_0 = 0.$$

Let u_0 be the normalized σ_0-plurisubharmonic potential of Lemma 1.8.11. Then, for every $t > 0$,

$$\sup_{u \in \mathrm{PSH}(Y,\sigma_j),\ \sup_Y u = 0} \|u - u_0\|_{L^1(Y)} \longrightarrow 0,$$

$$\sup_{u \in \mathrm{PSH}(Y,\sigma_j),\ \sup_Y u = 0} \mathrm{Cap}_\eta(\{|u - u_0| > t\}) \longrightarrow 0.$$

Moreover, the curvature measures $\sigma_j + \mathrm{dd^c} u$ of these potentials tend to zero in total variation, uniformly in u, since each has total variation A_j.

Proof Choose $C > 0$ with $\sigma_j \leq C\eta$ for every j. Every sequence of normalized σ_j-plurisubharmonic functions then lies in the compact family of normalized $C\eta$-plurisubharmonic functions of Theorem 1.4.1. Every L^1 limit u of a subsequence is normalized and, by passing to the limit in the sense of distributions, satisfies

$\sigma_0 + \mathrm{dd}^{\mathrm{c}} u \geq 0$. The preceding lemma gives $u = u_0$. If the first uniform limit failed, a sequence violating it would have a subsequence converging to this same limit, a contradiction.

For a potential u in the j-th normalized family, put $T = \sigma_j + \mathrm{dd}^{\mathrm{c}} u$. Positivity and Stokes' theorem give $\|T\|_{\mathrm{TV}} = A_j$, and $A_j \to \int_Y \sigma_0 = 0$. Since $\sigma_0 + \mathrm{dd}^{\mathrm{c}} u_0 = 0$,

$$\|\mathrm{dd}^{\mathrm{c}}(u - u_0)\|_{\mathrm{TV}} \leq A_j + \|\sigma_j - \sigma_0\|_{\mathrm{TV}} \longrightarrow 0$$

uniformly over that family. Apply Lemma 1.6.3 on a fixed finite cover of Y by concentric coordinate disks. The first limit and the bound above make each local capacity tend to zero uniformly, and the comparison between local and global capacity at the beginning of this section proves the second limit. The identity $\|T\|_{\mathrm{TV}} = A_j$ proves the final assertion. □

1.9 Comparing local regularizations

To glue local convolutions, we need them to agree on overlaps up to an error tending uniformly to zero. A bounded plurisubharmonic function need not be continuous, so this comparison cannot come from uniform convergence to the original function. Instead, the logarithmic convexity of its suprema over balls controls both the change of scale and the change of coordinates.

Let $U \subset \mathbb{C}^n$ be a domain and u a bounded plurisubharmonic function on U. For z in a fixed relatively compact subset of U and small $\delta > 0$, put

$$S_\delta u(z) = \sup_{|\zeta - z| \leq \delta} u(\zeta), \qquad A_\delta u(z) = \fint_{|\zeta - z| = \delta} u(\zeta)\, \mathrm{d}\sigma(\zeta), \qquad u_\delta = u * \rho_\delta,$$

where $\mathrm{d}\sigma$ is the Euclidean surface measure and ρ is a smooth nonnegative radial mollifier of integral one, supported in the unit ball, with $\rho_\delta(\zeta) = \delta^{-2n} \rho(\zeta/\delta)$. All balls below lie in a fixed larger relatively compact subset of U, and B denotes a bound for the oscillation of u on that subset.

Lemma 1.9.1 *For each fixed $A > 1$,*

$$S_{A\delta}u - S_\delta u \longrightarrow 0, \qquad S_\delta u - u_\delta \longrightarrow 0$$

uniformly on compact subsets as $\delta \downarrow 0$.

Proof The maximum of a plurisubharmonic function over concentric balls is a convex function of the logarithm of the radius. This follows by restricting to each complex line through the center and comparing, on an annulus, with the harmonic function that is affine in $\log|\zeta|$. Fix a radius $r > A\delta$ for which all the balls of radius r about points of the given compact set lie in the larger subset. Comparing secant slopes of this convex function between $\log\delta$, $\log(A\delta)$ and $\log r$ gives

$$0 \le S_{A\delta}u - S_\delta u \le \frac{B\log A}{\log(r/\delta)}, \tag{1.17}$$

which proves the first assertion.

To compare the maximum with the spherical mean, we use the Poisson kernel in real dimension $2n$. For a point at distance at most $\delta/2$ from the center, the normalized Poisson kernel of the ball of radius δ is bounded below by a positive dimensional constant c_n. Since u is bounded above by $S_\delta u$ and by its harmonic extension from the sphere of radius δ, we obtain

$$S_\delta u - S_{\delta/2}u \ge c_n(S_\delta u - A_\delta u).$$

These inequalities hold for bounded plurisubharmonic functions by local smoothing followed by a decreasing limit. By (1.17), $S_\delta u - A_\delta u$ therefore tends uniformly to zero.

For $0 < t \le 1$, the spherical mean is increasing in the radius, and

$$0 \le A_\delta u - A_{t\delta}u \le (S_\delta u - S_{t\delta}u) + (S_{t\delta}u - A_{t\delta}u).$$

By logarithmic convexity, the first term is at most $B\log(1/t)/\log(r/(t\delta))$, and by the preceding estimate the second is at most $C_nB/\log(r/(t\delta))$. Write the radial convolution as an average of the spherical means $A_{t\delta}u$ with respect to the probability density $\widehat{\rho}(t) = |\mathbb{S}^{2n-1}|t^{2n-1}\rho(t)$ on $[0,1]$, where $\rho(t)$ denotes the value of ρ at radius t. Since $\int_0^1 (1+\log(1/t))\widehat{\rho}(t)\,\mathrm{d}t < \infty$, integration gives

$$0 \le A_\delta u - u_\delta \le \frac{C_{n,\rho}B}{\log(r/\delta)}.$$

Combining the two comparisons proves the second assertion. □

Corollary 1.9.1 *Let $U, V \subset \mathbb{C}^n$ be domains, let $F : U \to V$ be biholomorphic, and let u be bounded and plurisubharmonic on U. Then*

$$u_\delta - \big((u \circ F^{-1}) * \rho_\delta\big) \circ F$$

tends locally uniformly to zero as $\delta \downarrow 0$.

Proof On a compact subset, F and its inverse have uniformly bounded first derivatives. Thus, for a fixed $A > 1$, the inverse image under F of the ball of radius δ about $F(z)$ lies between the balls about z of radii δ/A and $A\delta$. Consequently, $S_\delta(u \circ F^{-1})(F(z))$ and $S_\delta u(z)$ both lie between $S_{\delta/A}u(z)$ and $S_{A\delta}u(z)$, and the first assertion of Lemma 1.9.1 shows that their difference tends to zero uniformly. The second assertion of the lemma, applied to u and to $u \circ F^{-1}$, compares each of the two convolutions with the corresponding supremum regularization. □

1.10 Gluing with a small curvature error

The overlap estimate allows local regularizations to be glued by a regularized maximum. Small corrections near the boundary of each chart make the corresponding local branch irrelevant there, while convexity of the regularized maximum preserves a common lower curvature bound. The curvature error is measured by the Hermitian form ω.

For an integer $N \geq 1$, choose independent real random variables $Z_1, \ldots, Z_N$ with a common smooth even probability density supported in $[-1, 1]$, and define

$$M_\tau(t_1, \ldots, t_N) = \mathbb{E} \max_i (t_i + \tau Z_i) \quad (\tau > 0).$$

As a convolution, M_τ is smooth. It is convex and increasing in every argument, and, with $\mathbf{1} = (1, \ldots, 1)$, it satisfies

$$\max_i t_i \leq M_\tau(t) \leq \max_i t_i + \tau, \qquad M_\tau(t + c\mathbf{1}) = M_\tau(t) + c$$

for $t \in \mathbb{R}^N$ and $c \in \mathbb{R}$. If $t_i < \max_{j \neq i} t_j - 2\tau$, then the i-th argument can be removed without changing the value. Moreover, $M_\tau(t)$ is nondecreasing in τ, because it is a convex even function of τ, the distribution of each Z_i being symmetric.

The second identity expresses invariance under translations. If smooth real functions f_i, $1 \leq i \leq N$, satisfy $\mathrm{dd^c} f_i \geq -\gamma$ for a common smooth real $(1,1)$-form γ, then

$$\mathrm{dd^c} M_\tau(f_1, \ldots, f_N) \geq -\gamma. \tag{1.18}$$

Indeed, in the chain rule the first partial derivatives of M_τ are nonnegative and, by the translation identity, sum to one, while the real Hessian of the convex function M_τ contributes a semipositive $(1,1)$-form.

Proposition 1.10.1 *Let θ be a smooth real $(1,1)$-form, let ω be a Hermitian form, and let $u \in \mathrm{PSH}(X,\theta) \cap L^\infty(X)$. There are smooth functions v_j and positive numbers $\varepsilon_j \downarrow 0$ such that*

$$v_j \downarrow u, \qquad \theta + \varepsilon_j \omega + \mathrm{dd^c} v_j \geq 0.$$

Proof For fixed $\epsilon > 0$, we first glue the local convolutions of u by a regularized maximum, obtaining smooth functions that decrease to u and have curvature error $2\epsilon\omega$; a diagonal sequence then proves the proposition.

Step 1: local regularizations. Fix $\epsilon > 0$. By continuity of θ, we can choose finitely many nested coordinate neighborhoods $V_i \Subset W_i \Subset U_i$, with the V_i covering X, and smooth quadratic functions r_i such that

$$0 \leq \mathrm{dd^c} r_i - \theta \leq \epsilon\omega \quad \text{on } U_i.$$

To do so, freeze the coefficients of θ at the center of a chart, add a small positive constant form, and shrink the coordinate neighborhood. Then $p_i = u + r_i$ is a bounded plurisubharmonic function on U_i; let $p_{i,\delta}$ be its convolution in the coordinates of U_i.

On an overlap, express both p_i and p_j in the coordinates of U_j. Their difference is the smooth function $r_i - r_j$, so the difference of their convolutions in these coordinates tends uniformly to $r_i - r_j$. By Corollary 1.9.1, changing the coordinates in which p_i is convolved introduces another uniformly vanishing error. Thus, on the intersections of the closures of the W_i,

$$(p_{i,\delta} - r_i) - (p_{j,\delta} - r_j) \longrightarrow 0 \quad \text{uniformly.} \tag{1.19}$$

Step 2: gluing. Choose functions $\eta_i \in C^\infty(U_i, [-1,0])$ that vanish on V_i and equal -1 near the boundary of W_i, and a constant $C \geq 1$ with $\mathrm{dd^c}\eta_i \geq -C\omega$. The cover, the functions r_i, η_i and the constant C may depend on ϵ; they are fixed while δ tends to zero. Set

$$f_{i,\delta} = p_{i,\delta} - r_i + (\epsilon/C)\eta_i \quad \text{on } W_i.$$

Each of these functions satisfies $\mathrm{dd^c} f_{i,\delta} \geq -\theta - 2\epsilon\omega$. Every boundary point of W_i lies in some V_j, and there $\eta_j = 0$ while $\eta_i = -1$. By (1.19), for all small δ,

$$f_{i,\delta} < f_{j,\delta} - \epsilon/(2C)$$

on a neighborhood of that boundary point. Since the cover is finite, this separation holds uniformly.

Let $\tau(\delta) \downarrow 0$ as $\delta \downarrow 0$, with $\tau(\delta) < \epsilon/(8C)$, and define the value at each point as the regularized maximum $M_{\tau(\delta)}$ of the functions $f_{i,\delta}$ for those i with the point in W_i. A branch disappears only near the boundary of its W_i, where it lies below another branch by more than 2τ. By the removal property of M_τ, these local formulas therefore define a global smooth function $\psi_{\epsilon,\delta}$, and (1.18) gives

$$\theta + 2\epsilon\omega + \mathrm{dd^c}\psi_{\epsilon,\delta} \geq 0.$$

At every point there is a branch with $\eta_i = 0$, and $p_{i,\delta} \geq p_i$; hence $\psi_{\epsilon,\delta} \geq u$. For fixed ϵ, the local convolutions decrease with δ, and the regularized maximum decreases when both its arguments and τ decrease. Its pointwise limit is

$$\max_{i:x\in W_i} \big(u(x) + (\epsilon/C)\eta_i(x)\big) = u(x).$$

Thus $\psi_{\epsilon,\delta} \downarrow u$ as $\delta \downarrow 0$, and also in L^1.

Step 3: a diagonal sequence. Take $\epsilon_j \downarrow 0$ and put $v_j = \psi_{\epsilon_j,\delta_j} + 2^{-j}$, where δ_j is chosen so small that

$$\|\psi_{\epsilon_j,\delta_j} - u\|_{L^1} \leq 2^{-j}, \qquad v_j < v_{j-1} \quad (j \geq 2).$$

The second requirement can be met because $v_{j-1} \geq u + 2^{-j+1}$. Indeed, as $\delta \downarrow 0$, the continuous functions $\psi_{\epsilon_j,\delta} + 2^{-j} - v_{j-1}$ decrease pointwise to a function bounded above by -2^{-j}. Their sets of nonnegative values are decreasing compact sets with empty intersection, so one of them is empty. The resulting sequence (v_j) decreases, converges to u in L^1, and stays above u. Its pointwise limit is $(\theta + 2\epsilon_k\omega)$-plurisubharmonic for every k, hence θ-plurisubharmonic, and it equals u almost everywhere; by Lemma 1.3.3, it equals u everywhere. Taking $\varepsilon_j = 2\epsilon_j$ proves the proposition. □

1.11 Regularization in a fixed Hermitian background

For $\theta = \omega$, rescaling the approximants absorbs the curvature error into the positive background. Subtracting a constant first makes the approximants negative, so that this rescaling preserves their decreasing order.

Theorem 1.11.1 *For every $u \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$, there are smooth functions $u_j \downarrow u$ such that*

$$\omega + \mathrm{dd^c} u_j > 0.$$

The functions u_j are uniformly bounded.

Proof Subtracting a constant, we may assume $u \leq -2$. Apply Proposition 1.10.1 with $\theta = \omega$, obtaining smooth functions $v_j \downarrow u$ and positive numbers $\varepsilon_j \downarrow 0$ with $(1+\varepsilon_j)\omega + \mathrm{dd^c} v_j \geq 0$. The compact sets $\{v_j \geq -1\}$ decrease to the empty set, since $u \leq -2$. After discarding finitely many terms, we may therefore assume $v_j < 0$ everywhere. Put

$$u_j = \frac{v_j}{1+2\varepsilon_j}.$$

Then

$$\omega + \mathrm{dd^c} u_j \geq \frac{\varepsilon_j}{1+2\varepsilon_j}\omega > 0.$$

Since v_j is negative and decreases, while the positive denominator decreases to one, u_j also decreases, and it converges to u. Moreover, $u \le v_j \le u_j \le u_1$, which gives uniform boundedness. Adding back the subtracted constant proves the theorem. □

This regularization provides the approximation used for products and mass in Chapter 6. For an arbitrary smooth form θ, Proposition 1.10.1 only gives approximants whose curvature error tends to zero.

1.12 Singularity type and multiplier ideals

There are two natural ways to compare the singularities of quasi-plurisubharmonic functions on X. The first asks whether one function is bounded above by the other up to an additive constant; it leads to the ordinary singularity type. The second records only which holomorphic functions are locally square integrable against the weights e^{-ku}, $k > 0$; it leads to multiplier ideals. Domination implies the corresponding inclusion of multiplier ideals. A logarithmic pole on a disk shows that a single weight loses information, which is why the second comparison uses all positive weights.

Definition 1.12.1 Let u, v be quasi-plurisubharmonic functions on X. We write $u \preceq v$ if there is a constant $C \in \mathbb{R}$ such that $u \le v + C$ on X, and $u \sim v$ if both $u \preceq v$ and $v \preceq u$; in the latter case u and v have the same *singularity type*. When this has to be distinguished from the multiplier-ideal type introduced below, we speak of the *ordinary singularity type*, or simply the *ordinary type*.

Thus $u \preceq v$ means that u is at least as singular as v. For instance, a quasi-plurisubharmonic function with a logarithmic pole lies below every bounded potential in this order, but not conversely.

Proposition 1.12.1 *The relation $\preceq$ is a preorder, and $\sim$ is an equivalence relation. If u is quasi-plurisubharmonic and f is a smooth function on X, then $u + f \sim u$. In particular, all smooth functions on X have the same singularity type.*

Proof Reflexivity follows with $C = 0$. If $u \le v + C$ and $v \le w + D$, then $u \le w + C + D$, which proves transitivity. As for every preorder, comparison in both directions defines an equivalence relation. Since X is compact, a smooth function f satisfies $|f| \le A$ for some constant A, and then $u - A \le u + f \le u + A$. Taking $u = 0$ shows that every smooth function has the singularity type of the constants. □

Some later results require the singularities of a potential to be concentrated on a small closed set. A closed subset $A \subseteq X$ is *complete pluripolar* if every point of X has a neighborhood U with a plurisubharmonic function p on U such that $A \cap U = \{p = -\infty\}$. A quasi-plurisubharmonic function has *small unbounded locus* if it is locally bounded outside a closed complete pluripolar set.

Definition 1.12.2 Let $\mathcal{O}_X$ denote the sheaf of holomorphic functions on X. For a quasi-plurisubharmonic function u on X, the *multiplier ideal* $\mathcal{I}(u) \subseteq \mathcal{O}_X$ is the ideal

sheaf whose sections over an open set U are the holomorphic functions g on U for which $|g|^2 e^{-u}$ is locally integrable on U with respect to a smooth positive volume form. Its stalk at x is denoted by $\mathcal{I}(u)_x$.

Changing the volume form does not change local integrability: on relatively compact coordinate neighborhoods, the ratio of two smooth positive volume forms is bounded above and below by positive constants. In particular, the definition does not involve a choice of Hermitian metric, and it applies verbatim to quasi-plurisubharmonic functions on any complex manifold.

Proposition 1.12.2 *If $u \preceq v$, then $\mathcal{I}(ku) \subseteq \mathcal{I}(kv)$ for every real $k > 0$. If $u \sim v$, then these ideals agree for every $k > 0$.*

Proof Let g be a local holomorphic function on X. If $u \le v + C$, then $e^{-kv} \le e^{kC} e^{-ku}$. Multiplying by $|g|^2$ shows that local integrability of $|g|^2 e^{-ku}$ implies local integrability of $|g|^2 e^{-kv}$. If $u \sim v$, the same argument applies in both directions. □

Example 1.12.1 On a disk in $\mathbb{C}$ centered at the origin, with coordinate z, let $\lambda \ge 0$ and put $u(z) = \lambda \log |z|^2$ for $\lambda > 0$, while $u = 0$ for $\lambda = 0$. Then

$$\mathcal{I}(u)_0 = (z^{\lfloor \lambda \rfloor}).$$

Indeed, if a nonzero holomorphic germ has order m at the origin, its squared modulus is comparable to $|z|^{2m}$ near the origin. In polar coordinates, its weighted integral over a disk of sufficiently small radius $\epsilon > 0$ is finite precisely when

$$\int_0^{\epsilon} r^{2m-2\lambda+1}\, dr < \infty, \qquad \text{equivalently} \qquad m > \lambda - 1.$$

The smallest nonnegative integer satisfying this strict inequality is $\lfloor \lambda \rfloor$. When λ is an integer, the borderline exponent -1 occurs for $m = \lambda - 1$ and gives a divergent integral; this is where the strictness of the inequality matters.

The example also shows that a single multiplier ideal does not determine the singularity: different coefficients λ can have the same integer part. For a real weight $k > 0$, the same calculation applied to ku gives $\mathcal{I}(ku)_0 = (z^{\lfloor k\lambda \rfloor})$. The ideals at all weights $k > 0$ recover λ: if $0 \le \lambda < \mu$, the integer parts of $k\lambda$ and $k\mu$ differ as soon as $k(\mu - \lambda) > 1$.

We therefore compare multiplier ideals at all positive weights. For quasi-plurisubharmonic functions u, v, we write $u \preceq_{\mathcal{I}} v$ if $\mathcal{I}(ku) \subseteq \mathcal{I}(kv)$ for every real $k > 0$, and $u \sim_{\mathcal{I}} v$ if $\mathcal{I}(ku) = \mathcal{I}(kv)$ for every real $k > 0$. We call $\preceq_{\mathcal{I}}$ the *ideal order*; if $u \sim_{\mathcal{I}} v$, then u and v have the same *multiplier-ideal type*, or *ideal type*. By Proposition 1.12.2, $u \preceq v$ implies $u \preceq_{\mathcal{I}} v$, and $u \sim v$ implies $u \sim_{\mathcal{I}} v$. These relations make sense on any complex manifold. Their relation to envelopes and to global masses requires further arguments; see Chapter 16.

1.13 Analytic types and restriction

The simplest singularities of quasi-plurisubharmonic functions are logarithmic poles along the common zeros of finitely many holomorphic functions. The logarithmic growth of a general singularity at a point is measured by its Lelong number. Let u be a quasi-plurisubharmonic function on a complex manifold and let x be a point. Choose holomorphic coordinates centered at x and a smooth function q such that $p = u + q$ is plurisubharmonic near x, and write $B(x, r)$ for the Euclidean coordinate ball of radius r. The *Lelong number* of u at x is

$$\nu(u, x) = \lim_{r \downarrow 0} \frac{\sup_{B(x,r)} p}{\log r^2}.$$

By the local growth theorem recalled in [Xia], the limit exists and does not depend on the coordinates or on the correction q. With this normalization, $\log |z|^2$ has Lelong number one at the origin. For an irreducible analytic subset Z, the *generic Lelong number* of u along Z is

$$\nu(u, Z) = \inf_{x \in Z} \nu(u, x).$$

By Siu's theorem, recalled in Section 1.13.1, $\nu(u, x) = \nu(u, Z)$ for all $x \in Z$ outside a countable union of proper analytic subsets of Z.

For analytic singularities we follow the convention of [Xia]: we say that a quasi-plurisubharmonic function u has *analytic singularities* if near every point there are holomorphic functions $f_1, \dots, f_N$, not all identically zero, and a rational number $c > 0$ such that

$$u = c \log\bigl(|f_1|^2 + \cdots + |f_N|^2\bigr) + O(1), \qquad c \in \mathbb{Q}_{>0}.$$

The remainder is only required to be bounded; if it can be chosen smooth, we say that u has analytic singularities *with smooth remainder*. Given a coherent ideal sheaf $\mathfrak{a}$ and a common coefficient c, we say that u has *analytic type* $(c, \mathfrak{a})$ if this holds with local generators $f_1, \dots, f_N$ of $\mathfrak{a}$. The choice of generators does not matter: two finite systems of generators of the same ideal change the logarithm only by a bounded amount on smaller relatively compact open sets.

Proposition 1.13.1 *Analytic singularities are preserved by addition, finite maxima, and multiplication by positive rational numbers. Let u have analytic type $(c, \mathfrak{a})$, and let $Y \subset X$ be a connected complex submanifold on which $\mathfrak{a}$ does not vanish identically. Then the restriction $u|_Y$ is a quasi-plurisubharmonic function on Y, in particular not identically $-\infty$, and it has analytic type*

$$(c, \mathfrak{a}\mathcal{O}_Y).$$

Here $\mathfrak{a}\mathcal{O}_Y$ is the image ideal, generated by the restrictions to Y of local sections of $\mathfrak{a}$.

Proof For multiplication by a positive rational number, multiply the coefficient. Consider two presentations with coefficients c_1, c_2 and ideals $\mathfrak{a}_1, \mathfrak{a}_2$, and choose

a positive rational number d with $c_1 = kd$ and $c_2 = \ell d$, where k, ℓ are positive integers. Raising a sum of squared moduli of generators of $\mathfrak{a}_1$ to the power k gives, up to bounded factors, the corresponding sum for $\mathfrak{a}_1^k$; similarly for $\mathfrak{a}_2^\ell$. Products of generators of $\mathfrak{a}_1^k$ and $\mathfrak{a}_2^\ell$ therefore present the sum with coefficient d, since a product of sums of squares is a sum of squares of pairwise products.

For the maximum, apply the elementary inequalities

$$\max\{A, B\} \le A + B \le 2\max\{A, B\}, \qquad A, B \ge 0,$$

to the two sums of squared moduli of generators of $\mathfrak{a}_1^k$ and $\mathfrak{a}_2^\ell$. Taking logarithms shows that the maximum differs from d times the logarithm of their total by a bounded amount. These are local assertions; on the compact manifold, finitely many charts give the corresponding comparisons of ordinary singularity types.

For the restriction, restrict to Y the two-sided bounds that define the remainder. Since Y is connected and is not contained in the zero set of $\mathfrak{a}$, the common zero set of the restricted generators is a proper analytic subset of Y, so $u|_Y$ is finite on a dense open subset of Y. After a smooth local correction, the restriction theorem for plurisubharmonic functions shows that $u|_Y$ is quasi-plurisubharmonic, and the restricted bounds give the asserted presentation. □

For an arbitrary quasi-plurisubharmonic function, a vanishing generic Lelong number along a submanifold does not prevent the restriction from being identically $-\infty$. For example, on a small polydisk in $\mathbb{C}^n$ with coordinates $z = (z_1, \dots, z_n)$ and $|z_1| < \mathrm{e}^{-1}$, the function

$$u(z) = -\sqrt{-\log |z_1|^2}$$

is plurisubharmonic, because $t \mapsto -\sqrt{-t}$ is increasing and convex for $t < 0$. Its Lelong number vanishes at every point of $\{z_1 = 0\}$, but its restriction to this hyperplane is identically $-\infty$. For the analytic approximants constructed below, the analytic hypothesis in Proposition 1.13.1 excludes this behavior.

1.13.1 Lelong level sets

Siu's analyticity theorem states that, for every quasi-plurisubharmonic function u and every $c > 0$, the upper level set $\{x : \nu(u, x) \ge c\}$ is an analytic subset. After a smooth local correction, this is the theorem for closed positive currents, which we use in the form recalled in [Xia]; see Section 34.1 for the original source.

For a closed positive current, the Lelong monotonicity formula also bounds the trace mass of small balls. The resulting Hausdorff estimate shows that a closed positive (j, j)-current puts no mass on sets of zero Hausdorff $2(n - j)$-measure.

Corollary 1.13.1 *Let T be a closed positive (j,j)-current on a complex manifold of dimension n, with $1 \le j < n$. Its coefficient measures vanish on every Borel set of zero Hausdorff $2(n-j)$-measure.*

Proof In a coordinate chart put $\kappa = \mathrm{dd}^{\mathrm{c}}|z|^2$ and $\mu = T \wedge \kappa^{n-j}$. By the Lelong monotonicity formula in bidimension $(n-j, n-j)$, the function $r \mapsto r^{-2(n-j)}\mu(B(x,r))$ is nondecreasing; see [Dem12, Chapter III, formulas (5.5)–(5.8), pp. 158–159]. Fix a relatively compact inner chart and a radius $r_0 > 0$ such that all balls of radius r_0 centered in it lie in a fixed compact subset of the chart. Their masses are bounded by the mass of that compact set. Hence

$$\mu(B(x,r)) \le C r^{2(n-j)}, \qquad 0 < r \le r_0,$$

uniformly for centers in the inner chart. A Borel set in the inner chart with zero Hausdorff $2(n-j)$-measure can be covered by balls $B(x_i, r_i)$ with $\sum_i r_i^{2(n-j)}$ arbitrarily small, so it has zero μ-mass. Since T is positive, the total variation of each of its coefficient measures is bounded by a constant multiple of μ. A countable cover by charts proves the assertion. □

The non-strict inequality in Siu's theorem cannot be replaced by a strict one, even on a compact Kähler manifold.

Example 1.13.1 Let $X = \mathbb{P}^2$, with homogeneous coordinates $[x : y : z]$, and let σ be the Fubini–Study form normalized by $\int_X \sigma^2 = 1$. Put $\|Z\|^2 = |x|^2 + |y|^2 + |z|^2$, $a_j = 2^{-j}$ and $\lambda_j = 2^{-j-1}$ for $j \ge 1$. The global function

$$u([Z]) = \log \frac{|y|^2}{\|Z\|^2} + \sum_{j \ge 1} \lambda_j \log \frac{|x - a_j z|^2}{(1 + a_j^2)\|Z\|^2}$$

belongs to $\mathrm{PSH}(X, \frac{3}{2}\sigma)$. For the line $D = \{y = 0\}$ and the points $p_j = [a_j : 0 : 1]$, it satisfies

$$\{\nu(u, \cdot) \ge 1\} = D, \qquad \{\nu(u, \cdot) > 1\} = \{p_j : j \ge 1\}.$$

The second set is not analytic.

Proof For a linear form ℓ with coefficient vector of norm one, the function $v_\ell = \log(|\ell(Z)|^2/\|Z\|^2)$ is nonpositive and satisfies $\mathrm{dd}^{\mathrm{c}} v_\ell = [\ell = 0] - \sigma$. Its $L^1(X, \sigma^2)$ norm is finite and independent of ℓ, because the unitary group $U(3)$ acts on homogeneous coordinates, preserves σ, and acts transitively on such forms. Since $\sum_j \lambda_j = 1/2$, the partial sums of the series defining u decrease to an L^1 function. They have the common curvature lower bound $-\frac{3}{2}\sigma$, so their limit is quasi-plurisubharmonic and

$$T := \tfrac{3}{2}\sigma + \mathrm{dd}^{\mathrm{c}} u = [D] + \sum_{j \ge 1} \lambda_j [L_j], \qquad L_j = \{x - a_j z = 0\}.$$

The series of positive closed currents converges, since every line has σ-trace mass one and the coefficients are summable.

We compute the Lelong numbers from the local mass formula. In affine coordinates $w = (w_1, w_2)$ centered at a point q, put $\kappa = \mathrm{dd^c}|w|^2$. An affine complex line H at distance d from q satisfies

$$\int_{H\cap B(q,r)} \kappa = (r^2 - d^2)_+.$$

Consequently $r^{-2}\int_{H\cap B(q,r)} \kappa$ is at most one and tends to $\mathbf{1}_H(q)$ as $r \downarrow 0$; a line that does not meet the chart contributes zero. Tonelli's theorem and dominated convergence for the summable coefficients therefore give

$$\nu(u, q) = \nu(T, q) = \mathbf{1}_D(q) + \sum_{j\geq 1} \lambda_j \mathbf{1}_{L_j}(q).$$

Here we used that a smooth local correction does not change the Lelong number. The computation also covers points at which infinitely many lines accumulate.

The lines L_j meet D at the distinct points p_j and meet one another only at $p_\infty = [0 : 1 : 0] \notin D$. Thus $\nu(u, p_j) = 1+\lambda_j$, whereas $\nu(u, q) = 1$ for $q \in D \setminus \{p_j : j \geq 1\}$. Outside D, the Lelong number is at most $\sum_j \lambda_j = 1/2$. This proves the two level-set identities. Finally, $p_j \to p_* = [0 : 0 : 1]$ and $\nu(u, p_*) = 1$, so the strict level set is not closed and hence not analytic. □

1.14 The local Bergman estimates

Demailly's approximation of plurisubharmonic functions by functions with analytic singularities is built from Bergman kernels of weighted spaces of holomorphic functions. In this section we recall the local construction and its estimates. Fix a bounded pseudoconvex domain $\Omega \subset \mathbb{C}^n$ and a plurisubharmonic function ψ on Ω. Write $\mathrm{d}\lambda$ for Euclidean volume and $B(x, r)$ for the Euclidean ball of radius $r > 0$ about x. For a positive integer m, define the weighted Hilbert space of holomorphic functions

$$\mathcal{H}_m = \left\{ f \in \mathcal{O}(\Omega) : \|f\|_m^2 := \int_\Omega |f|^2 \mathrm{e}^{-m\psi}\, \mathrm{d}\lambda < \infty \right\}.$$

Choose an orthonormal basis $(g_{m,j})_j$ of $\mathcal{H}_m$ and define $\beta_m = m^{-1} \log \sum_j |g_{m,j}|^2$. The sum is the squared norm of point evaluation,

$$\sum_j |g_{m,j}(x)|^2 = \sup_{\|f\|_m \leq 1} |f(x)|^2,$$

and is therefore independent of the basis. By the local finite generation part of Bergman regularization, β_m has analytic type $(1/m, \mathcal{I}(m\psi))$ on relatively compact open subsets of Ω. This follows from the generation of the multiplier ideal by weighted L^2 holomorphic functions and from local L^2 division; see [Dem11, Proposition 5.7

and Section 14.A]. We use this local statement, together with the point-extension estimate in the proof below, as a standard input.

Proposition 1.14.1 *There are constants C_1, C_2 independent of m such that, for $B(x,r) \Subset \Omega$,*

$$\psi(x) - \frac{C_1}{m} \le \beta_m(x) \le \sup_{B(x,r)} \psi + \frac{1}{m} \log \frac{C_2}{r^{2n}}. \tag{1.20}$$

Consequently $\beta_m \to \psi$ pointwise and in L^1_{loc}, and

$$\max\{\nu(\psi,x) - n/m, 0\} \le \nu(\beta_m,x) \le \nu(\psi,x). \tag{1.21}$$

Proof For $\|f\|_m \le 1$, the submean inequality gives

$$|f(x)|^2 \le C_2 r^{-2n} \int_{B(x,r)} |f|^2 \, d\lambda \le C_2 r^{-2n} e^{m \sup_{B(x,r)} \psi}.$$

Taking the supremum over the unit ball of $\mathcal{H}_m$ and then the logarithm proves the upper bound.

For the lower bound, suppose that $\psi(x) > -\infty$. The local Ohsawa–Takegoshi point-extension theorem gives a holomorphic f with $f(x) = 1$ and

$$\int_\Omega |f|^2 e^{-m\psi} \, d\lambda \le C e^{-m\psi(x)},$$

where the constant is independent of the plurisubharmonic weight and of m. After normalizing f in $\mathcal{H}_m$, we see that the squared norm of point evaluation is at least $C^{-1} e^{m\psi(x)}$, which proves the lower bound. At a pole of ψ the lower bound holds trivially.

Choosing $r = 1/m$ in the upper bound and using upper semicontinuity of ψ proves pointwise convergence. On a fixed relatively compact set, the same estimates bound β_m above by a constant and below by $\psi - C_1/m$. Since ψ is locally integrable, dominated convergence also gives convergence in L^1_{loc}.

For the Lelong estimate, take suprema over $B(x,r)$ in the two inequalities, bounding the right-hand side of the upper one by a supremum over $B(x,2r)$. Divide by $\log r^2 < 0$ and let $r \downarrow 0$. After the division, the term $-(2n/m)\log r$ contributes $-n/m$, while the constant terms disappear. This proves the two inequalities in (1.21); since Lelong numbers are nonnegative, the lower bound may be replaced by its maximum with zero. □

In [Dem11], the local weight is $e^{-2m\phi}$ and Lelong numbers are normalized by $\log|z|$. With $\psi = 2\phi$, these conventions give exactly the formulas above; in particular, the loss is n/m for the weight $e^{-m\psi}$ and the normalization by $\log|z|^2$.

The same construction and estimates hold for every real $m > 0$. The coefficient $1/m$ of the resulting logarithmic presentation is rational exactly when m is rational, and we speak of an analytic type only in that case. The global sequence constructed below is indexed by integers.

For a quasi-plurisubharmonic function u, the generators of $\mathcal{I}(mu)$ also control the multiplier ideals of u at nearby weights; a small loss in the weight compensates for the finite Bergman index.

Lemma 1.14.1 *Let u be quasi-plurisubharmonic, let $m > 0$, and let a_m be a function which locally satisfies $a_m = m^{-1} \log \sum_k |g_k|^2 + O(1)$, where the g_k generate $\mathcal{I}(mu)$. For $t > 0$ and $s > 1$,*

$$\mathcal{I}(sta_m) \subseteq \mathcal{I}(tu) \qquad \text{whenever} \qquad m \geq \frac{st}{s-1}.$$

Moreover, $u \preceq a_m$ locally, and hence $\mathcal{I}(tu) \subseteq \mathcal{I}(ta_m)$ for every $t > 0$.

Proof On a sufficiently small coordinate neighborhood, choose generators $g_1, \ldots, g_N$ of $\mathcal{I}(mu)$ and put $B = (\sum_k |g_k|^2)\mathrm{e}^{-mu}$. After shrinking the neighborhood, B is integrable and $a_m = m^{-1} \log \sum_k |g_k|^2 + O(1)$ with a bounded remainder. If $f \in \mathcal{I}(sta_m)$, shrink once more so that f is bounded and $A = |f|^2\mathrm{e}^{-sta_m}$ is integrable. Then, almost everywhere,

$$|f|^2\mathrm{e}^{-tu} \leq C|f|^{2-2/s} A^{1/s} B^{t/m}.$$

Hölder's inequality with exponents s and $s/(s-1)$ applies because $st/(m(s-1)) \leq 1$, and it shows that the left side is locally integrable, also in the case of equality in the bound for m. Finally, the local Bergman lower estimate of Proposition 1.14.1 gives $u \preceq a_m$ locally; bounded smooth corrections affect neither this comparison nor any of the ideals. □

1.15 The global curvature bound

We return to the compact manifold X with its Hermitian form ω. Demailly's global regularization theorem glues the local Bergman constructions while controlling the curvature error. We use it as a classical input in the following form.

Theorem 1.15.1 (Demailly regularization) *Let u be quasi-plurisubharmonic on X and let γ be a continuous real $(1,1)$-form with $\mathrm{dd^c}u \geq \gamma$. There are quasi-plurisubharmonic functions u_m, defined for all sufficiently large positive integers m, and numbers $\epsilon_m \downarrow 0$ such that*

(1) *u_m has analytic type $(1/m, \mathcal{I}(mu))$;*
(2) *$u_m \geq u$ and $u_m \to u$ pointwise and in $L^1(X)$;*
(3) *$\mathrm{dd^c}u_m \geq \gamma - \epsilon_m\omega$;*
(4) *$\max\{\nu(u,x) - n/m, 0\} \leq \nu(u_m, x) \leq \nu(u,x)$ for all x.*

The sequence (u_m) need not be monotone.

This is the form of [Dem11, Theorem 14.12] used in this book. The local generators in the construction are the weighted Bergman generators of $\mathcal{I}(mu)$; smooth local corrections do not change this ideal. On overlaps the local Bergman sums are comparable, so the glued logarithm keeps the analytic type $(1/m, \mathcal{I}(mu))$. The construction freezes the continuous lower bound γ on sufficiently small coordinate balls, and its curvature error combines the modulus of continuity of γ with an overlap term that tends to zero as m increases. It is this global curvature estimate, and not merely the local convergence of Proposition 1.14.1, that we take from the theorem.

Corollary 1.15.1 *Let θ be a smooth real $(1,1)$-form on X and $u \in \mathrm{PSH}(X,\theta)$. The approximants u_m of Theorem 1.15.1 for $\gamma = -\theta$ satisfy*

$$\theta + \mathrm{dd^c}u_m \geq -\epsilon_m\omega.$$

In particular, they have analytic type $(1/m, \mathcal{I}(mu))$.

Proof Apply Theorem 1.15.1 to u with the lower bound $\gamma = -\theta$; the theorem does not require γ to be closed. Adding θ to the curvature inequality gives the assertion. In the normalization of [Dem11], the theorem is applied to the potential $u/2$, since $\frac{\mathrm{i}}{\pi}\partial\bar\partial(u/2) = \mathrm{dd^c}u$. □

Thus the approximants keep the curvature lower bound up to an error that tends to zero. Their multiplier ideals determine the limit of their ordinary envelopes; see Theorem 16.5.1.

1.15.1 Regularization of closed currents

We also use the regularization of closed currents in the form recalled in [Xia]. Let $T = \eta + \mathrm{dd^c}v$ be a closed real $(1,1)$-current, where η is a smooth closed form and v is

quasi-plurisubharmonic, and set $\nu(T,x)=\nu(v,x)$. Suppose that $T\ge\gamma$ for a smooth real $(1,1)$-form γ. Smooth regularization gives smooth representatives $T_j=\eta+\mathrm{dd^c}v_j$ with

$$T_j\ge\gamma-C\lambda_j\omega,$$

where $C>0$ is a fixed constant and the continuous functions λ_j decrease pointwise to $\nu(T,\cdot)$. If all Lelong numbers of T vanish, Dini's theorem shows that $\lambda_j\to0$ uniformly, so the loss of positivity becomes uniformly small. Analytic regularization instead gives representatives S_j with analytic singularities and

$$S_j\ge\gamma-\varepsilon_j\omega,\qquad\varepsilon_j\downarrow0,\qquad\nu(S_j,x)\le\nu(T,x).$$

Thus analytic regularization preserves strict positivity up to a small loss and creates no positive Lelong number at a point where the Lelong number of T vanishes.

1.15.2 Smooth remainders after resolution

For arguments on a modification, the bounded remainder in an analytic presentation is sometimes insufficient. The following version of regularization gives a smooth remainder after resolution.

Theorem 1.15.2 (Demailly regularization) *Let α be a smooth real $(1,1)$-form and let $u\in\mathrm{PSH}(X,\alpha)$. There are numbers $\delta_j\downarrow0$ and functions $\widetilde{u}_j\in\mathrm{PSH}(X,\alpha+\delta_j\omega)$ decreasing to u with the following properties. Each $\widetilde{u}_j$ is smooth outside an analytic pole set, and there is a modification $\pi_j:Y_j\to X$, obtained by a finite sequence of blowups with smooth centers, such that locally on Y_j*

$$\pi_j^*\widetilde{u}_j=\sum_\ell a_\ell\log|s_\ell|^2+b,\qquad a_\ell>0,\quad b\in C^\infty.$$

Here the s_ℓ are local holomorphic defining functions of divisors, the $a_\ell>0$ are real numbers, and b is a smooth real function. The divisors may be taken to have simple normal crossings.

This classical theorem is applied to the closed current $\mathrm{dd^c}u$ with the smooth lower bound $-\alpha$; see Section 34.1 for its source. The lower bound need not be closed, and X need not be Kähler. What matters here is the smooth remainder b after resolution; an analytic type, whose remainder is merely bounded, would not suffice. The sequence $(\widetilde{u}_j)$ need not be the multiplier-ideal sequence of Theorem 1.15.1, and we do not claim that the conclusions of the two theorems hold for one and the same sequence. If $\theta+\mathrm{dd^c}u\ge\varepsilon\omega$ for some $\varepsilon>0$, applying the theorem with $\alpha=\theta-\varepsilon\omega$ and discarding the terms with $\delta_j\ge\varepsilon$ gives approximants with $\theta+\mathrm{dd^c}\widetilde{u}_j\ge(\varepsilon-\delta_j)\omega>0$; thus strict positivity is preserved.

1.16 Multiplier ideals and logarithmic poles

For a logarithmic pole along a submanifold, weighted integrability of a holomorphic germ is determined by its vanishing order in the normal directions. For general singularities, the valuative characterization of multiplier ideals and the strong openness theorem, both recalled in [Xia], make the comparison of multiplier ideals compatible with maxima, sums and increasing limits.

In local coordinates $(z, w) \in \mathbb{C}^d \times \mathbb{C}^k$, with $d \geq 0$ and $k \geq 1$, let $Y = \{w = 0\}$ and denote its ideal by $\mathcal{I}_Y$.

Lemma 1.16.1 *If a quasi-plurisubharmonic function has the form $u = c \log |w|^2 + O(1)$ with $c > 0$ and locally bounded remainder, then for every $t > 0$,*

$$\mathcal{I}(tu) = \mathcal{I}_Y^{\max\{\lfloor tc \rfloor - k + 1, 0\}}.$$

The zeroth power is the full structure sheaf.

Proof The bounded remainder changes the weight only by bounded positive factors. Expand a nonzero holomorphic germ $g(z, w)$ in homogeneous polynomials in w, and let a be the smallest degree whose term does not vanish identically. On smaller product neighborhoods, $|g(z, w)| \leq C|w|^a$. Hence $a + k > tc$ suffices for weighted integrability, since the corresponding radial integral in $\rho = |w|$ is

$$\int_0^{\varepsilon} \rho^{2a - 2tc + 2k - 1} \, \mathrm{d}\rho < +\infty.$$

Conversely, let z be a point near the origin at which the term of degree a does not vanish identically in w. Integration of $|g(z, w)|^2$ over the spheres $|w| = \rho$ gives a positive leading term of order ρ^{2a}, so the radial integral in w diverges when $a + k \leq tc$, logarithmically in the case of equality. Such points z form a nonempty open set in every sufficiently small neighborhood, and Fubini's theorem shows that g is not weighted-integrable near the origin. For $d = 0$ this is the radial calculation at a point. Thus g is weighted-integrable exactly when $a \geq \lfloor tc \rfloor - k + 1$, that is, when g lies in the power of $\mathcal{I}_Y$ given in the statement. □

Cutoff functions allow us to insert small isolated logarithmic poles into any Hermitian background.

Lemma 1.16.2 *Let ω be a Hermitian form on X, and fix distinct points $p_1, \dots, p_N$ of X. There are constants $C_j > 0$ such that, whenever $a_j > 0$ and $\sum_j C_j a_j < 1$, there is $u \in \mathrm{PSH}(X, \omega)$, smooth off these points, with*

$$u = a_j \log |z|^2 + O(1) \quad \text{near } p_j, \qquad \omega + \mathrm{dd}^{\mathrm{c}} u \geq \left(1 - \sum_j C_j a_j\right) \omega.$$

Here z denotes local coordinates centered at p_j. The function can be chosen to vanish outside arbitrarily small disjoint coordinate neighborhoods, with the constants depending on those neighborhoods.

Proof Choose disjoint coordinate balls centered at the points p_j and smooth cutoffs χ_j supported in them and equal to one near their centers. The function $\chi_j \log |z|^2$, extended by zero, is plurisubharmonic near its pole and smooth elsewhere, so its complex Hessian is bounded below by $-C_j\omega$. Set $u = \sum_j a_j \chi_j \log |z|^2$. These lower bounds give the asserted current inequality, and the remaining properties follow from the disjointness of the supports. □

Theorem 1.16.1 *Let u, v be plurisubharmonic functions near a point of $\mathbb{C}^n$. By a* local modification *we mean a modification π, with smooth source, of a neighborhood of this point.*

(1) *The inclusions $\mathcal{I}(ku) \subseteq \mathcal{I}(kv)$ for every real $k > 0$ are equivalent to the inequalities $\nu(u \circ \pi, y) \geq \nu(v \circ \pi, y)$ at every point y of the source of every local modification π. Likewise, equality of the multiplier ideals at every positive weight is equivalent to equality of all these Lelong numbers.*

(2) *If p_j is an increasing sequence of plurisubharmonic functions converging almost everywhere to a plurisubharmonic function p, then, for each point x and each $\lambda > 0$,*

$$\mathcal{I}(\lambda p_j)_x = \mathcal{I}(\lambda p)_x \quad \text{for all sufficiently large } j.$$

In the first item, the neighborhoods may be shrunk as necessary; we never need to extend a local modification to a modification of a compact manifold. The second item is the increasing-limit form of the strong openness theorem used in [Xia]. Since adding a smooth function changes neither multiplier ideals nor Lelong numbers, both items apply to quasi-plurisubharmonic functions after the local correction of Proposition 1.1.1.

Lemma 1.16.3 *Let u, u', v, v' be quasi-plurisubharmonic functions on X. For any quasi-plurisubharmonic h, one has*

$$u + h \sim_{\mathcal{I}} v + h \quad \Longleftrightarrow \quad u \sim_{\mathcal{I}} v.$$

If $u \sim_{\mathcal{I}} v$ and $u' \sim_{\mathcal{I}} v'$, then

$$\max(u, u') \sim_{\mathcal{I}} \max(v, v'), \qquad u + u' \sim_{\mathcal{I}} v + v', \qquad au \sim_{\mathcal{I}} av \quad (a > 0).$$

Proof Fix a coordinate neighborhood $U \subset X$ and a modification $\pi : Y \to U$ with smooth source. At every $y \in Y$, the elementary rules for the Lelong numbers of maxima, sums and positive multiples give

$$\begin{aligned} \nu(\max(u,u')\circ\pi, y) &= \min\{\nu(u\circ\pi, y), \nu(u'\circ\pi, y)\},\\ \nu((u+u')\circ\pi, y) &= \nu(u\circ\pi, y) + \nu(u'\circ\pi, y),\\ \nu(au\circ\pi, y) &= a\nu(u\circ\pi, y). \end{aligned}$$

These rules are unaffected by smooth local corrections. Since $u \sim_{\mathcal{I}} v$ and $u' \sim_{\mathcal{I}} v'$, the first item of Theorem 1.16.1 shows that the right-hand sides do not change when u, u' are replaced by v, v'. The converse direction of the same item, applied on each coordinate neighborhood, gives the three asserted equivalences.

For the cancellation rule, suppose that $u + h \sim_{\mathcal{I}} v + h$. By the first item of Theorem 1.16.1, the pullbacks $(u + h)\circ\pi$ and $(v + h)\circ\pi$ have the same Lelong numbers. The common summand $h \circ \pi$ is quasi-plurisubharmonic, so its Lelong numbers are finite, and subtracting them shows that $u \circ \pi$ and $v \circ \pi$ have the same Lelong numbers. Hence $u \sim_{\mathcal{I}} v$ by the same item. The reverse implication is the addition rule proved above. □

A residual with zero Lelong numbers can still be unbounded, but it does not change any multiplier ideal, even after addition to another potential.

Lemma 1.16.4 *Let q be quasi-plurisubharmonic on a complex manifold and suppose that $\nu(q, x) = 0$ at every point. Then e^{-tq} is locally integrable for every $t > 0$. For every quasi-plurisubharmonic v and every $t > 0$,*

$$\mathcal{I}\big(t(v + q)\big) = \mathcal{I}(tv).$$

Proof Fix a point x and add a smooth correction to make q plurisubharmonic on a bounded pseudoconvex coordinate neighborhood. Form the weighted Bergman space of Proposition 1.14.1 at weight t. If every member vanished at x, the Cauchy estimates, together with the local upper bound for q, would give

$$\sup_{\|g\|_t \le 1} |g(z)| \le C|z - x|$$

near x. Its Bergman potential would consequently have Lelong number at least $1/t$, contradicting (1.21). There is therefore a weighted square-integrable holomorphic function nonzero at x. On a smaller neighborhood it is bounded away from zero, so its weighted norm proves integrability of e^{-tq}. Smooth corrections do not change this conclusion. Thus $q \sim_{\mathcal{I}} 0$; the addition rule in Lemma 1.16.3 gives $v + q \sim_{\mathcal{I}} v$, which is precisely the asserted equality at every weight. □

Let v, w be quasi-plurisubharmonic functions on an open set, and let Y be a complex submanifold on which $v|_Y$ is not identically $-\infty$. The restriction and subadditivity theorems give the two inclusions recalled in [Xia] and [Dem11, Section 15]:

$$\mathcal{I}(v|_Y) \subseteq \mathcal{I}(v)\mathcal{O}_Y, \qquad \mathcal{I}(v+w) \subseteq \mathcal{I}(v)\mathcal{I}(w). \tag{1.22}$$

The first follows from the local Ohsawa–Takegoshi extension theorem. For the second, the weighted Hilbert space of holomorphic functions on a product is the Hilbert tensor product of the two weighted spaces, so the multiplier ideal of $v(x) + w(y)$ on the product is generated by products of generators of $\mathcal{I}(v)$ and $\mathcal{I}(w)$; the first inclusion, applied to the diagonal, then gives the second. These local results for plurisubharmonic functions extend to quasi-plurisubharmonic functions, in the weight convention of this book, by smooth corrections.

Multiplier ideals commute with pullback by holomorphic submersions. Here the extension $\mathcal{I}\mathcal{O}_Z$ of an ideal sheaf $\mathcal{I}$ on Y is the ideal sheaf on Z generated by the pullbacks of its local sections.

Lemma 1.16.5 *Let $p : Z \to Y$ be a holomorphic submersion of complex manifolds and let $u \in \mathrm{QPSH}(Y)$. For every $t > 0$,*

$$\mathcal{I}(tu \circ p) = \mathcal{I}(tu)\mathcal{O}_Z.$$

Proof Work in product coordinates (z, ζ) with $p(z, \zeta) = z$. Write α for a multi-index in the fiber variables and $\mathrm{d}\lambda_\zeta$ for their Euclidean volume. A germ in the ideal on the right is a finite sum of bounded holomorphic multiples of pullbacks of germs that are square integrable against $\mathrm{e}^{-tu(z)}$. Fubini's theorem shows that it is weighted-integrable on a sufficiently small product neighborhood.

Conversely, let $F(z, \zeta)$ be a weighted-integrable holomorphic germ and expand it in the fiber variables,

$$F(z, \zeta) = \sum_\alpha f_\alpha(z)\zeta^\alpha.$$

The coefficient estimate for a holomorphic function on a polydisk gives, on smaller product neighborhoods,

$$|f_\alpha(z)|^2 \le C_\alpha \int |F(z, \zeta)|^2 \, \mathrm{d}\lambda_\zeta.$$

Multiplying by $\mathrm{e}^{-tu(z)}$ and integrating in z shows that each coefficient germ f_α belongs to $\mathcal{I}(tu)$. Let J be the extension of this ideal to the local ring R of holomorphic germs on the product. Every finite Taylor sum of F belongs to J, and the remainder of total fiber degree at least N belongs to $(\zeta)^N$. Thus the class of F in R/J lies in $(\zeta)^N(R/J)$ for every N. By the Krull intersection theorem for the finitely generated module R/J over the Noetherian local ring R, the intersection of these submodules is zero. Hence $F \in J$. Smooth corrections and smooth positive volume densities do not change the integrability conditions. □

Example 1.16.1 Exact multiplier-ideal pullback can fail at a critical fiber. On a polydisk in $\mathbb{C}^n$, $n \geq 1$, let $f(z_0, \dots, z_{n-1}) = z_0^2$ and put $v(t) = \frac{1}{2}\log|t|^2$. At the origin,

$$\mathcal{I}(v) = \mathcal{O}, \qquad \mathcal{I}(v \circ f) = (z_0) \neq \mathcal{I}(v)\mathcal{O}.$$

Proof On the curve the coefficient is $1/2$, so the multiplier ideal is the zeroth power of the maximal ideal. Upstairs $v \circ f = \log|z_0|^2$ has coefficient one along the smooth divisor $\{z_0 = 0\}$. Apply Lemma 1.16.1 in codimension one to get its first ideal power. □

This calculation concerns a fixed weight. For a surjective holomorphic map from a connected compact manifold to a curve, with connected fibers, pullback still preserves and reflects all-weight ideal types by Corollary 1.22.1.

1.16.1 Weighted distance from a sum of multiplier ideals

Membership in a multiplier ideal is a local integrability condition. On a pseudoconvex domain one can ask, more quantitatively, how small the weighted norm of a holomorphic function can be made by subtracting global sections of such ideals. A sharp L^2 estimate answers this question for one weight. Applied successively, with the remaining weights kept in the auxiliary weight at each step, it gives a product bound for several weights.

Throughout this subsection, $\Omega \subset \mathbb{C}^n$ is a pseudoconvex domain, $n \geq 1$, and dV denotes Euclidean volume. For a plurisubharmonic weight ρ on Ω, put

$$\|f\|_\rho^2 = \int_\Omega |f|^2 e^{-\rho}\, dV.$$

For a plurisubharmonic function v on Ω, we write $\Gamma(\Omega, \mathcal{I}(v))$ for the space of holomorphic functions on Ω whose germs belong to $\mathcal{I}(v)$ at every point. Membership requires only local weighted integrability, not a finite global norm.

We first prove a division estimate with two summands. Its sharp constant comes from keeping the full sum of the twisting functions in the $\bar\partial$-estimate.

Lemma 1.16.6 *Let ψ, ϕ_1, ϕ_2 be plurisubharmonic functions on Ω, and suppose that $S = e^{\phi_1} + e^{\phi_2} < 1$. If f is holomorphic and*

$$J = \int_\Omega \frac{|f|^2 e^{-\psi}}{S^2}\, dV < +\infty,$$

then there are holomorphic F_1, F_2 with $F_1 + F_2 = f$ and

$$\int_\Omega \left(|F_1|^2 e^{-\phi_1} + |F_2|^2 e^{-\phi_2}\right) e^{-\psi}\, dV \leq J. \tag{1.23}$$

Proof *Step 1: a twisted $\bar\partial$-estimate.* Suppose first that Ω is bounded, that the weights are smooth on a neighborhood of $\overline{\Omega}$ with $S<1$ there, and that $\Phi=\log S$ is strictly plurisubharmonic. Set $\chi=\phi_1+\phi_2+\psi$ and $A=(\Phi_{j\bar k})$. For a $(0,1)$-form b, write $|b|_A^2$ for its squared norm with respect to the dual of this positive Hermitian matrix. We claim that every $\bar\partial$-closed $(0,1)$-form b for which the right-hand side below is finite admits a solution u of

$$\bar\partial u=b, \qquad \int |u|^2 \mathrm{e}^{\Phi-\chi}\,\mathrm{d}V \le \int (1-\mathrm{e}^{\Phi})|b|_A^2 \mathrm{e}^{-\chi}\,\mathrm{d}V. \tag{1.24}$$

To prove this, define for $x<0$

$$T(x)=-\log(1-\mathrm{e}^{x}), \qquad \eta(x)=\frac{-x}{1-\mathrm{e}^{x}}-1, \qquad \lambda(x)=-\frac{\eta'(x)}{T'(x)}.$$

The inequality $-x>1-\mathrm{e}^{x}$ gives $\eta>0$. Also $\eta'=-[1-(1-x)\mathrm{e}^{x}]/(1-\mathrm{e}^{x})^2<0$, whereas $T'>0$, so $\lambda>0$. Direct differentiation gives

$$\eta T'-\eta'=1, \qquad \eta T''-\eta''-\frac{(\eta')^2}{\lambda}=0, \qquad \frac{\mathrm{e}^{-T}}{\eta+\lambda}=\mathrm{e}^{x}.$$

Use the weight $h=\mathrm{e}^{-\chi-T(\Phi)}$ on the trivial line bundle and evaluate the twisting functions at Φ. The twisted curvature is

$$\begin{aligned} B_0 &= \eta\,\mathrm{i}\partial\bar\partial(\chi+T(\Phi))-\mathrm{i}\partial\bar\partial\eta-\mathrm{i}\lambda^{-1}\partial\eta\wedge\bar\partial\eta \\ &= \eta\,\mathrm{i}\partial\bar\partial\chi+\mathrm{i}\partial\bar\partial\Phi \ge \mathrm{i}\partial\bar\partial\Phi. \end{aligned}$$

Let Λ denote contraction by the Euclidean Kähler form and $\bar\partial_h^{*}$ the weighted adjoint. For a compactly supported $(n,1)$-form v, the twisted Bochner identity and the weighted Cauchy–Schwarz inequality give

$$\langle [B_0,\Lambda]v,v\rangle_h \le \|\sqrt{\eta+\lambda}\,\bar\partial_h^{*}v\|_h^2+\|\sqrt{\eta}\,\bar\partial v\|_h^2. \tag{1.25}$$

More explicitly, the cross term is bounded by $\lambda|\bar\partial_h^{*}v|^2+\lambda^{-1}|(\bar\partial\eta)^{*}v|^2$; the latter term is exactly the commutator contribution of $\mathrm{i}\lambda^{-1}\partial\eta\wedge\bar\partial\eta$. The terms of type $(n+1,1)$ vanish, and the remaining connection norm has a favorable sign.

The Hilbert space existence argument applied to (1.25) therefore gives

$$\int \frac{|u|^2 h}{\eta+\lambda}\,\mathrm{d}V \le \int |b|_A^2 h\,\mathrm{d}V.$$

To see the coefficient, project a test form to $\ker\bar\partial$. On this kernel the second term of (1.25) vanishes, and the Cauchy–Schwarz inequality in the curvature norm bounds the functional $v\mapsto\langle b,v\rangle_h$ by $(\int|b|_A^2h)^{1/2}\|\sqrt{\eta+\lambda}\,\bar\partial_h^{*}v\|_h$. The Riesz representation theorem gives a solution with the asserted norm. The twisting functions are bounded on Ω, since Φ is smooth and bounded away from both $-\infty$ and 0. The argument first uses a complete Kähler metric; approximating the Euclidean metric by the Euclidean

metric plus small positive multiples of a complete metric gives the Euclidean statement. Under the identification with canonical-bundle-valued forms, the $(n,0)$ norm integral and the curvature-dual $(n,1)$ integral have the same coordinate expressions as above. Since $h = \mathrm{e}^{-\chi}(1-\mathrm{e}^{\Phi})$, the identities for T, η, λ now give (1.24).

Step 2: division for smooth weights. Put $v_i = \mathrm{e}^{\phi_i}/S$ and $\ell = (v_1 f, v_2 f)$. Equip $\mathbb{C}^2$ with the diagonal metric $(\mathrm{e}^{-\phi_1}, \mathrm{e}^{-\phi_2})$. Then ℓ is orthogonal to the kernel line of the sum map, generated by $(1,-1)$, and $|\ell|^2 = |f|^2/S$. Write $\delta = \phi_1 - \phi_2$. The Hessian formula gives

$$A = v_1(\phi_{1,j\bar{k}}) + v_2(\phi_{2,j\bar{k}}) + v_1 v_2(\delta_j \overline{\delta_k}),$$
$$\bar{\partial}(v_1 f) = f v_1 v_2 \bar{\partial}\delta.$$

Thus $v_1 v_2 |\bar{\partial}\delta|_A^2 \le 1$ and, for $b = \bar{\partial}(v_1 f)$,

$$|b|_A^2 \mathrm{e}^{-\chi} \le \frac{|f|^2 \mathrm{e}^{-\psi}}{S^2}.$$

Solve (1.24) for this b and set $F = \ell - u(1,-1)$. Since $v_1 + v_2 = 1$, the vector $F = (F_1, F_2)$ is holomorphic and its components sum to f. The squared norm of $(1,-1)$ is $\mathrm{e}^{-\phi_1} + \mathrm{e}^{-\phi_2} = S\mathrm{e}^{-\phi_1-\phi_2}$. Orthogonality and (1.24) consequently give

$$\int |F|^2 \mathrm{e}^{-\psi} = \int \frac{|f|^2 \mathrm{e}^{-\psi}}{S} + \int |u|^2 \mathrm{e}^{\Phi-\chi}$$
$$\le \int \frac{|f|^2 \mathrm{e}^{-\psi}}{S^2}.$$

This proves (1.23) for smooth weights.

Step 3: general weights. Exhaust Ω by bounded pseudoconvex domains with compact closures in Ω. On each of them, convolve the weights on a slightly larger neighborhood and add a sufficiently small positive multiple of $|z|^2$. These smooth plurisubharmonic weights dominate the original weights, converge to them almost everywhere, preserve $S < 1$ on the chosen closure, and make Φ strictly plurisubharmonic. The corresponding integrals J are bounded by the original one. On every compact subset the weights have common upper bounds, so (1.23) gives uniform unweighted local L^2 bounds for both components. The holomorphic mean-value inequality and a diagonal extraction give holomorphic limits. Almost-everywhere convergence of the weights and Fatou's lemma yield (1.23) on Ω, and $F_1 + F_2 = f$ passes to the limit. □

Proposition 1.16.1 *Let ψ and ϕ be plurisubharmonic functions on Ω with $\phi < 0$, and let $p > 1$. For holomorphic f with $I = \|f\|^2_{\psi+\phi} < +\infty$, define*

$$c = \inf\{\|g\|^2_\psi : g \in \mathcal{O}(\Omega), \quad f - g \in \Gamma(\Omega, \mathcal{I}(p\phi + \psi))\}.$$

Then $c \le (1 - 1/p)I$.

Proof For $t > 0$, apply Lemma 1.16.6 with

$$\phi_1 = \log \frac{t}{1+t} + p\phi, \qquad \phi_2 = -\log(1+t).$$

Their exponential sum is $S = (1 + te^{p\phi})/(1+t) < 1$. The integral J of the lemma is finite, since $\|f\|^2_\psi \le I$ and $S \ge 1/(1+t)$. The first component F_1 belongs to $\Gamma(\Omega, \mathcal{I}(p\phi + \psi))$, so the second component $F_2 = f - F_1$ is admissible for c, and the norm estimate gives

$$\frac{c}{1+t} \le \int_\Omega \frac{|f|^2 e^{-\psi}}{(1+te^{p\phi})^2}\, dV.$$

Set $t = x^p$ and integrate over $x > 0$. With $\kappa_k = \int_0^\infty (1+x^p)^{-k}\, dx$, Tonelli's theorem and the change of variable $x \mapsto xe^\phi$ give $c\kappa_1 \le I\kappa_2$; the pole set of ϕ is Lebesgue null. Since $p > 1$, both integrals are finite, and integrating the derivative of $x/(1+x^p)$ over $(0,\infty)$ gives $\kappa_2 = (1 - 1/p)\kappa_1$. The argument does not require the infimum to be attained. □

Theorem 1.16.2 *Let ψ and $\phi_1, \dots, \phi_r$ be plurisubharmonic functions on Ω, with $r \ge 1$ and $\phi_i < 0$, and choose $p_i > 1$. For holomorphic f with*

$$I = \|f\|^2_{\psi + \sum_i \phi_i} < +\infty,$$

put

$$c = \inf\left\{ \|g\|^2_\psi : g \in \mathcal{O}(\Omega), \quad f - g \in \sum_{i=1}^r \Gamma(\Omega, \mathcal{I}(p_i\phi_i + \psi)) \right\}.$$

Then

$$c \le \prod_{i=1}^r \left(1 - \frac{1}{p_i}\right) I. \tag{1.26}$$

For $r \le n$, this constant is optimal for the stated class of data.

Proof Set $\psi_i = \psi + \sum_{j>i} \phi_j$, $a_i = 1 - 1/p_i$, and $f_0 = f$. For arbitrary $\varepsilon_i > 0$, Proposition 1.16.1 successively gives holomorphic f_i such that

$$\|f_i\|^2_{\psi_i} \le a_i \|f_{i-1}\|^2_{\psi_i + \phi_i} + \varepsilon_i,$$
$$f_{i-1} - f_i \in \Gamma(\Omega, \mathcal{I}(p_i\phi_i + \psi_i)).$$

Since $\psi_i \le \psi$, these ideals are contained in $\mathcal{I}(p_i\phi_i + \psi)$. As $f - f_r$ is the sum of the differences $f_{i-1} - f_i$, the function f_r is admissible for c. Moreover, $\psi_i + \phi_i = \psi_{i-1}$ for $i \ge 1$ and $\psi_r = \psi$, so iteration gives

$$c \le \left(\prod_i a_i\right) I + \sum_{i=1}^{r} \varepsilon_i \prod_{j>i} a_j .$$

Letting every ε_i tend to zero proves (1.26).

For sharpness when $r \le n$, take the unit polydisk $\Omega = \Delta^n$, $f = 1$, $\psi = 0$, and $\phi_i = p_i^{-1} \log |z_i|^2$ for $i \le r$. By Lemma 1.16.1, $\mathcal{I}(p_i\phi_i) = (z_i)$. Every admissible g equals one on $Y = \{z_1 = \cdots = z_r = 0\}$, hence $g(0) = 1$. Orthogonality of the monomials on the polydisk gives $\|g\|_0^2 \ge \pi^n$, with equality for $g = 1$. Direct radial integration gives $I = \pi^n \prod_i p_i/(p_i - 1)$, so equality holds in (1.26). □

The congruence condition in Theorem 1.16.2 involves a sum of global sections, and the successive remainders in its proof are global; a condition on a single germ would not produce them. The estimate holds for any number of weights, whereas the optimality assertion uses distinct coordinate directions and therefore requires $r \le n$.

1.16.2 The optimal constant in dimension one

In this subsection, $\Omega \subset \mathbb{C}$ is a pseudoconvex domain with Euclidean area $\mathrm{d}V$, and we use the weighted norms and spaces of global sections of Section 1.16.1. In one variable, every multiplier ideal is determined by vanishing orders at points. This allows us to combine the weights into a single one before applying the one-weight estimate, and leads to a better constant than the product bound.

Lemma 1.16.7 *For a subharmonic function u on Ω and $x \in \Omega$,*

$$\mathcal{I}(u)_x = (z - x)^{\lfloor \nu(u,x) \rfloor} \mathcal{O}_{\Omega,x}. \tag{1.27}$$

These ideals form a locally principal ideal sheaf.

Proof With the normalization of $\mathrm{dd^c}$ fixed in the conventions, $\mu = \mathrm{dd^c} u$ is a positive Radon measure and $a = \mu(\{x\}) = \nu(u, x)$. After removal of this atom, the distribution $u - a \log |z-x|^2$ has positive complex Hessian, so it has a subharmonic representative v, and $\mathrm{dd^c} v$ has no atom at x. Since subharmonic functions that agree almost everywhere agree everywhere,

$$u = a \log |z - x|^2 + v.$$

We claim that, for each $t > 0$, the function e^{-tv} is integrable on some neighborhood of x. Indeed, since $\mathrm{dd^c} v$ has no atom at x, there is a disk $D = D(x, R) \Subset \Omega$ with $M = (\mathrm{dd^c} v)(D) < 1/t$. On D write

$$v(z) = \int_D \log |z - y|^2 \, \mathrm{d}(\mathrm{dd^c} v)(y) + h(z),$$

where h is harmonic: the integral is locally integrable by Fubini's theorem and has complex Hessian $\mathrm{dd^c}v$ on D, so it differs from v by a harmonic distribution. If $M = 0$, the claim follows from harmonicity. For $M > 0$, Jensen's inequality for the probability measure $(\mathrm{dd^c}v)/M$ gives

$$\exp\left(-t\int_D \log|z-y|^2\,\mathrm{d}(\mathrm{dd^c}v)(y)\right) \le \frac{1}{M}\int_D |z-y|^{-2tM}\,\mathrm{d}(\mathrm{dd^c}v)(y).$$

Since $tM < 1$, the integral of $|z-y|^{-2tM}$ over $z \in D(x, R/2)$ is bounded uniformly in $y \in D$. The harmonic function h is bounded below on this smaller disk, so Tonelli's theorem proves the claim. (Truncating the logarithmic kernel justifies Jensen's inequality at its poles.)

A nonzero holomorphic germ of order k at x is a unit times $(z-x)^k$. Since v is locally bounded above, weighted integrability requires $k+1 > a$; equality is excluded by the logarithmic divergence of the radial integral. Conversely, if $k+1 > a$, choose $b > 1$ such that $b(a-k) < 1$. Then $|z-x|^{2k-2a}$ belongs locally to L^b, and e^{-v} belongs locally to $L^{b/(b-1)}$ by the claim, so Hölder's inequality proves integrability. Thus the germ belongs to $\mathcal{I}(u)_x$ exactly when $k \ge \lfloor a \rfloor$.

The points y with $\nu(u, y) \ge 1$ form a locally finite set, since each of them carries an atom of mass at least one of the locally finite measure $\mathrm{dd^c}u$. Near any point, therefore, the ideal sheaf is generated by a single power of a coordinate, which proves the last assertion. □

The distance condition below involves a sum of spaces of global sections. In one variable, this sum coincides with the space of global sections of the sum of the ideal sheaves.

Lemma 1.16.8 *If $u_1, \ldots, u_r$ are subharmonic functions on Ω, then*

$$\Gamma\left(\Omega, \sum_{i=1}^r \mathcal{I}(u_i)\right) = \sum_{i=1}^r \Gamma(\Omega, \mathcal{I}(u_i)). \tag{1.28}$$

Proof For $r = 1$ there is nothing to prove, so let $r \ge 2$. Put $J_i = \mathcal{I}(u_i)$ and $J = \sum_i J_i$. By Lemma 1.16.7, these sheaves are locally free of rank one. At each point, the order of J is the smallest of the orders of the J_i, and a local generator of an ideal J_i attaining this order also generates J. Consequently the sum map $\bigoplus_i J_i \to J$ is locally split, and its kernel E is a holomorphic vector bundle of rank $r-1$.

Fix $f \in \Gamma(\Omega, J)$. Gluing local holomorphic lifts of f with a smooth partition of unity gives a smooth section s of $\bigoplus_i J_i$ whose image is f. Since f is holomorphic, $\beta = \bar\partial s$ is an E-valued $(0,1)$-form. It suffices to solve $\bar\partial v = \beta$ for a section v of E, for then $s - v$ is a holomorphic lift of f.

We solve this equation using a bundle metric of positive curvature. Choose a smooth strictly subharmonic exhaustion function $\rho \ge 1$ of Ω. The Kähler metric

$$\omega_* = \mathrm{i}\,\mathrm{d}z \wedge \mathrm{d}\bar z + \mathrm{i}\partial\bar\partial\rho^2$$

is complete: it dominates $2\mathrm{i}\partial\rho\wedge\bar\partial\rho$, so ρ has bounded gradient with respect to it, and therefore every curve leaving all compact subsets has infinite length.

Equip E with a smooth Hermitian metric h. Choose a smooth increasing convex function χ on $[1,+\infty)$ so that the metric $h_\chi = h\mathrm{e}^{-\chi(\rho)}$ has

$$\mathrm{i}\Theta_{E,h_\chi}\geq\omega_*\,\mathrm{Id}_E,\qquad\int_\Omega|\beta|^2_{h_\chi,\omega_*}\,\mathrm{d}V_{\omega_*}<+\infty.$$

These two requirements can be imposed successively on the compact sublevel sets of ρ: increase χ' so that $\chi'(\rho)$ times the positive Hessian of ρ dominates the negative part of the curvature, and increase χ so that the integral over each shell $\{m\leq\rho<m+1\}$ is at most 2^{-m}. Increasing the slopes preserves the inequalities already achieved.

Use the global frame $\mathrm{d}z$ of the canonical bundle K_Ω to identify E-valued $(0,q)$-forms with $(E\otimes K_\Omega^{-1})$-valued $(1,q)$-forms, and give K_Ω^{-1} its flat coordinate metric. Its curvature is zero, and ω_* dominates the Euclidean metric, so the identified form β remains L^2. The Bochner–Kodaira inequality for compactly supported forms w of type $(1,1)$ gives

$$\|\bar\partial^*w\|^2\geq\langle[\mathrm{i}\Theta_{E,h_\chi},\Lambda_{\omega_*}]w,w\rangle\geq\|w\|^2.$$

Here we used that there are no $(1,2)$-forms. By completeness, cutoffs and smoothing extend this inequality to the domain of the adjoint. Since β is L^2, the Cauchy–Schwarz inequality bounds the functional $w\mapsto\langle w,\beta\rangle$ by $\|\beta\|\|\bar\partial^*w\|$, and the Riesz representation theorem gives a distributional solution v of $\bar\partial v=\beta$. Thus $s-v$ is distributionally holomorphic, hence holomorphic in every bundle chart, and it is the required global lift. No global weighted norm condition is imposed on its components. □

Theorem 1.16.3 *Let ψ and $\phi_1,\dots,\phi_r$ be subharmonic functions on Ω, with $r\geq1$ and $\phi_i<0$, and choose $p_i>1$. For holomorphic f with $I=\|f\|^2_{\psi+\sum_i\phi_i}<+\infty$, define*

$$c=\inf\left\{\|g\|^2_\psi:g\in\mathcal{O}(\Omega),\quad f-g\in\sum_{i=1}^r\Gamma(\Omega,\mathcal{I}(p_i\phi_i+\psi))\right\},\qquad s=\sum_{i=1}^r\frac{1}{p_i}.$$

Then

$$c\leq\max\{1-s,0\}\,I.\tag{1.29}$$

For every fixed choice of the exponents, this constant is optimal over the stated class of data. If $s\geq1$, the function $g=0$ is admissible.

Proof Put $J_i=\mathcal{I}(p_i\phi_i+\psi)$ and $J=\sum_iJ_i$. At a point x, write $A=\nu(\psi,x)$ and $B_i=\nu(\phi_i,x)$. By Lemma 1.16.7, the order of J_x is $\min_i\lfloor A+p_iB_i\rfloor$.

Suppose first that $s<1$, and put $P=1/s>1$. The numbers P/p_i sum to one, so

$$\min_i p_iB_i\leq\sum_i\frac{P}{p_i}p_iB_i=P\sum_iB_i.$$

Taking integer parts and using Lemma 1.16.7 gives $\mathcal{I}(P\sum_i \phi_i + \psi) \subseteq J$. By Lemma 1.16.8, every global section of this smaller ideal sheaf lies in $\sum_i \Gamma(\Omega, J_i)$, so every remainder admissible for the one-weight problem is admissible for c. Proposition 1.16.1 with $\phi = \sum_i \phi_i$ and $p = P$ therefore gives $c \le (1-1/P)I = (1-s)I$.

Now let $s \ge 1$. Since $I < +\infty$, we have $f \in \Gamma(\Omega, \mathcal{I}(\psi + \sum_i \phi_i))$. If $f \equiv 0$ there is nothing to prove; otherwise let k be its order at x. Then $k + 1 > A + \sum_i B_i$. If its germ did not belong to J_x, we would have $k + 1 \le A + p_i B_i$ for every i. With $L = k + 1 - A > 0$, this would give $\sum_i B_i \ge sL \ge L$, a contradiction. Hence $f \in \Gamma(\Omega, J)$, and Lemma 1.16.8 shows that $g = 0$ is admissible.

For sharpness when $s < 1$, take the unit disk, $\psi = 0$, $f = 1$, and $\phi_i = p_i^{-1}\log|z|^2$. Then $J_i = (z)$ for all i, so an admissible g has $g(0) = 1$. Orthogonality of the monomials on the disk gives $c = \pi$, attained by $g = 1$, whereas $I = \pi/(1 - s)$. If $s \ge 1$, keep these weights and take $f = z^q$ with an integer $q \ge 0$ satisfying $q + 1 > s$. Then $I = \pi/(q + 1 - s) > 0$ and $c = 0$, so the constant 0 cannot be replaced by a negative number. □

Consequently, for $r \ge 2$ the product constant of Theorem 1.16.2 is not optimal on plane domains. The argument above relies on all local ideals being principal; it does not determine the optimal constant when $n \ge 2$ and $r > n$.

1.16.3 Distance for several hyperplane weights

In this subsection, $n \ge 2$, $B \subset \mathbb{C}^n$ is the unit ball, and dV is Euclidean volume. If the weights have logarithmic poles along several hyperplanes through the origin, every admissible remainder must take a prescribed value at their common zero. On the other hand, the input norm stays finite as long as the combined radial exponent is below the dimension. Together these observations give a positive distance even in part of the range where the planar distance of Theorem 1.16.3 vanishes.

Example 1.16.2 Fix $r > n$ and $p > r/n$. There are negative plurisubharmonic functions $\phi_1, \ldots, \phi_r$ on B for which

$$I = \int_B \mathrm{e}^{-\sum_i \phi_i}\, \mathrm{d}V < +\infty$$

and

$$\inf\left\{ \int_B |g|^2\, \mathrm{d}V : g \in \mathcal{O}(B), \quad 1 - g \in \sum_{i=1}^{r} \Gamma(B, \mathcal{I}(p\phi_i)) \right\} = \frac{\pi^n}{n!} > 0. \qquad (1.30)$$

In particular, for $r/n < p \le r$, the distance is positive although $\sum_i 1/p = r/p \ge 1$.

Proof Choose distinct real numbers $t_1, \ldots, t_r$ and unit linear forms

$$\ell_i(z) = \frac{\sum_{k=0}^{n-1} t_i^k z_{k+1}}{(\sum_{k=0}^{n-1} t_i^{2k})^{1/2}}.$$

Any n of these forms are linearly independent, since the determinant of their unnormalized coefficients is a nonzero Vandermonde determinant. Put $\phi_i = p^{-1} \log |\ell_i|^2$. Since the coefficient vectors of the ℓ_i have norm one, $|\ell_i(z)| < 1$ on B, so the ϕ_i are negative plurisubharmonic functions. By Lemma 1.16.1, $\mathcal{I}(p\phi_i) = (\ell_i)$.

At a nonzero point, at most $n-1$ of the forms vanish. These forms are linearly independent and can be used as part of a holomorphic coordinate system, while the other forms are bounded away from zero on a small neighborhood of the point. Hence

$$W(z) = \prod_{i=1}^{r} |\ell_i(z)|^{-2/p}$$

is locally integrable off the origin, because each factor $|\ell_i|^{-2/p}$ has exponent $2/p < 2$ (note that $p > r/n > 1$). By compactness, W is integrable on every closed annulus. Set $s = r/p$ and let $\mathrm{d}\sigma$ denote surface measure on the unit sphere. Homogeneity and polar integration over such an annulus show that

$$A = \int_{|\zeta|=1} \prod_i |\ell_i(\zeta)|^{-2/p}\, \mathrm{d}\sigma(\zeta) < +\infty.$$

Tonelli then gives

$$I = A \int_0^1 \rho^{2n-1-2s}\, \mathrm{d}\rho = \frac{A}{2(n-s)} < +\infty,$$

since $s < n$. This takes care of the common zero at the origin as well as of the individual hyperplanes.

Every global section of (ℓ_i) vanishes at the origin. Thus every admissible g in (1.30) satisfies $g(0) = 1$. For each $z \in B$, the holomorphic function $\lambda \mapsto g(\lambda z)$ is defined on a disk of radius greater than one, and the submean inequality for the

subharmonic function $|g(\lambda z)|^2$ gives

$$\frac{1}{2\pi}\int_0^{2\pi} |g(e^{i\tau}z)|^2\,d\tau \geq |g(0)|^2 = 1.$$

Integrating in z and using the rotation invariance of B proves $\int_B |g|^2\,dV \geq \mathrm{Vol}(B) = \pi^n/n!$, also when the integral is infinite. The constant $g = 1$ is admissible and attains this bound. □

Hence, for these equal exponents, the optimal universal constant in an estimate of the distance by a multiple of I is at least $\pi^n/(n!I) > 0$. In particular, the vanishing of the optimal constant for $s \geq 1$ in Theorem 1.16.3 does not extend to higher dimensions. The example does not determine the optimal constant for $r > n$.

1.17 Lelong numbers and divisorial estimates

Lelong numbers measure the logarithmic concentration of a positive current. Along a divisor, a lower bound for the generic Lelong number allows us to subtract the corresponding multiple of the divisor without losing positivity. At points, the local mass formula controls Lelong numbers under convergence and uniformly in a fixed background. For a prime divisor E on a complex manifold, $[E]$ denotes its current of integration, and $\nu(w, E)$ is the generic Lelong number along E of a quasi-plurisubharmonic function w, as defined in Section 1.13.

We use the following local consequence of Siu's decomposition theorem, recalled in [Xia] and [Dem11]. If T is a closed positive $(1,1)$-current and E is a prime divisor, the restriction of (the coefficient measures of) T to E equals the generic Lelong number of T along E times $[E]$. In particular, removing finitely many of these divisorial components from T leaves a positive current. Distinct prime divisors do not contribute overlapping mass, since their intersections have codimension at least two. All these are local statements about closed currents.

Lemma 1.17.1 *Let M be a complex manifold, let β be a smooth real $(1,1)$-form on M, let $w \in \mathrm{PSH}(M,\beta)$, and let $E_1, \ldots, E_N$ be distinct prime divisors on M, with $N \geq 1$. Then*

$$\beta + dd^c w - \sum_{j=1}^{N} \nu(w, E_j)[E_j] \geq 0.$$

The form β need not be closed.

Proof Work on a coordinate ball and choose a smooth function ρ with $dd^c\rho \geq \beta$. The current

$$T = dd^c(w + \rho) = (\beta + dd^c w) + (dd^c\rho - \beta)$$

is closed and positive. A smooth form, viewed through its coefficient measures, assigns zero mass to every proper analytic set. Thus T and $\beta + dd^c w$ have the same

restriction to $\bigcup_j E_j$, and the consequence of Siu's theorem stated above identifies this restriction with $\sum_j \nu(w, E_j)[E_j]$. Subtracting it from the positive current $\beta + \mathrm{dd}^{\mathrm{c}} w$ leaves the restriction of $\beta + \mathrm{dd}^{\mathrm{c}} w$ to the complement of $\bigcup_j E_j$, which is positive. This proves the inequality locally, hence globally. Note that $\beta + \mathrm{dd}^{\mathrm{c}} w$ itself need not be closed. □

Order makes the support theorem a rigidity statement for potentials: two ordered quasi-plurisubharmonic functions whose Hessians agree outside an analytic set already differ by a constant.

Lemma 1.17.2 *Let $u \le v$ be quasi-plurisubharmonic on a connected compact complex manifold X, and let $Z \subsetneq X$ be analytic. If $\mathrm{dd}^{\mathrm{c}} u = \mathrm{dd}^{\mathrm{c}} v$ on $X \setminus Z$, then $v = u + C$ for a real constant C.*

Proof The current $S = \mathrm{dd}^{\mathrm{c}}(v-u)$ is real, closed, of order zero and supported on Z. By the support theorem in [Dem12, Chapter III, Corollaries 2.11 and 2.14, pp. 141–143],

$$S = \sum_{j=1}^{m} c_j [Z_j], \qquad c_j = \nu(v, Z_j) - \nu(u, Z_j) \le 0, \tag{1.31}$$

where Z_j are the prime divisorial components of Z. Indeed, the support theorem first gives real constants c_j such that $S - \sum_j c_j [Z_j]$ is supported in codimension at least two; this closed current of order zero then vanishes by the same theorem. Near a generic smooth point of Z_j, with local equation $z_1 = 0$, the function $v - u - c_j \log |z_1|^2$ has zero complex Hessian and is therefore smooth and pluriharmonic. This identifies c_j with the difference of the generic Lelong numbers, and $c_j \le 0$ because $u \le v$.

Thus $\mathrm{dd}^{\mathrm{c}}(u - v) = -S \ge 0$. Hence the locally integrable distribution $u - v$ has a global plurisubharmonic representative, which is constant by the maximum principle on the compact connected manifold X. Since quasi-plurisubharmonic functions that agree almost everywhere agree everywhere, $v = u + C$ for a constant C. □

Every closed real $(1,1)$-current is the sum of a smooth closed form and the complex Hessian of a global distribution, and positivity of the current makes this potential quasi-plurisubharmonic. This decomposition allows us to attach an ordinary singularity type to a divisorial current.

Lemma 1.17.3 *Let Z be a complex manifold and T a closed real $(1,1)$-current on Z. There are a smooth closed real $(1,1)$-form β and a real distribution v such that*

$$T = \beta + \mathrm{dd}^{\mathrm{c}} v.$$

If $T \ge 0$, then v is quasi-plurisubharmonic. Any two distributional potentials in such decompositions differ by a smooth function.

Proof The local dd^{c}-Poincaré lemma gives real distributional potentials v_i on the sets of a cover of Z by coordinate neighborhoods, with $T = \mathrm{dd}^{\mathrm{c}} v_i$; for positive T these potentials are plurisubharmonic. See [Dem12, Chapter III, Section 1.18 and

Proposition 1.19]. On overlaps $\mathrm{dd}^{\mathrm{c}}(v_i - v_j) = 0$. Taking the Euclidean trace shows that $v_i - v_j$ is a harmonic distribution, so it is smooth by elliptic regularity.

Choose a smooth locally finite partition of unity (χ_i) subordinate to the cover and put $v = \sum_i \chi_i v_i$, each term being extended by zero as a distribution. On the jth neighborhood,

$$v - v_j = \sum_i \chi_i (v_i - v_j)$$

is smooth. Thus $\beta = T - \mathrm{dd}^{\mathrm{c}} v = -\mathrm{dd}^{\mathrm{c}}(v - v_j)$ is smooth on each neighborhood, hence on Z, and it is real and closed. For positive T, the same identity expresses v locally as a plurisubharmonic function plus a smooth function. Finally, if $T = \beta + \mathrm{dd}^{\mathrm{c}} v = \beta' + \mathrm{dd}^{\mathrm{c}} v'$ are two such decompositions, then $\mathrm{dd}^{\mathrm{c}}(v - v') = \beta' - \beta$ is smooth; taking a smooth Hermitian trace and applying elliptic regularity shows that $v - v'$ is smooth. □

For a potential whose complex Hessian is a divisorial current minus a smooth form, ordinary domination, ideal domination and the corresponding inequalities for generic Lelong numbers along the divisors are all equivalent. Countably many divisors are allowed, provided the divisorial current has finite mass.

Lemma 1.17.4 *Let Y be a connected compact complex manifold. Let (D_j) be a finite or countable family of distinct prime divisors on Y and $c_j > 0$ real coefficients such that $S = \sum_j c_j [D_j]$ is a positive current of finite mass, and let β be a smooth real $(1,1)$-form on Y. Let $v \in \mathrm{QPSH}(Y)$ satisfy*

$$\mathrm{dd}^{\mathrm{c}} v = S - \beta.$$

Then, for $a \in \mathrm{QPSH}(Y)$, the following conditions are equivalent:

$$a \preceq v, \qquad a \preceq_{\mathcal{I}} v, \qquad \nu(a, D_j) \geq c_j \quad \text{for every } j.$$

Proof We first note that $\nu(v, D_j) = c_j$. Indeed, the restriction of S to D_j is $c_j [D_j]$: distinct divisors intersect in codimension at least two, and such sets carry no mass of any divisor current, also after countable summation. Smooth forms give every divisor zero mass. The local form of Siu's decomposition, applied after a smooth correction, therefore gives $\nu(v, D_j) = c_j$.

Ordinary domination implies ideal domination by Proposition 1.12.2, and ideal domination implies the asserted inequalities for generic Lelong numbers by Theorem 1.16.1. It remains to prove that these inequalities imply ordinary domination.

Choose a Hermitian form Λ with $a \in \mathrm{PSH}(Y, \Lambda)$. By Lemma 1.17.1 and the inequalities $\nu(a, D_j) \geq c_j$, each finite partial sum of S can be subtracted from $\Lambda + \mathrm{dd}^{\mathrm{c}} a$ without losing positivity. Letting the partial sums increase to S gives

$$\Lambda + \mathrm{dd}^{\mathrm{c}} a - S \geq 0.$$

Consequently $\mathrm{dd}^{\mathrm{c}}(a - v) \geq \beta - \Lambda$. Hence the integrable function $a - v$ has a quasi-plurisubharmonic representative, which is bounded above on the compact manifold Y. This yields $a \leq v + C$ almost everywhere, and Lemma 1.3.3 extends this inequality everywhere. Thus $a \preceq v$. □

Together, the two preceding lemmas attach a canonical ordinary singularity type to a countable divisorial current of finite mass.

Corollary 1.17.1 *Let Z be a connected compact complex manifold, let (D_j) be a finite or countable family of distinct prime divisors on Z, and let $c_j > 0$. Suppose that $S = \sum_j c_j [D_j]$ is a closed positive current of finite mass. Then there are quasi-plurisubharmonic functions v on Z satisfying*

$$\mathrm{dd}^{\mathrm{c}} v = S - \beta$$

for a smooth closed real $(1,1)$-form β, and any two such functions differ by a smooth function. In particular, they determine a canonical ordinary singularity type, which depends only on S.

Proof Lemma 1.17.3, applied to $T = S$, gives the decomposition, with v quasi-plurisubharmonic since $S \geq 0$, and shows that any two such potentials differ by a smooth function. By Proposition 1.12.1, they have the same ordinary singularity type. □

Lemma 1.17.5 *Let u_j, u be quasi-plurisubharmonic functions on a complex manifold with a common smooth lower curvature bound, that is, $\mathrm{dd}^{\mathrm{c}} u_j \geq -\beta$ and $\mathrm{dd}^{\mathrm{c}} u \geq -\beta$ for one smooth real $(1,1)$-form β. If $u_j \to u$ in L^1_{loc}, then at every point x,*

$$\nu(u, x) \geq \limsup_j \nu(u_j, x).$$

Proof On a coordinate ball about x, add one smooth function to all the potentials to make them plurisubharmonic, and write p_j, p for the resulting functions. Let n be the dimension and κ the Euclidean form of the chart. Distributional convergence gives weak convergence of the positive trace measures $\mathrm{dd}^{\mathrm{c}} p_j \wedge \kappa^{n-1}$ to $\mathrm{dd}^{\mathrm{c}} p \wedge \kappa^{n-1}$. For every sufficiently small radius r such that the sphere of radius r about x has zero mass for the limit measure, the masses of the balls converge. The Lelong monotonicity formula bounds each $\nu(p_j, x)$ by the normalized trace mass of p_j on such a ball. Taking the upper limit in j, and then letting these radii decrease to zero, gives $\limsup_j \nu(p_j, x) \leq \nu(p, x)$. Since smooth additions do not change Lelong numbers, this proves the lemma. □

Lemma 1.17.6 *Let Z be a connected compact complex manifold and let β be a smooth real $(1,1)$-form. There is a finite constant C_β such that*

$$\nu(v, z) \leq C_\beta \qquad \text{for every } v \in \mathrm{PSH}(Z, \beta) \text{ and every } z \in Z.$$

In particular, the generic Lelong numbers of all $v \in \mathrm{PSH}(Z, \beta)$ along all prime divisors are bounded by C_β. No normalization of the potentials is needed.

Proof Since adding a constant does not change Lelong numbers, we may assume that $\sup_Z v = 0$. By Theorem 1.4.1, these normalized potentials have a common L^1 bound. Cover Z by finitely many triples of concentric coordinate balls, a smaller, an intermediate and a larger one, such that the smaller balls cover Z. On each larger

ball choose a fixed smooth quadratic function r with $\mathrm{dd^c} r \geq \beta$, so that $p = v + r$ is plurisubharmonic there. The functions p obtained in this way have uniformly bounded local L^1 norms.

Write $d = \dim Z$ and let κ be the Euclidean form in the chart. Choose a nonnegative smooth cutoff χ supported in the larger ball and equal to one on an intermediate ball. Positivity and distributional integration by parts give

$$\int_{\text{intermediate ball}} \mathrm{dd^c} p \wedge \kappa^{d-1} \leq \int \chi \, \mathrm{dd^c} p \wedge \kappa^{d-1} = \int p \, \mathrm{dd^c} \chi \wedge \kappa^{d-1} \leq C \|p\|_{L^1}.$$

Every point of the smaller ball is the center of a Euclidean ball of a fixed radius contained in the intermediate ball. The local Lelong monotonicity formula, recalled in [Xia], bounds the Lelong number at this center by a fixed multiple of the trace mass of the intermediate ball. The finite cover gives one bound on Z. Since smooth additions and additive constants do not change Lelong numbers, this proves the assertion for the original potentials. □

The Bergman estimates also control Lelong numbers on a fixed local modification. A *local divisor over* X is a prime divisor E on the source of a local modification $\pi : Z \to U$ of a coordinate neighborhood $U \subset X$, that is, a modification with smooth source Z. For a quasi-plurisubharmonic function u on X, let $\nu(u \circ \pi, E)$ be the generic Lelong number of $u \circ \pi$ along E. For a holomorphic function or an ideal sheaf, ord_E denotes the generic vanishing order along E (for an ideal, the minimum of the orders of its local generators). Let $\mathrm{Jac}\, \pi$ be the holomorphic Jacobian determinant of π in local coordinates. Write

$$\nu_E(u) = \nu(u \circ \pi, E), \qquad A_U(E) = 1 + \mathrm{ord}_E(\mathrm{Jac}\, \pi).$$

The second number is the *log discrepancy* of E. Local modifications are not required to extend over the compact manifold.

Lemma 1.17.7 *For a quasi-plurisubharmonic function u on X, every local divisor E over X, and every real $m > 0$, one has*

$$\max\left\{\nu_E(u) - \frac{A_U(E)}{m}, 0\right\} \leq \frac{1}{m} \mathrm{ord}_E \mathcal{I}(mu) \leq \nu_E(u).$$

Here $\mathrm{ord}_E \mathcal{I}(mu)$ is the order along E of the pulled-back ideal. Consequently, if locally $a_m = m^{-1} \log \sum_k |f_{m,k}|^2 + O(1)$, where the $f_{m,k}$ generate $\mathcal{I}(mu)$, then $\nu_E(a_m) \to \nu_E(u)$ as $m \to \infty$.

Proof The upper estimate follows from the local Bergman lower bound in Proposition 1.14.1: the logarithm of the sum of squared moduli of local generators of $\mathcal{I}(mu)$, divided by m, is at least u up to a locally bounded term. Pulling back and taking generic Lelong numbers along E reverses this inequality.

For the lower estimate, take a local generator f of the ideal and set $k = \mathrm{ord}_E(f \circ \pi)$. Near a generic point of E, choose a local coordinate z_1 defining E. Divisorial removal (Lemma 1.17.1), after a smooth correction, gives

$$u \circ \pi \le \nu_E(u) \log |z_1|^2 + C.$$

Shrink around a point where the factors of $f \circ \pi$ and of the Jacobian complementary to the powers of z_1 do not vanish. The change-of-variables formula and local integrability of $|f|^2 \mathrm{e}^{-mu}$ then require integrability in z_1 of

$$|z_1|^{2(k+A_U(E)-1-m\nu_E(u))}.$$

This implies $k + A_U(E) > m\nu_E(u)$, and in particular the weaker non-strict lower bound in the statement. Taking the minimum over a finite set of local generators and using that orders are nonnegative proves the lower estimate. Since $\nu_E(a_m) = m^{-1} \operatorname{ord}_E \mathcal{I}(mu)$, the last assertion follows by letting $m \to \infty$. □

For rational $m > 0$, the function a_m has analytic singularities in the sense of Section 1.13; the estimate for real m does not require this.

Blowing up a point converts the divisorial estimate into a pointwise order bound on any local modification.

Lemma 1.17.8 *Let U be a complex manifold of dimension n, let u be quasi-plurisubharmonic on U, and let $\pi : Y \to U$ be a modification with smooth source. Fix $y \in Y$ and an integer $m \ge 1$. Write J_π for the holomorphic Jacobian in local coordinates near y. If a nonzero holomorphic germ g at $\pi(y)$ belongs to $\mathcal{I}(mu)$, then*

$$\operatorname{ord}_y(g \circ \pi) \ge m\nu(u \circ \pi, y) - n - \operatorname{ord}_y J_\pi.$$

Proof If $n \ge 2$, let $\rho : \widetilde{Y} \to Y$ be the blowup of y and let E be its exceptional divisor. For $n = 1$, take ρ to be the identity and $E = \{y\}$. Set $F = \pi \circ \rho$ and write J_F for its local holomorphic Jacobian determinant. Generic orders along E give

$$\nu(u \circ F, E) = \nu(u \circ \pi, y), \qquad \operatorname{ord}_E(g \circ F) = \operatorname{ord}_y(g \circ \pi).$$

On a standard blowup chart the Jacobian of ρ has order $n - 1$ along E. The chain rule therefore gives the log discrepancy over U as

$$A_U(E) = 1 + \operatorname{ord}_E J_F = n + \operatorname{ord}_y J_\pi.$$

Since $g \in \mathcal{I}(mu)$, the order of $g \circ F$ along E is at least the order of this ideal. The lower estimate in Lemma 1.17.7, applied to F, therefore proves the inequality. □

Lemma 1.17.9 *Let v be quasi-plurisubharmonic on X, and let a have analytic singularities on X. If $v \preceq_{\mathcal{I}} a$, then $v \preceq a$. More precisely, it suffices to assume the finitely many inequalities*

$$\nu(v \circ \pi, E) \ge \nu(a \circ \pi, E)$$

for the prime components E of the divisor obtained by principalizing, on one log resolution π, the ideal of an analytic presentation of a.

Proof Principalize the coherent ideal of an analytic presentation of a by a log resolution $\pi : Y \to X$ with smooth Y. In suitable local coordinates $z_1, \dots, z_n$ on Y,

$$a \circ \pi = \sum_{i=1}^{r} b_i \log |z_i|^2 + B, \qquad b_i \geq 0, \qquad B \in L^\infty_{\mathrm{loc}},$$

where $r \leq n$. The finitely many inequalities in the statement give $\nu(v \circ \pi, \{z_i = 0\}) \geq b_i$; if $v \preceq_{\mathcal{I}} a$, these inequalities follow from Theorem 1.16.1. Add a smooth local function to $v \circ \pi$ to make it plurisubharmonic. Divisorial removal for this closed positive complex Hessian shows that

$$v \circ \pi - \sum_i b_i \log |z_i|^2$$

has a quasi-plurisubharmonic representative; here the difference is first interpreted off the divisor, or as a locally integrable distribution. Such a representative is locally bounded above. Since B is locally bounded, $v \circ \pi \leq a \circ \pi + C$ on each relatively compact chart of Y, away from the divisor. Since π is proper, finitely many such charts cover the inverse image of a smaller coordinate neighborhood in X, which makes C uniform there. Push the inequality down off the analytic exceptional set; as quasi-plurisubharmonic functions are determined by their values almost everywhere, it then holds everywhere. Finitely many neighborhoods cover the compact manifold, so $v \leq a + C$ globally.

The only input from resolution of singularities is the principalization of a coherent ideal. Divisorial removal is applied to the closed positive complex Hessian obtained after a local smooth correction, so no closed background on X is needed. □

Lemma 1.17.10 *Let u, v be quasi-plurisubharmonic on X, and let s have analytic singularities on X. Suppose that $u + v \leq s + O(1)$, and let U_m, V_m be quasi-plurisubharmonic functions of analytic types $(1/m, \mathcal{I}(mu))$ and $(1/m, \mathcal{I}(mv))$. Then there are numbers $\delta_m \downarrow 0$ such that*

$$U_m + V_m \leq (1 - \delta_m)s + O(1) \quad \textit{for all sufficiently large integers } m.$$

The bounded error may depend on m.

Proof If s is bounded, upper bounds for U_m and V_m give the assertion with $\delta_m = 1/m$ for $m > 1$. Otherwise principalize the ideal of s by a log resolution $\pi : \widetilde{X} \to X$ with smooth $\widetilde{X}$. Let E_i be the components of the resulting divisor, with positive coefficients c_i in $s \circ \pi$; in local coordinates z_i defining these components, the singular part of $s \circ \pi$ is $\sum_i c_i \log |z_i|^2$. Set $A_i = 1 + \mathrm{ord}_{E_i}(\mathrm{Jac}\, \pi)$. The hypothesis and Lemma 1.17.7 give

$$\nu(U_m \circ \pi, E_i) + \nu(V_m \circ \pi, E_i) \geq \nu(u \circ \pi, E_i) + \nu(v \circ \pi, E_i) - \frac{2A_i}{m} \geq c_i - \frac{2A_i}{m}.$$

Choose a positive integer $N \geq \max_i 2A_i/c_i$ and put $\delta_m = N/m$, which is less than one for large m. Then the right-hand side above is at least $(1-\delta_m)c_i$. After a smooth local correction, divisorial removal from the positive Hessian of $(U_m + V_m)\circ\pi$ shows that

$$(U_m + V_m)\circ\pi - (1-\delta_m)\sum_i c_i \log|z_i|^2$$

has a quasi-plurisubharmonic representative, which is locally bounded above. A finite cover of $\widetilde{X}$ by charts and descent along the proper map π, as in the proof of Lemma 1.17.9, therefore give $U_m + V_m \leq (1-\delta_m)s + O(1)$. The bounded constant may depend on m. □

1.18 Potential regularity and metric distance

A Hölder modulus of continuity of the potential controls the trace mass of a positive current on small balls. Averaging the lengths of segments against this trace measure then bounds the distance of the metric defined by the current on its regular locus. This turns regularity of the potential into a metric estimate without any pointwise bound on the Hessian.

Let $U \subset \mathbb{C}^n$ be a coordinate domain with Euclidean form $\omega_{\mathrm{E}} = \mathrm{dd^c}|z|^2$ and Euclidean volume $\mathrm{d}\lambda$. Let $0 < \alpha \leq 1$, let θ be a smooth real $(1,1)$-form on U, and let $v \in C^{0,\alpha}(U)$ satisfy $T = \theta + \mathrm{dd^c}v \geq 0$. Write $\mu = T \wedge \omega_{\mathrm{E}}^{n-1}$ for the trace measure of T.

Theorem 1.18.1 *For every open set $V \Subset U$ there are constants $C, r_0 > 0$ such that*

$$\mu(B(x,r)) \leq C r^{2n-2+\alpha}, \qquad x \in V, \quad 0 < r < r_0. \tag{1.32}$$

The total variation of every coefficient measure of T is bounded by a constant multiple of μ. Hence the coefficient measures of T vanish on sets of zero Hausdorff $(2n-2+\alpha)$-measure, and all Lelong numbers of v vanish. The estimate implies neither absolute continuity of μ nor a pointwise bound for the Hessian of v.

Suppose in addition that T is a smooth Hermitian form η on $U \setminus A$ for a proper analytic subset $A \subset U$. For $x, y \in U \setminus A$, let $d_\eta^U(x,y)$ be the infimum of the η-lengths of piecewise smooth paths in $U \setminus A$ joining x and y. Then every point of U has a neighborhood $V \Subset U$ such that, for a constant C,

$$d_\eta^U(x,y) \leq C|x-y|^{\alpha/2}, \qquad x, y \in V \setminus A. \tag{1.33}$$

In particular, all sequences in $V \setminus A$ converging to a given point of $A \cap V$ are Cauchy for d_η^U and have a common limit in the metric completion. If these local hypotheses hold in charts covering X, with a proper analytic subset $A \subset X$ and a Hermitian form η on $X \setminus A$, then the metric completion of $X \setminus A$ for its intrinsic η-distance is compact, and the identity of $X \setminus A$ extends to a continuous surjection of X onto it. The metric η is incomplete when $A \neq \varnothing$. Both exponents in (1.32) and (1.33) are sharp.

Proof Choose a nonnegative cutoff function χ equal to one on $B(x,r)$ and supported in $B(x,2r)$, with second derivatives bounded by Cr^{-2}. Positivity and integration by parts, after subtracting the constant $v(x)$ from v, give

$$\mu(B(x,r)) \le C_1 r^{2n} + C_2 r^{2n-2} \operatorname{osc}_{B(x,2r)} v \le C r^{2n-2+\alpha}.$$

Here we used that the constant $v(x)$ integrates to zero against $\mathrm{dd^c}\chi \wedge \omega_{\mathrm{E}}^{n-1}$. The matrix (a_{ij}) of Radon–Nikodym derivatives of the coefficient measures with respect to μ is positive semidefinite almost everywhere, so $|a_{ij}| \le (a_{ii} + a_{jj})/2$. A ball cover proves the assertion about Hausdorff null sets. After a smooth local correction making v plurisubharmonic, dividing (1.32) by r^{2n-2} shows that all Lelong numbers vanish.

For the distance estimate, let $m = 2n$ and let τ be the Euclidean trace of η. Then $\tau \, \mathrm{d}\lambda \le C\mu$ on the regular locus and $|\xi|_\eta \le C\sqrt{\tau}|\xi|_{\mathrm{E}}$ for tangent vectors ξ. Polar integration bounds the average η-length of the segments from x to the points of $B(x,R)$ by a constant times $\int_{B(x,R)} \sqrt{\tau}(\zeta)|\zeta - x|^{1-m} \, \mathrm{d}\lambda(\zeta)$. On a dyadic annulus of radius s, the Cauchy–Schwarz inequality and (1.32) bound the contribution to this integral by $Cs^{1-m}s^{m/2}s^{(m-2+\alpha)/2} = Cs^{\alpha/2}$. Summing over the annuli gives the bound $CR^{\alpha/2}$.

Now let $x, y \in V \setminus A$, and average the lengths of the broken segments $[x,z] \cup [z,y]$ over z in the ball of radius $|x-y|/2$ about the midpoint of x and y. By the preceding bound, some such path has length at most $C|x-y|^{\alpha/2}$. For almost every z, both segments avoid A: proper analytic sets are locally countable unions of smooth strata of real codimension at least two, and the cones from a fixed regular point over these strata have zero volume. If V is small enough, all these paths stay inside U.

By this estimate, all regular sequences converging to a point of A have a common limit in the completion, and the identity of the regular locus extends continuously across A. By compactness, the image of this extension is the entire completion; different points of A may be identified. A sequence converging to a point of A cannot converge in the metric to a regular point, since η is bounded below by a positive multiple of the Euclidean metric on a small closed neighborhood of that point. Hence the metric η is incomplete when A is nonempty. Finally, the local model $v = |z|^\alpha + |w|^2$, in coordinates $(z,w) \in \mathbb{C} \times \mathbb{C}^{n-1}$, has trace mass of exact order $r^{2n-2+\alpha}$ on balls centered on $\{z=0\}$, and the distance to $\{z=0\}$ is of exact order $|z|^{\alpha/2}$; this proves both sharpness claims. In later applications to potentials with logarithmic poles, the theorem is applied to the positive residual current that remains after the divisorial part has been removed. □

1.18.1 Dini moduli and limits of distances

The annular argument of Theorem 1.18.1 also applies to a continuous potential whose modulus of continuity is not a power; what matters is a Dini condition on the square

root of the modulus. This gives uniform distance estimates for families whose Hölder constants are not controlled.

Keep the coordinate domain $U \subset \mathbb{C}^n$ with its Euclidean form ω_{E} and volume $\mathrm{d}\lambda$, but now let $v \in C^0(U)$ and let θ be a smooth real $(1,1)$-form with $T = \theta + \mathrm{dd}^{\mathrm{c}} v \geq 0$. On the relatively compact charts under consideration, choose a nondecreasing function $m : (0, r_0) \to [0, +\infty)$ with $m(r) \to 0$ as $r \to 0$ such that

$$|v(x) - v(y)| \leq m(|x - y|), \qquad |x - y| < r_0.$$

Put

$$D(r) = r + \int_0^r \frac{\sqrt{m(t)}}{t}\, \mathrm{d}t. \tag{1.34}$$

Theorem 1.18.2 *Assume that $D(r_0/2) < +\infty$ and that T is a smooth Hermitian form η on $U \setminus A$ for a proper analytic subset $A \subset U$. Then every point of U has a neighborhood $V \Subset U$ with constants $C, r_1 > 0$ such that, for $x, y \in V$,*

$$d_\eta^U(x, y) \leq C D(8|x - y|), \qquad x, y \notin A, \quad |x - y| < r_1.$$

The constants depend only on the charts and an upper bound for $|\theta|$; the dependence on v enters only through D. All sequences in $V \setminus A$ converging to a given point of $A \cap V$ have a common limit in the metric completion. If these hypotheses hold on a finite cover of a compact connected manifold by charts, the metric completion of the regular locus is compact, and the identity of the regular locus extends to a continuous surjection of the manifold onto it. If A is nonempty, the metric η on the regular locus is incomplete.

Proof Write $d = 2n$ and $\mu = T \wedge \omega_{\mathrm{E}}^{n-1}$. The same cutoff calculation as in Theorem 1.18.1, with a constant subtracted from v, gives

$$\mu(B(x, s)) \leq C\big(s^d + s^{d-2} m(2s)\big).$$

This uses only the bound for θ; closedness of θ is not needed. If τ is the Euclidean trace of η, then $\tau\, \mathrm{d}\lambda \leq C\mu$ on the regular locus. Polar integration bounds the average length of the segments from a regular point x to the points of $B(x, R)$ by

$$C \int_{B(x,R)} \sqrt{\tau(\zeta)}\, |\zeta - x|^{1-d}\, \mathrm{d}\lambda(\zeta).$$

On an annulus of outer radius s, the Cauchy–Schwarz inequality and the trace bound make the contribution to this integral at most

$$C s^{1-d} s^{d/2} \big(s^d + s^{d-2} m(2s)\big)^{1/2} \leq C\big(s + \sqrt{m(2s)}\big).$$

For $s_j = 2^{-j} R$, monotonicity gives

$$\sum_{j\ge 0}\sqrt{m(2s_j)}\le\frac{1}{\log 2}\int_0^{4R}\frac{\sqrt{m(t)}}{t}\,\mathrm{d}t.$$

Indeed, $\sqrt{m(2s_j)}\log 2$ is at most the integral of $\sqrt{m(t)}/t$ over $[2s_j,4s_j]$, and these intervals have disjoint interiors; no doubling condition on m is needed. The average length is therefore at most $CD(4R)$.

For $x,y\in V\setminus A$, average the lengths of the broken segments $[x,z]\cup[z,y]$ over z in the ball of radius $|x-y|/2$ about the midpoint of x and y, applying the preceding bound with $R=2|x-y|$ at each endpoint. Since the volume of this ball is comparable to R^d, some broken path has length at most $CD(8|x-y|)$. As in the proof of Theorem 1.18.1, almost every such path avoids A, and for small V it stays inside U.

Since $D(r_0/2)<+\infty$, we have $D(r)\to 0$ as $r\to 0$. Hence any two regular sequences converging to the same point are Cauchy and have the same limit in the completion. The argument for the completion in the proof of Theorem 1.18.1 applies with this modulus. A positive lower bound for η near a regular point prevents a sequence converging to a point of A from converging in the metric to the regular point. This also proves incompleteness when A is nonempty. □

Corollary 1.18.1 *In the setting of Theorem 1.18.2, let V be as in the theorem. For $0<\beta\le 1$, a modulus $m(r)\le Cr^{\beta}$ gives $d_\eta^U(x,y)\le C'|x-y|^{\beta/2}$ for sufficiently close $x,y\in V\setminus A$. If instead*

$$m(r)\le C(-\log r)^{-a},\qquad a>2,$$

then for sufficiently close $x,y\in V\setminus A$,

$$d_\eta^U(x,y)\le C'(-\log|x-y|)^{1-a/2}.$$

These are only sufficient conditions; we do not claim that the Dini condition is necessary.

Proof Integrating the square root of the power modulus gives a multiple of $r^{\beta/2}$. For the logarithmic modulus, the substitution $s=-\log t$ gives

$$\int_0^r\frac{(-\log t)^{-a/2}}{t}\,\mathrm{d}t=\frac{(-\log r)^{1-a/2}}{a/2-1}.$$

In either case the term r in $D(r)$ is bounded by the asserted rate for small r. The theorem now gives both estimates; the fixed dilation of the argument of D changes only the constants. □

Corollary 1.18.2 *Let ω_0 be a Hermitian form on X and d_{ω_0} the distance of the associated Riemannian metric. For each j, let $T_j = \theta_j + \mathrm{dd}^{\mathrm{c}} v_j \geq 0$, where θ_j is a smooth real $(1,1)$-form, v_j is continuous, and T_j is a smooth Hermitian form off a proper analytic subset A_j. Assume*

$$|\theta_j|_{\omega_0} \leq \Lambda, \qquad |v_j(x) - v_j(y)| \leq m(d_{\omega_0}(x,y)),$$

with one fixed Λ and one nondecreasing modulus m tending to zero such that the function in (1.34) satisfies $D(r_0/2) < +\infty$. By Theorem 1.18.2, the identity of $X \setminus A_j$ extends to a continuous surjection of X onto the metric completion of $X \setminus A_j$; let d_j be the pseudometric on X obtained by pulling back the completed distance. Then the diameters of the d_j are uniformly bounded, and a subsequence converges uniformly on $X \times X$ to a continuous pseudometric. If $T_j \geq c\omega_0$ on the regular loci for one $c > 0$, the limit is a metric and dominates $\sqrt{c}\, d_{\omega_0}$.

Proof A finite fixed chart cover and the theorem give common constants $C, r_1 > 0$ such that

$$d_j(x,y) \leq C D(C d_{\omega_0}(x,y)), \qquad d_{\omega_0}(x,y) < r_1.$$

For a pair meeting A_j, approximate it by regular pairs in the manifold topology. The completed distance and D are continuous, so the same estimate holds for all such pairs in $X \times X$. No uniform bound on the geometry of the analytic sets enters the constants. Dividing a minimizing geodesic of d_{ω_0} into a uniformly bounded number of short pieces and using the triangle inequality gives a uniform diameter bound. The triangle inequality also gives

$$|d_j(x,y) - d_j(x',y')| \leq d_j(x,x') + d_j(y,y'),$$

so the distance functions are equicontinuous. The Arzelà–Ascoli theorem gives a subsequence d_{j_k} converging uniformly on $X \times X$ to a function d_∞. Nonnegativity, symmetry, vanishing on the diagonal and the triangle inequality pass to the limit. The lower bound $T_j \geq c\omega_0$ gives $d_j \geq \sqrt{c}\, d_{\omega_0}$, first for regular pairs and then for all pairs, which proves the last assertion.

Without this lower bound the limit may degenerate. For $\varepsilon_j \downarrow 0$, take $\theta_j = \varepsilon_j \omega_0$ and $v_j = 0$, with $A_j = \varnothing$. These data satisfy the hypotheses with $m(r) = r^2$, and $d_j = \sqrt{\varepsilon_j}\, d_{\omega_0}$ converges uniformly to zero. □

1.19 Obstacle envelopes

Given an obstacle function, one looks for the largest θ-plurisubharmonic function lying below it. The local upper-envelope theorem constructs this envelope as soon as the competitors have a common upper bound, and normalized compactness provides such a bound for an obstacle that is finite almost everywhere or prescribed on a non-pluripolar compact set. Letting the obstacles $\min(u + C, 0)$ increase with C produces the envelope $P_\theta[u]$ of the ordinary singularity type of u.

A smooth real $(1,1)$-form θ is called *big* if there are $\rho \in \mathrm{PSH}(X,\theta)$ and $\delta > 0$ such that

$$\theta + \mathrm{dd^c}\rho \geq \delta\omega.$$

Here ω is any Hermitian form; changing it changes δ but not the condition. The definition does not require θ to be closed.

Let θ be a smooth real $(1,1)$-form. For an extended-real function f on X, defined at least outside a pluripolar set (the *obstacle*), write

$$P_\theta(f) = \left(\sup\{v \in \mathrm{PSH}(X,\theta) : v \leq f \text{ q.e.}\}\right)^* .$$

As in Section 1.6, q.e. (quasi-everywhere) means outside a pluripolar set. The functions v in the supremum are called *competitors*; the empty supremum is $-\infty$. For obstacles $f_1, \ldots, f_N$, we write $P_\theta(f_1, \ldots, f_N) = P_\theta(\min_i f_i)$; when the f_i belong to $\mathrm{PSH}(X,\theta)$, this is their *rooftop envelope*. For an upper semicontinuous obstacle, the pointwise constraint $v \leq f$ gives the same competitors: by the local submean inequality and upper semicontinuity of f, a quasi-plurisubharmonic function lying below f almost everywhere lies below it everywhere.

If the family of competitors is nonempty and uniformly bounded above, then $P_\theta(f) \in \mathrm{PSH}(X,\theta)$. To apply the local upper-envelope theorem while keeping the exact lower bound $-\theta$, fix a constant positive form κ in local coordinates. For each $\epsilon > 0$, shrink the coordinate neighborhood and choose a constant form θ' with $-\epsilon\kappa \leq \theta - \theta' \leq \epsilon\kappa$. A smooth function r with $\mathrm{dd^c} r = \theta' + \epsilon\kappa$ makes every competitor plus r plurisubharmonic, so the local envelope theorem gives $\theta + \mathrm{dd^c} P_\theta(f) \geq -2\epsilon\kappa$ there. Letting ϵ tend to zero proves the exact bound. The same local theorem shows that the regularization changes the supremum only on a pluripolar set.

The following observation gives the upper bound for an unbounded obstacle. Suppose that $f \leq A$, for a real constant A, on a Borel set E with $\mathrm{Vol}(E) = \int_E \mathrm{d}V > 0$, where $\mathrm{d}V$ is the volume form fixed in Theorem 1.4.1. If h is a competitor, put $\widetilde{h} = h - \sup_X h$. By Theorem 1.4.1,

$$(\sup_X h - A)\,\mathrm{Vol}(E) \leq \int_E |\widetilde{h}|\,\mathrm{d}V \leq C_\theta \quad \text{whenever } \sup_X h > A.$$

Thus $\sup_X h \leq A + C_\theta/\mathrm{Vol}(E)$ for every competitor. In particular, the competitors for a measurable obstacle that is finite almost everywhere have a common upper bound: apply this to a sublevel set $\{f \leq A\}$ of positive volume.

An obstacle bound on a non-pluripolar compact set also bounds every competitor globally, even when that set has zero smooth volume.

Lemma 1.19.1 *Let θ be a smooth real $(1,1)$-form on X, let $K \subseteq X$ be compact and non-pluripolar, and let $w \in C(K,\mathbb{R})$. There is a constant $C = C(\theta, K, w)$ such that every $a \in \mathrm{PSH}(X,\theta)$ satisfying $a \leq w$ quasi-everywhere on K has $\sup_X a \leq C$.*

Proof Otherwise there are such functions a_j with

$$M_j := \sup_X a_j \geq 2^j + \max_K w.$$

The normalized functions $v_j = a_j - M_j \le 0$ have uniformly bounded L^1 norms by Theorem 1.4.1. Choose $A > 0$ with $\theta \le A\omega$. The partial sums

$$s_N = \sum_{j=1}^{N} 2^{-j} v_j$$

decrease, have uniformly bounded L^1 norms, and satisfy $\mathrm{dd^c} s_N \ge -A\omega$. By Corollary 1.4.1, their limit s is a quasi-plurisubharmonic function; in particular, s is not identically $-\infty$.

Let $N_j \subseteq K$ be a pluripolar set outside which $a_j \le w$ on K. On $K \setminus \bigcup_j N_j$ one has $v_j \le -2^j$ for every j, hence $s = -\infty$. The pole set $\{s = -\infty\}$ of the quasi-plurisubharmonic function s is pluripolar, and so is the countable union of the N_j. Their union would contain all of K, contradicting the hypothesis on K. □

Suppose that $\mathrm{PSH}(X, \theta)$ is nonempty. Then the envelope of the zero obstacle,

$$V_\theta = P_\theta(0),$$

belongs to $\mathrm{PSH}(X, \theta)$: the competitors are bounded above by zero, and they include $u - \sup_X u$ for every $u \in \mathrm{PSH}(X, \theta)$. In particular,

$$u - \sup_X u \le V_\theta \qquad (u \in \mathrm{PSH}(X, \theta)).$$

A potential $v \in \mathrm{PSH}(X, \theta)$ has *minimal singularities* if $u \preceq v$ for every $u \in \mathrm{PSH}(X, \theta)$. By the last inequality, V_θ has minimal singularities, and every potential v with minimal singularities satisfies $v \sim V_\theta$. If $\theta \ge 0$, then 0 is a competitor, and hence $V_\theta = 0$.

Lemma 1.19.2 *Let η be a smooth semipositive real $(1,1)$-form on X. If an obstacle f is finite almost everywhere and bounded below quasi-everywhere by a constant, then $P_\eta(f)$ is a bounded η-plurisubharmonic function.*

Proof Since $\eta \ge 0$, constants are η-plurisubharmonic, so the constant lower bound of f is a competitor. The finite-sublevel argument above gives a common upper bound for all competitors. Hence $P_\eta(f)$ is an η-plurisubharmonic function lying between these two constants. □

Proposition 1.19.1 *If $f \in C^0(X)$, then $P_\omega(f)$ is continuous. Moreover,*

$$\|P_\omega(f) - P_\omega(g)\|_\infty \le \|f - g\|_\infty \quad (f, g \in C^0(X)).$$

Proof The constant $\min_X f$ is a competitor, so $p = P_\omega(f)$ is bounded. The local envelope theorem gives $p \le f$ quasi-everywhere, and continuity of f makes this inequality hold everywhere. By Theorem 1.11.1, there are smooth ω-plurisubharmonic functions $v_j \downarrow p$. Fix $\epsilon > 0$. The continuous functions $v_j - f$ decrease to a function that is at most zero, so $v_j \le f + \epsilon$ everywhere for all large j; otherwise the decreasing compact sets $\{v_j - f \ge \epsilon\}$ would have nonempty intersection. Hence $v_j - \epsilon$ is a competitor, and

$$p \le v_j \le p + \epsilon.$$

Thus $v_j \to p$ uniformly, which proves continuity. The last inequality follows from the monotonicity of P_ω in the obstacle and the identity $P_\omega(g + c) = P_\omega(g) + c$ for constants c, applied with $c = \|f - g\|_\infty$. □

Definition 1.19.1 For $u \in \mathrm{PSH}(X, \theta)$, set

$$P_\theta[u] = \left(\lim_{C \to +\infty} P_\theta(u + C, 0) \right)^* = \left(\sup\{h \in \mathrm{PSH}(X, \theta) : h \preceq u,\ h \le 0\} \right)^*.$$

We call u an *envelope fixed point*, or an *ordinary model*, if $P_\theta[u] = u$; in the Kähler literature such potentials are called *model potentials*. For $F \in C^\infty(X, \mathbb{R})$, replacing the constraint $h \le 0$ by $h \le F$ defines $P_{\theta,F}[u]$.

The two expressions agree, because the family in the second one is the increasing union over C of the families defining $P_\theta(u + C, 0)$. They do not change if zero is replaced by V_θ, since every θ-plurisubharmonic function below zero lies below V_θ. The competitors include $u - \sup_X u$ and are bounded above by zero, so $P_\theta[u] \in \mathrm{PSH}(X, \theta)$ and $u - \sup_X u \le P_\theta[u] \le 0$. In particular, $u \preceq P_\theta[u]$; this does not assert that $P_\theta[u] - u$ is bounded.

Directly from the definition, $P_\theta[u]$ depends only on the ordinary singularity type of u, and

$$u \preceq v \quad \Longrightarrow \quad P_\theta[u] \le P_\theta[v].$$

Replacing the condition $h \preceq u$ by $h \sim_{\mathcal{I}} u$ gives the multiplier-ideal envelope $P_\theta[u]_{\mathcal{I}}$ of Definition 16.2.1. This is a different operator; its relation to $P_\theta[u]$ is studied in Chapter 16.

For a bounded obstacle in a big background, exceptional sets in the competitor inequality can be removed by a small singular perturbation.

Lemma 1.19.3 *Let θ be big, let f be a bounded function on X, and let $u \in \mathrm{PSH}(X, \theta)$ satisfy $u \le f$ quasi-everywhere. Then there are $u_t \in \mathrm{PSH}(X, \theta)$, $t > 0$, such that $u_t \le f$ everywhere and $u_t \to u$ almost everywhere as $t \downarrow 0$.*

Proof Choose $\rho \in \mathrm{PSH}(X,\theta)$ with $\theta + \mathrm{dd}^{\mathrm{c}}\rho \geq \kappa\omega$ for some $\kappa > 0$. The exceptional set $E = \{u > f\}$ is pluripolar. The global form of Josefson's theorem on compact complex manifolds gives a quasi-plurisubharmonic function χ with $\chi = -\infty$ on E; see [Xia, Theorem 1.1.5]. After rescaling and adding a constant, we may assume that $\chi \leq 0$ and $\mathrm{dd}^{\mathrm{c}}\chi \geq -\omega$. Subtract a constant from ρ so that $\rho \leq \inf_X f$. With $s = t/\kappa$, put

$$u_t = \frac{u + t\chi + s\rho}{1+s}.$$

All three functions in the numerator are finite almost everywhere, so u_t is not identically $-\infty$. Moreover,

$$\theta + \mathrm{dd}^{\mathrm{c}}u_t = \frac{\theta + \mathrm{dd}^{\mathrm{c}}u + t\mathrm{dd}^{\mathrm{c}}\chi + s(\theta + \mathrm{dd}^{\mathrm{c}}\rho)}{1+s} \geq 0.$$

Outside E, both u and ρ are at most f, while $\chi \leq 0$, so $u_t \leq f$. On E the numerator is $-\infty$. Finally, $u_t \to u$ wherever all three functions are finite, which is a set of full measure. □

For an obstacle prescribed only on a compact set, the same perturbation shows that pluripolar exceptions in the constraint do not change the regularized envelope.

Proposition 1.19.2 *Let θ be big, let $K \subseteq X$ be compact and non-pluripolar, and let ψ be a bounded real function on K. Set*

$$R = \sup\{u \in \mathrm{PSH}(X,\theta) : u \leq \psi \text{ on } K\},$$
$$Q = \sup\{u \in \mathrm{PSH}(X,\theta) : u \leq \psi \text{ q.e. on } K\}.$$

Then $R^* = Q^*$ belongs to $\mathrm{PSH}(X,\theta)$ and has minimal singularities; it is bounded if $\theta \geq 0$. Moreover, this regularized envelope does not change if the pointwise constraint is imposed only on $K \setminus E$, for any pluripolar subset $E \subseteq K$.

Proof Put $m = \inf_K \psi$ and $M = \sup_K \psi$. Since θ is big, $\mathrm{PSH}(X,\theta)$ is nonempty, and $V_\theta \leq 0$; hence $V_\theta + m$ belongs to the family defining R. Applying Lemma 1.19.1 with the constant obstacle M gives a common upper bound C for the larger family defining Q. The upper-envelope argument at the beginning of Section 1.19 therefore shows that R^* and Q^* belong to $\mathrm{PSH}(X,\theta)$.

Now fix a competitor u for Q and define a bounded function on X by

$$f(x) = \begin{cases} \psi(x), & x \in K, \\ \max\{\sup_X u, M\}, & x \notin K. \end{cases}$$

Then $u \leq f$ quasi-everywhere. By Lemma 1.19.3, there are $u_t \in \mathrm{PSH}(X,\theta)$ satisfying $u_t \leq f$ everywhere and $u_t \to u$ almost everywhere. Each u_t is a competitor for R, so $R^* \geq u$ almost everywhere, and Lemma 1.3.3 gives this inequality everywhere. Taking the supremum over u and regularizing yields $R^* \geq Q^*$; the inclusion of the competitor families gives the reverse inequality.

Write $F = R^* = Q^*$. Since $F \leq C$, the potential $F - C$ is a competitor for V_θ. Thus

$$V_\theta + m \le F \le V_\theta + C,$$

which proves minimal singularities and, when $\theta \ge 0$, boundedness.

Finally, if $E \subseteq K$ is pluripolar, the family constrained on $K \setminus E$ lies between the families defining R and Q, so its regularized supremum also equals F. Note that this argument uses the upper bound obtained from the compact set K, even when $K \setminus E$ is not compact. □

A potential with minimal singularities stays away from the poles of a strictly positive potential with analytic singularities, in the following sense.

Lemma 1.19.4 *Let $\rho \in \mathrm{PSH}(X, \theta)$ have analytic singularities with smooth remainder and satisfy $\theta + \mathrm{dd^c}\rho \ge \varepsilon\omega$ for some $\varepsilon > 0$. Set $\Omega = \{\rho > -\infty\}$. If $\varphi \in \mathrm{PSH}(X, \theta)$ has minimal singularities and is continuous on Ω, then $\varphi - \rho$ is continuous, bounded below, and proper on Ω: all its sublevel sets are compact in Ω.*

Proof Adding constants to ρ and φ does not affect the assertions, so we may assume that $\rho \le 0$ and $\sup_X \varphi = 0$. Since φ has minimal singularities, there is a constant C with $\varphi \ge V_\theta - C$. Choose $M \ge 0$ with $\theta \ge -M\omega$. If $a \in (0,1)$ is sufficiently close to one, then

$$\theta + \mathrm{dd^c}(a\rho) = a(\theta + \mathrm{dd^c}\rho) + (1-a)\theta \ge \big(a\varepsilon - (1-a)M\big)\omega > 0.$$

Thus $a\rho$ is a competitor for V_θ, and therefore

$$0 \ge \varphi \ge V_\theta - C \ge a\rho - C,$$

and hence

$$\varphi - \rho \ge (1-a)(-\rho) - C. \tag{1.35}$$

By hypothesis φ is continuous on Ω, and ρ is smooth there because it has analytic singularities with smooth remainder. Hence $\varphi - \rho$ is continuous on Ω, and by (1.35) it is bounded below. Since $\rho \to -\infty$ at $X \setminus \Omega$, the sets $\{\rho \ge -c\}$ are compact subsets of Ω, and (1.35) places every sublevel set of $\varphi - \rho$ in one of them. Being closed in Ω, each sublevel set is therefore compact. □

1.19.1 A hyperplane Green envelope on the ball

For a logarithmic pole along a hyperplane section of the unit ball, the envelope can be computed explicitly by restricting to the complex lines normal to the hyperplane. The example also shows how envelopes of bounded obstacles recover the finite part of a logarithmic pole, and that continuity inside the domain does not imply continuity up to the boundary.

In this subsection let $n \ge 2$, let $m \ge 1$ be an integer, and write

$$B = \{(\zeta, w) \in \mathbb{C} \times \mathbb{C}^{n-1} : |\zeta|^2 + |w|^2 < 1\}, \qquad D = B \cap \{\zeta = 0\}.$$

Define G_m as the pointwise supremum of the functions $u \in \mathrm{PSH}(B)$ such that $u \le 0$ and, near every point of D, $u \le m \log|\zeta|^2 + C$ for some local constant C. In particular, $u = -\infty$ on D. The constants need not stay bounded as the point of D approaches ∂B.

Proposition 1.19.3 *The envelope G_m is given by*

$$G_m(\zeta, w) = m \log \frac{|\zeta|^2}{1 - |w|^2}. \tag{1.36}$$

It is plurisubharmonic and continuous on B with values in $[-\infty, 0)$. The finite part $G_m - m \log|\zeta|^2$, first defined off D, extends smoothly across D as the plurisubharmonic function

$$H_m(w) = -m \log(1 - |w|^2).$$

Proof The function $-\log(1 - |w|^2)$ is smooth and plurisubharmonic on $|w| < 1$: its complex Hessian is

$$\left(\frac{\delta_{jk}}{1 - |w|^2} + \frac{\overline{w}_j w_k}{(1 - |w|^2)^2} \right)_{j,k}.$$

Thus the right-hand side of (1.36) is plurisubharmonic; it is negative on B and satisfies the pole condition, so it is a competitor. For the reverse inequality, fix a competitor u and a point w with $|w| < 1$. The restriction $u(\cdot, w)$ is either identically $-\infty$ or subharmonic on the disk of radius $R = (1 - |w|^2)^{1/2}$. In the latter case, $u(\zeta, w) - m \log|\zeta|^2$ is subharmonic on the punctured disk and, by the pole condition, bounded above near zero, so it extends as a subharmonic function across zero.

Since $u \le 0$, this extension is at most $-m \log r^2$ on every circle $|\zeta| = r < R$. The maximum principle and then $r \uparrow R$ give

$$u(\zeta, w) \le m \log \frac{|\zeta|^2}{R^2}.$$

On D both sides are $-\infty$. Taking the supremum over u proves the formula. Near a point of D, the function H_m is bounded and the logarithmic term tends to $-\infty$, which proves continuity there as an extended-real function. □

For a finite continuous obstacle Φ on B, put

$$P_B\Phi = \left(\sup\{v \in \mathrm{PSH}(B) : v \le \Phi\}\right)^*.$$

The local upper-envelope theorem used in Section 1.19 applies whenever this family is nonempty and locally uniformly bounded above. Continuity of Φ ensures that the regularized envelope still satisfies $P_B\Phi \le \Phi$.

Proposition 1.19.4 *For $t > 0$, define*

$$\Phi_t(\zeta, w) = \min\{-m \log |\zeta|^2, t\}, \qquad V_t = P_B \Phi_t,$$

with $\Phi_t = t$ on D. Then $0 \le V_t \le t$, and

$$-m \log\bigl(1 - (1 - \mathrm{e}^{-t/m})|w|^2\bigr) \le V_t(\zeta, w) \le H_m(w). \tag{1.37}$$

In particular, $V_t \uparrow H_m$ pointwise on all of B, including D. The convergence is uniform on every compact subset, with

$$0 \le H_m - V_t \le \frac{m\mathrm{e}^{-t/m} R^2}{1 - R^2} \qquad \textit{where } |w| \le R < 1. \tag{1.38}$$

Proof The obstacle is continuous, nonnegative and at most t. Zero is a competitor, so the upper-envelope theorem gives $V_t \in \mathrm{PSH}(B)$ with $0 \le V_t \le \Phi_t \le t$. Consequently $m \log |\zeta|^2 + V_t$ is a competitor for G_m, and Proposition 1.19.3 gives $V_t \le H_m$ off D. At a point $(0, w)$, the submean inequality on any sufficiently small circle in the normal line gives the same bound, since H_m does not depend on ζ.

For the lower bound, set $a_t = 1 - \mathrm{e}^{-t/m}$ and $F_t(w) = -m \log(1 - a_t|w|^2)$. The Hessian calculation above, with $|w|^2$ replaced by $a_t|w|^2$, shows that F_t is plurisubharmonic. Moreover, $0 \le F_t \le t$, and $F_t \le H_m \le -m \log |\zeta|^2$ on $B \setminus D$ because $|\zeta|^2 < 1 - |w|^2$. Thus $F_t \le \Phi_t$ everywhere, and hence $F_t \le V_t$. Finally,

$$H_m - F_t = m \log\left(1 + \frac{\mathrm{e}^{-t/m}|w|^2}{1 - |w|^2}\right) \le \frac{m\mathrm{e}^{-t/m}|w|^2}{1 - |w|^2}.$$

This proves (1.38) and the convergence; the monotonicity of V_t in t follows from that of Φ_t. □

Example 1.19.1 At every point $p = (0, w_0) \in \partial B$ with $|w_0| = 1$, the cluster set of G_m at p, that is, the set of limits of G_m along sequences in B converging to p, is all of $[-\infty, 0]$. Indeed, set $w_s = (1 - s^2)^{1/2} w_0$ for $0 < s < 1$. For every fixed $0 < a < 1$, the points (as, w_s) belong to B, tend to p as $s \to 0$, and satisfy $G_m = m \log a^2$. Choosing $a = a_s < 1$ with $a_s \to 1$ gives the limit zero, whereas the points (s^2, w_s) give $G_m = m \log s^2 \to -\infty$. These realize every value in $[-\infty, 0]$, and negativity excludes all others. Thus G_m, although continuous on B, has no continuous extension to any point of ∂B in the closure of D.

1.20 The minimum principle

An infimum of plurisubharmonic functions need not be plurisubharmonic. Kiselman's minimum principle describes an important exception: the infimum over a real parameter t of a family u_t whose complexification $u_{\operatorname{Re} z}$ is plurisubharmonic in the joint variables. Freezing the coefficients of the background form, we show that the principle preserves the exact lower curvature bound $-\theta$.

Lemma 1.20.1 *Let $I \subset \mathbb{R}$ be a nonempty open interval, set $S_I = \{z \in \mathbb{C} : \operatorname{Re} z \in I\}$, and let $\pi : X \times S_I \to X$ be the projection. Let $(u_t)_{t\in I}$ be a family of functions on X such that $U(x,z) = u_{\operatorname{Re} z}(x)$ is quasi-plurisubharmonic on $X\times S_I$ and $\pi^*\theta + \mathrm{dd}^{\mathrm{c}} U \geq 0$. For each x, the function $t \mapsto u_t(x)$ is finite and convex or identically $-\infty$. The finite alternative holds for almost every x.*

Proof A local smooth correction making U plurisubharmonic can be chosen to depend only on x. Hence the restriction of U to $\{x\} \times S_I$ is subharmonic or identically $-\infty$. In the first case its distributional Laplacian is the second derivative of $t \mapsto u_t(x)$, which is therefore nonnegative. The resulting convex representative is finite on I, and by the submean inequality it agrees everywhere with the subharmonic function. Finally, U is locally integrable on the product, and Fubini's theorem, applied on products of coordinate balls with a fixed rectangle in S_I, excludes the identically $-\infty$ alternative for almost every x. □

Corollary 1.20.1 *Let $I \subset \mathbb{R}$ be a nonempty open interval. A radial function $z \mapsto q(\log|z|^2)$ is subharmonic on the annulus $\{z : \log|z|^2 \in I\}$ if and only if q is finite and convex on I. If the function identically equal to $-\infty$ is also regarded as subharmonic, the alternative $q \equiv -\infty$ has to be added.*

Proof The holomorphic covering map $z = \mathrm{e}^{w/2}$ pulls the function back to $q(\operatorname{Re} w)$, and the argument of Lemma 1.20.1 proves necessity. Conversely, a finite convex function q has nonnegative distributional second derivative. Thus $q(\operatorname{Re} w)$ is subharmonic, and subharmonicity descends through the local biholomorphisms of the covering. □

Proposition 1.20.1 *Under the hypotheses of Lemma 1.20.1, the function*

$$q(x) = \inf_{t\in I} u_t(x)$$

is either θ-plurisubharmonic or identically $-\infty$; in particular, the infimum need not be regularized. If I is bounded, then $q \in \mathrm{PSH}(X,\theta)$.

Proof The classical local Kiselman principle states that if a plurisubharmonic function on the product of a domain with a strip does not depend on the imaginary part of the strip variable, then its infimum over the real part is plurisubharmonic or identically $-\infty$; the interval of the real part may be unbounded. We use this local result from [Xia].

Fix $x_0 \in X$, choose local holomorphic coordinates centered at x_0, and let κ be their Euclidean form. Fix $\eta > 0$. On a sufficiently small coordinate ball the constant form $\beta = \theta(x_0)$ satisfies

$$\beta - \eta\kappa \le \theta \le \beta + \eta\kappa.$$

Choose a quadratic function r with $\mathrm{dd}^{\mathrm{c}} r = \beta + \eta\kappa$. Then $U + r \circ \pi$ is plurisubharmonic on the product of the ball with S_I. Its infimum over the parameter is $q + r$, so the local principle shows that $q + r$ is plurisubharmonic or identically $-\infty$ on the ball; in the first case

$$\mathrm{dd}^{\mathrm{c}} q \ge -\beta - \eta\kappa \ge -\theta - 2\eta\kappa.$$

In a fixed atlas, the Euclidean forms are bounded by a fixed multiple of ω, so letting $\eta \downarrow 0$ proves the exact lower bound $\mathrm{dd}^{\mathrm{c}} q \ge -\theta$. Since a plurisubharmonic function cannot be identically $-\infty$ on a nonempty open set, the local alternative propagates across overlapping balls on the connected manifold X. Thus either $q \in \mathrm{PSH}(X, \theta)$ or $q \equiv -\infty$. No regularization is needed, because an infimum of upper semicontinuous functions is upper semicontinuous.

Now suppose that I is bounded. By Lemma 1.20.1, the function $t \mapsto u_t(x)$ is finite and convex for almost every x, and a supporting affine function at any point of I bounds it from below on the bounded interval I. Hence $q(x) > -\infty$ almost everywhere, which excludes the alternative $q \equiv -\infty$. □

For example, the proposition applies to $u_t - t\tau$ for a fixed real number τ. On an unbounded interval the infimum may be identically $-\infty$; this alternative will encode the cutoff of a test curve (Definition 18.1.1).

1.20.1 Pointwise Legendre transforms

The minimum principle can also show that a supremum is already upper semicontinuous. For a concave family of potentials, the regularized Legendre transform is a potential on a product. The minimum principle identifies its inverse transforms with the original family everywhere, and applying the one-variable duality once more identifies the regularization with the pointwise supremum. We first state this duality precisely, including its behavior at the endpoints; the general Legendre–Fenchel theorem is recalled in [Xia, appendix on convex analysis].

Lemma 1.20.2 *Let $c \in \mathbb{R}$. Suppose $g : \mathbb{R} \to [-\infty, 0]$ is upper semicontinuous, concave and decreasing, finite somewhere, and equal to $-\infty$ on (c, ∞). Then*

$$f(t) = \sup_{\tau < c} \bigl(g(\tau) + t\tau\bigr), \qquad t > 0,$$

is finite and convex, satisfies $f(t) \le ct$, and obeys

$$g(\tau) = \inf_{t > 0} \bigl(f(t) - t\tau\bigr), \qquad \lim_{t \downarrow 0} f(t) = \sup_{\tau < c} g(\tau).$$

Conversely, every finite convex f on $(0,\infty)$ with $f(t) \le ct$ is recovered by the first formula from $g(\tau) = \inf_{t>0}(f(t) - t\tau)$, and satisfies the same endpoint identity. The formulas also hold for $g \equiv -\infty$, with $f \equiv -\infty$.

Proof Since g is decreasing and finite somewhere, it is finite on a half-line $(-\infty, \tau_1)$. Hence the defining supremum is finite for $t > 0$: it is bounded above by ct and below by any one of its finite terms. Concavity and upper semicontinuity give $g(c) = \lim_{\tau\uparrow c} g(\tau)$, so including $\tau = c$ does not change the supremum. The Legendre transform $t \mapsto \sup_\tau(g(\tau) + t\tau)$ of $-g$ is infinite for $t < 0$. At $t = 0$ it equals $m = \sup_{\tau<c} g(\tau)$, and the bounds

$$g(\tau) + t\tau \le f(t) \le m + ct$$

show that $f(t) \to m$ as $t \downarrow 0$. The biconjugacy theorem for the closed convex function $-g$ therefore gives the inverse formula; the value at $t = 0$ may be omitted without changing the infimum.

Conversely, start with f. At each $t > 0$, choose the slope p of a supporting line of f. The upper bound $f(s) \le cs$ as $s \to \infty$ forces $p \le c$. If $p < c$, the supporting line gives $g(p) = f(t) - tp$, so the first formula recovers $f(t)$. If $p = c$, then $f(s) - cs$ is constant for $s \ge t$, because this function is convex and bounded above, hence decreasing, while its supporting line at t is horizontal. Consequently, for every $\tau < c$,

$$f(t) - ct \le g(\tau) \le f(t) - t\tau.$$

and letting $\tau \uparrow c$ again recovers $f(t)$. In particular, g is finite somewhere. As an infimum of affine functions with slopes $-s < 0$, it is upper semicontinuous, concave and decreasing. Letting $s \downarrow 0$ in the bound $f(s) - s\tau \le s(c - \tau)$ gives $g \le 0$, and letting $s \to \infty$ gives $g = -\infty$ for $\tau > c$. The endpoint identity now follows from the first part. The case of functions identically equal to $-\infty$ follows directly from the formulas. □

Fix $c \in \mathbb{R}$, and let $\Gamma_\tau \in \mathrm{PSH}(X,\theta)$ for $\tau < c$ be functions with $\Gamma_\tau \le 0$ such that $\tau \mapsto \Gamma_\tau(x)$ is concave and decreasing for every x. Extend the family to $\tau = c$ by the decreasing limit $\Gamma_c = \lim_{\tau\uparrow c} \Gamma_\tau$, and by $\Gamma_\tau \equiv -\infty$ for $\tau > c$. Define the forward transform of the family by

$$U_t(x) = \sup_{\tau<c}\big(\Gamma_\tau(x) + t\tau\big), \qquad t > 0. \tag{1.39}$$

For a family $(u_t)_{t>0}$, the inverse transform is

$$\widehat{u}_\tau(x) = \inf_{t>0}\big(u_t(x) - t\tau\big). \tag{1.40}$$

Lemma 1.20.3 *At each x, the extended function $\tau \mapsto \Gamma_\tau(x)$ is upper semicontinuous and concave, or identically $-\infty$. Its forward transform satisfies*

$$\Gamma_\tau(x) = \inf_{t>0}\big(U_t(x) - t\tau\big) \qquad (\tau \in \mathbb{R}).$$

Proof Fix $\tau < c$ and let $\tau_j \uparrow \tau$. The decreasing limit of the functions Γ_{τ_j} dominates Γ_τ, so it belongs to $\mathrm{PSH}(X,\theta)$. Choose $r \in (\tau, c)$. Outside the pole set of Γ_r, the concave function $s \mapsto \Gamma_s(x)$ is finite near τ and hence continuous there. Thus the decreasing limit equals Γ_τ almost everywhere, and hence everywhere by Lemma 1.3.3. This proves left continuity at every $\tau < c$; at c it holds by definition. Since the function is decreasing, left continuity gives upper semicontinuity, also where the value is $-\infty$, and concavity survives the extension. The inverse formula is Lemma 1.20.2 at each x. □

Theorem 1.20.1 *For the preceding family $(\Gamma_\tau)_{\tau<c}$, the pointwise supremum in (1.39) is already upper semicontinuous on $X \times (0,\infty)$. Its complexification $U(x,z) = U_{\mathrm{Re}\, z}(x)$ is quasi-plurisubharmonic on $X \times \{\mathrm{Re}\, z > 0\}$ and satisfies $\pi^*\theta + \mathrm{dd}^{\mathrm{c}} U \geq 0$, where $\pi : X \times \{\mathrm{Re}\, z > 0\} \to X$ is the projection. Each slice belongs to* $\mathrm{PSH}(X,\theta)$.

Proof Each term $(x,z) \mapsto \Gamma_\tau(x) + \tau\,\mathrm{Re}\, z$ of the supremum satisfies the current inequality on the product, since $\mathrm{Re}\, z$ is pluriharmonic. The bound $\Gamma_\tau \leq 0$ gives $U_t \leq ct$, while any fixed $\tau_0 < c$ gives the minorant $\Gamma_{\tau_0} + t\tau_0$. By the local upper-envelope theorem, as in Section 1.19, the upper semicontinuous regularization V of U on the product is quasi-plurisubharmonic, satisfies $\pi^*\theta + \mathrm{dd}^{\mathrm{c}} V \geq 0$, and agrees with U almost everywhere. It does not depend on $\mathrm{Im}\, z$ and satisfies $V_t \leq ct$. The pointwise supremum U is measurable, since by the left continuity in Lemma 1.20.3 the parameters may be restricted to rational numbers.

By Fubini's theorem, there is a set $Z \subset X$ of zero smooth volume, containing the pole set of Γ_{τ_0}, such that $U_t(x) = V_t(x)$ for almost every $t > 0$ whenever $x \notin Z$. For such x, both sides are finite convex functions of t, by Lemmas 1.20.1 and 1.20.2, so by continuity the equality holds for every $t > 0$.

For each $\tau < c$, Proposition 1.20.1 gives

$$\chi_\tau = \inf_{t>0}(V_t - t\tau) \in \mathrm{PSH}(X,\theta) \cup \{-\infty\}.$$

Off Z it equals Γ_τ by Lemma 1.20.3. In particular, χ_τ is not identically $-\infty$, and Lemma 1.3.3 gives $\chi_\tau = \Gamma_\tau$ everywhere. At each x, the convex function $t \mapsto V_t(x)$ can be recovered from these inverse transforms by Lemma 1.20.2, also when it is identically $-\infty$. We obtain

$$V_t(x) = \sup_{\tau<c}\bigl(\chi_\tau(x) + t\tau\bigr) = U_t(x).$$

Finally, the minorant $\Gamma_{\tau_0} + t\tau_0$ shows that no slice U_t is identically $-\infty$, so every slice belongs to $\mathrm{PSH}(X,\theta)$. □

1.21 Chern-connection regularization

Convolution in local coordinates does not directly produce global approximants with a controlled lower curvature bound. Demailly's regularization instead averages over the

fibers of the tangent bundle, using the Chern connection of ω, and a Kiselman-type minimum of these averages controls the loss of positivity. The classical curvature estimate for this minimum holds in a Hermitian background, while the L^1 and gradient bounds for the averages are elementary.

Fix $C_0 > 0$ and $u \in \mathrm{PSH}(X, \omega)$ with $-C_0 \le u \le 0$. Distances, gradients and norms of tensors are taken with respect to the Riemannian metric associated with ω.

For small $t > 0$, let $R_t u$ be Demailly's regularization of u formed with the Chern connection of ω. It averages u over the image of the ball of radius t in each tangent space, with a fixed smooth nonnegative radial kernel of integral one. The map used for this purpose is a smooth realization of the holomorphic part of the formal fiberwise expansion of the exponential map; it need not be holomorphic in the fiber. The following classical estimate controls the Kiselman-type transform of these averages, including its mixed base–fiber terms; see Section 34.1 for the sources.

Lemma 1.21.1 *There are constants $A, K > 0$ and $t_* > 0$, depending only on (X, ω) and C_0, such that $R_t u$ is smooth for $0 < t < t_*$,*

$$-C_0 \le R_t u \le 0, \qquad R_t u + K t^2 \downarrow u \quad \text{as } t \downarrow 0.$$

For $0 < \delta < t_*$ and $c > 0$, the bounded function

$$\Phi_{c,\delta} = \inf_{0<t\le\delta} \left\{ R_t u + K(t^2 - \delta^2) + K(t - \delta) - c \log(t/\delta) \right\}$$

is quasi-plurisubharmonic and satisfies

$$\omega + \mathrm{dd}^{\mathrm{c}} \Phi_{c,\delta} \ge -(Ac + 2K\delta)\omega.$$

At every point, the infimum is attained at some $t > 0$.

We use only this curvature estimate from the classical theory. The linear term $K(t - \delta)$ is needed in the Hermitian case, where it absorbs the mixed base–fiber terms in the complex Hessian of the regularization. Since $-c \log(t/\delta)$ tends to $+\infty$ as $t \downarrow 0$ while u is bounded, the infimum is attained away from zero. We need neither smoothness of the minimizing radius nor smoothness of the transform across the region where this radius equals δ.

Next we prove two elementary estimates for the averaging operators. They do not rely on any volume identity from Kähler geometry.

Lemma 1.21.2 *For all sufficiently small $t > 0$,*

$$\|R_t u - u\|_{L^1(\mathrm{d}V)} \le Ct^2, \qquad \|\nabla R_t u\|_\infty \le C/t.$$

The constants are uniform for $-C_0 \le u \le 0$.

Proof Let z be local coordinates on X and $\xi \in \mathbb{C}^n$ the fiber variable with respect to a smooth orthonormal frame of the tangent bundle. Write $\rho(|\xi|^2)$ for the fixed radial averaging kernel, normalized with respect to Lebesgue measure $\mathrm{d}\xi$ and supported in $|\xi| \le 1$. In these coordinates the averaging map F gives

$$R_t u(z) = \int u(F(z, t\xi))\rho(|\xi|^2)\,\mathrm{d}\xi, \qquad F(z, 0) = z.$$

The map F is smooth in these variables, and its fiber differential at zero is an isomorphism. Let R_t^* be the formal adjoint of R_t with respect to $\mathrm{d}V$, so that $\int_X (R_t a)b\,\mathrm{d}V = \int_X a\,R_t^* b\,\mathrm{d}V$. We first claim that

$$R_t^* 1 = 1 + O(t^2)$$

uniformly. To see this, insert a smooth partition of unity in the variable z, each term being compactly supported in a chart on which the frame is defined. For fixed ξ, change variables $x = F(z, t\xi)$ on a neighborhood of the support of a term. The inverse map and its Jacobian have uniform Taylor expansions in t. The term of order zero in the transformed density is the chosen partition function at x, and the term of order one is linear in ξ, so it integrates to zero against the even radial kernel. The remaining density is bounded by $Ct^2\mathrm{d}V(x)$, since the second derivatives of all maps, partition functions and volume coefficients are bounded on these finitely many compact charts. Summing over the partition functions proves the claim.

Consequently,

$$\left|\int_X (R_t u - u)\,\mathrm{d}V\right| = \left|\int_X u(R_t^* 1 - 1)\,\mathrm{d}V\right| \le Ct^2.$$

By Lemma 1.21.1, $R_t u - u \ge -Kt^2$. A real function $a \ge -Kt^2$ satisfies $|a| \le a + 2Kt^2$; applying this to $a = R_t u - u$ and integrating gives the first estimate.

For the derivative bound, change variables in the fiber to write $R_t u(z) = \int_X u(x) k_t(z, x)\,\mathrm{d}V(x)$. In local coordinates the smooth kernel k_t is supported where $|x - z| \le Ct$ and satisfies

$$|\nabla_z k_t(z, x)| \le Ct^{-2n-1}.$$

Indeed, the inverse fiber map and its Jacobian have uniformly bounded derivatives, and differentiating the rescaled radial argument introduces at most one factor t^{-1} in addition to t^{-2n}. Since the kernel is smooth with compact support, there are no boundary terms. Integration over a ball of volume at most Ct^{2n} gives $\int |\nabla_z k_t|\,\mathrm{d}V \le C/t$, and multiplication by the uniform bound for u proves the assertion. □

The first estimate relies on the cancellation of the odd first-order term against the even kernel, and not on conservation of Monge–Ampère mass.

1.21.1 The general curvature modulus

Let θ now be any smooth real $(1,1)$-form and let $u \in \mathrm{PSH}(X,\theta) \cap L^\infty(X)$. We use the same averaging operators and the same metric.

We first state the classical input for this background. The classical Chern-connection regularization theorem applies to the closed current $\mathrm{d}^\mathrm{c}u$ with the smooth, possibly nonclosed, lower bound $-\theta$; the curvature of the Chern connection on the tangent bundle is bounded by a fixed multiple of ω. The theorem gives a constant $K_0 > 0$ such that

$$R_t u + K_0 t^2 \downarrow u.$$

To state its curvature estimate, use local coordinates z on X and a complex radius variable w, and put $t = |w|$. Write $\zeta \in T^{1,0}_z X$ and $\eta \in \mathbb{C}$ for the base and radius components of a tangent vector, and set $\lambda(z,t) = t\partial_t(R_t u(z) + K_0 t^2)$. Then λ is nonnegative and increasing in t, and there are constants $A, C > 0$ and a function $\epsilon_0(t) \geq 0$ with $\epsilon_0(t) \downarrow 0$ as $t \downarrow 0$ such that the complex Hessian of $(z,w) \mapsto R_{|w|}u(z)$ is bounded below by the base form $-\theta - A\lambda(z,t)\omega - \epsilon_0(t)\omega$, evaluated on ζ, minus mixed and vertical error terms bounded by $C(|\zeta||\eta| + |\eta|^2)$. This is the classical regularization estimate for a smooth lower bound.

Lemma 1.21.3 *For K sufficiently large, there is an increasing function $\epsilon(\delta) \geq 0$ tending to zero at zero such that, for every small $\delta > 0$ and every $c > 0$, the function*

$$\Phi_{c,\delta} = \inf_{0<t\leq\delta} \{R_t u + K(t^2 - \delta^2) + K(t - \delta) - c\log(t/\delta)\}$$

is bounded and quasi-plurisubharmonic and satisfies

$$\theta + \mathrm{d}^\mathrm{c}\Phi_{c,\delta} \geq -(Ac + \epsilon(\delta))\omega.$$

The infimum is attained away from zero. Moreover, $R_t u + Kt^2 \downarrow u$ as $t \downarrow 0$.

Proof Take $K \geq K_0$ and put $H(z,t) = R_t u(z) + Kt^2 + Kt$. As a function of $\log t$, H is increasing and strictly convex, because $R_t u + K_0 t^2$ has nonnegative increasing logarithmic derivative and the added terms have positive second logarithmic derivative. Its logarithmic derivative $\widetilde{\lambda} = t\partial_t H$ is at least λ.

The complex Hessian of $K|w|$ has a positive vertical term proportional to $K/|w|$. For sufficiently small $|w| = t$, this term absorbs the vertical error and, by the inequality

$$C|\zeta||\eta| \leq C't|\zeta|^2 + \frac{K}{8t}|\eta|^2,$$

also the mixed error. After increasing the constants and replacing λ by the larger $\widetilde{\lambda}$, we find that the complex Hessian of $(z,w) \mapsto H(z,|w|)$ is bounded below by the

base form

$$-\theta - (A\widetilde{\lambda} + \epsilon(t))\omega,$$

where ϵ is an increasing majorant of $\epsilon_0(t) + C't$.

Since u is bounded, the term $-c\log(t/\delta)$ tends uniformly to $+\infty$ as $t \downarrow 0$, so the minimum occurs on a compact interval of radii away from zero. Strict convexity in $\log t$ makes the minimizing radius unique. At an interior minimum $\widetilde{\lambda} = c$, while at the upper endpoint $t = \delta$ one has $\widetilde{\lambda} \le c$. No differentiability of the minimizing radius is needed.

In more detail, localize near a point of X and fix $a > 0$. By continuity of the minimizers and of $\widetilde{\lambda}$, there is an interval of radii containing the minimizers at all nearby points on which $\widetilde{\lambda} \le c + a$. If the minimum is attained at the upper endpoint, keep the upper endpoint δ; an open interval approaching it has the same infimum. Because of the uniform logarithmic term, the lower endpoint can be chosen below all minimizers, and since $\widetilde{\lambda}$ is increasing, the bound $\widetilde{\lambda} \le c + a$ holds throughout the chosen interval. The local Kiselman minimum principle for functions depending only on $|w|$, applied after a local quadratic correction, now gives the lower curvature bound with error $A(c + a) + \epsilon(\delta)$, up to an arbitrarily small error from freezing the smooth base forms. Letting these errors and a tend to zero proves the asserted current inequality and the quasi-plurisubharmonicity. Finally, $K \ge K_0$ preserves the monotone convergence of $R_t u + Kt^2$ to u. □

The classical theorem only gives some modulus ϵ; we do not claim that $\epsilon(\delta)$ is linear in δ. The cancellation and kernel arguments in the proof of Lemma 1.21.2 still give

$$\|R_t u - u\|_{L^1(\mathrm{d}V)} \le Ct^2, \qquad \|\nabla R_t u\|_\infty \le C/t,$$

because the averaging map is unchanged, u is bounded, and these arguments use only the monotone lower bound $R_t u - u \ge -Kt^2$.

For continuous potentials, the curvature loss of the averages becomes uniformly small.

Lemma 1.21.4 *Let α be a smooth real $(1,1)$-form on X, and let $u \in \mathrm{PSH}(X,\alpha) \cap C^0(X)$. There are smooth real functions u_j and numbers $\varepsilon_j \downarrow 0$ such that $u_j \to u$ uniformly and*

$$\alpha + \mathrm{dd^c} u_j \ge -\varepsilon_j \omega.$$

Proof Use the Chern averaging operators and the classical estimate stated before Lemma 1.21.3, with α in place of θ. For some $K_0, A > 0$ and $\epsilon_0(t) \to 0$, put $\lambda(x,t) = t\partial_t(R_t u(x) + K_0 t^2)$. The estimate with vanishing radius component gives

$$\alpha + \mathrm{dd^c} R_t u \ge -(A\lambda(\cdot,t) + \epsilon_0(t))\omega.$$

The function λ is nonnegative, continuous for $t > 0$, and increasing in t. For fixed x, the convex function $s \mapsto R_{\mathrm{e}^s} u(x) + K_0 \mathrm{e}^{2s}$ has the finite limit $u(x)$ as $s \to -\infty$. Its nonnegative derivative must therefore tend to zero, since a positive limit of the derivative would make the function tend to $-\infty$. Thus $\lambda(x,t) \to 0$ as $t \to 0$, and for any sequence $t_j \downarrow 0$, Dini's theorem gives $\|\lambda(\cdot,t_j)\|_\infty \to 0$.

The averaging kernels have mass one and only sample points at distance at most Ct from the base point. Uniform continuity of u therefore gives $\|R_t u - u\|_\infty \to 0$. Set $u_j = R_{t_j} u$, and let $\varepsilon_j \to 0$ be a decreasing positive majorant of $A\|\lambda(\cdot, t_j)\|_\infty + \epsilon_0(t_j)$.□

1.21.2 Hölder reference approximation and weighted smoothing

The Chern averages preserve a Hölder norm uniformly. Their small lower-curvature loss can therefore be absorbed by rescaling, without changing the limiting potential.

Lemma 1.21.5 *If $u \in \mathrm{PSH}(X, \omega) \cap C^{0,\alpha}(X)$ with $0 < \alpha \le 1$, there are smooth $u_j \in \mathrm{PSH}(X, \omega)$ tending uniformly to u, with a common $C^{0,\alpha}$ bound. If $\sup_X u = 0$, the approximants can also be normalized by $\sup_X u_j = 0$.*

Proof Use the Chern averages $R_t u$ in Lemma 1.21.4. For a sequence $t_j \downarrow 0$ there are $\varepsilon_j \downarrow 0$ such that

$$\omega + \mathrm{dd}^{\mathrm{c}} R_{t_j} u \ge -\varepsilon_j \omega, \qquad R_{t_j} u \longrightarrow u \quad \text{uniformly.}$$

We also have a uniform Hölder bound. In a coordinate chart with a smooth orthonormal tangent frame, the averaging formula is

$$R_t u(x) = \int u(F(x, t\xi))\rho(|\xi|^2)\, \mathrm{d}\xi.$$

On a smaller chart, smoothness of F bounds $\mathrm{dist}(F(x, t\xi), F(y, t\xi))$ by $C\,\mathrm{dist}(x, y)$, uniformly for small t and $|\xi| \le 1$. Integrating the Hölder inequality for u gives the same bound for $R_t u$. A finite cover and the common supremum bound handle pairs outside a common smaller chart.

Set $u_j = R_{t_j} u/(1 + \varepsilon_j)$. Then

$$\omega + \mathrm{dd}^{\mathrm{c}} u_j = \frac{\varepsilon_j \omega + (\omega + \mathrm{dd}^{\mathrm{c}} R_{t_j} u)}{1 + \varepsilon_j} \ge 0.$$

These functions converge uniformly with a common Hölder bound. Subtracting their suprema gives the asserted normalization when $\sup_X u = 0$. □

Lemma 1.21.6 *Let $u \in \mathrm{PSH}(X, \omega) \cap C^{0,\alpha}(X)$, $0 < \alpha \le 1$, and let μ be a positive measure with $\mu \le A\omega_u^n$. For bounded $\varphi \in \mathrm{PSH}(X, \omega)$ with $-M \le \varphi \le 0$, the Chern averages satisfy*

$$\|R_t \varphi - \varphi\|_{L^1(\mu)} \le C t^{2\alpha/(\alpha+2n)}$$

for small $t > 0$. The constant is uniform under fixed bounds for A, M and $\|u\|_{C^{0,\alpha}}$.

Proof First we check a common lower curvature bound for the averages. The base part of the classical Chern curvature estimate stated before Lemma 1.21.3 gives

$$\omega + \mathrm{dd}^{\mathrm{c}} R_t \varphi \ge -(A_0 \lambda(\cdot, t) + \epsilon_0(t))\omega, \qquad \lambda(x, t) = t\partial_t (R_t \varphi(x) + K_0 t^2).$$

Its constants are fixed under the stated bounded range. In the local kernel form used in Lemma 1.21.2,

$$k_t(x,y) = t^{-2n} a\big(x, (y-x)/t, t\big),$$

with uniformly bounded first derivatives and compact support in its rescaled second variable. Differentiating with respect to t at fixed x, y and changing variables shows that

$$\int |t\partial_t k_t(x,y)|\,\mathrm{d}y \le C.$$

Thus $|t\partial_t R_t\varphi| \le CM$, so λ is uniformly bounded and the displayed curvature estimate supplies one fixed lower bound $\mathrm{dd^c} R_t\varphi \ge -C\omega$. Both $R_t\varphi$ and φ also lie in $[-M, 0]$.

Apply Corollary 1.8.2 to this pair, whose common lower bound has just been established. By Lemma 1.21.2, its smooth-volume L^1 error is at most Ct^2. Domination by $A\omega_{t\prime}^n$ therefore gives

$$\int |R_t\varphi - \varphi|\,\mathrm{d}\mu \le C\|R_t\varphi - \varphi\|_{L^1(\mathrm{d}V)}^{\alpha/(\alpha+2n)} \le Ct^{2\alpha/(\alpha+2n)}.$$

1.21.3 A linear error for a smooth background

Throughout this subsection, θ is a smooth real $(1,1)$-form that is big. By Theorem 1.15.2 and the remark following it, there is a strict potential $\rho \in \mathrm{PSH}(X,\theta)$, that is, $\theta + \mathrm{dd^c}\rho \ge \varepsilon\omega$ for some $\varepsilon > 0$, which is smooth outside an analytic pole set and has a smooth remainder after resolution. Put $\Omega = X \setminus \{\rho = -\infty\}$. For normalized potentials that are locally bounded on Ω, the next lemma improves the curvature error of Lemma 1.21.3 to a linear one.

Lemma 1.21.7 *Let $a \in \mathrm{PSH}(X,\theta)$ satisfy $\sup_X a = 0$, and suppose that a is locally bounded on Ω. There are constants $A, K, C > 0$ such that the averaging operators R_t of Lemma 1.21.1 satisfy*

$$R_t a + Kt^2 \downarrow a, \qquad \|R_t a - a\|_{L^1(\mathrm{d}V)} \le Ct^2.$$

For small $\delta > 0$ and $c > 0$, the transform on Ω

$$\Phi_{c,\delta} = \inf_{0<t\le\delta} \{R_t a + K(t^2 - \delta^2) + K(t-\delta) - c\log(t/\delta)\}$$

extends canonically to X and satisfies

$$a - K(\delta^2 + \delta) \le \Phi_{c,\delta} \le R_\delta a \le 0, \qquad \theta + \mathrm{dd^c}\Phi_{c,\delta} \ge -(Ac + C\delta)\omega. \tag{1.41}$$

At each point of Ω the infimum is attained at a positive radius. On every compact set $K_1 \Subset \Omega$, for sufficiently small t, $\|\nabla R_t a\|_{L^\infty(K_1)} \le C_{K_1}/t$.

Proof *Step 1: the classical expansion.* Apply the classical Chern-connection regularization expansion to the closed current $\mathrm{dd^c}a$ and the smooth lower bound $-\theta$. It gives monotonicity and logarithmic convexity: for a constant $K_0 > 0$, the function $\lambda(x,t) = t\partial_t(R_t a(x) + K_0 t^2)$ is nonnegative and increasing in t. Instead of inferring a rate from the unspecified modulus in that theorem, we estimate the error terms of the expansion directly, using the smoothness of θ.

Choose the auxiliary curvature form to be $A\omega$, with A large enough that the Chern curvature plus $A\omega \otimes \mathrm{Id}$ is nonnegative on every decomposable tensor. Equivalently, after absorbing the normalization constants, the Chern curvature coefficients $R_{j\bar{k}\ell\bar{m}}$ in a unitary frame satisfy

$$\sum R_{j\bar{k}\ell\bar{m}} \xi_j \bar{\xi}_k \zeta_\ell \bar{\zeta}_m \ge -A|\xi|^2|\zeta|^2$$

for all tangent vectors ξ, ζ. Such an A exists by compactness. Pairing this inequality with the nonnegative eigenvalues of a positive complex Hessian bounds its curvature contraction from below by $-A$ times its trace, with no further error term.

Step 2: a frozen quadratic correction. Fix $x \in X$ and a complex radius variable $w \ne 0$, and put $t = |w|$. Write $\xi \in T^{1,0}_x X$ and $\tau \in \mathbb{C}$ for the base and radius components of a tangent vector. In a coordinate chart of uniform size about x, write $\beta = \mathrm{dd^c}|z|^2$ and choose a quadratic function $q_{x,t}$ with

$$\mathrm{dd^c} q_{x,t} = \theta(x) + Bt\beta,$$

where the constant B is chosen so large that $a + q_{x,t}$ is plurisubharmonic on a ball of radius of order t containing the support of the averages at x and at nearby points. This is possible by the bound $\|\theta(y) - \theta(x)\| \le C|y - x|$ on such a ball. For the Hessian calculation at (x, w), the quadratic function is held fixed; its coefficients and all needed derivatives are uniformly bounded.

Step 3: the error terms. By normalized compactness, $\|a\|_{L^1}$ is bounded. On each fixed larger chart, add one fixed strictly plurisubharmonic quadratic function Q to a.

For the trace measure $\mu = \mathrm{dd}^{\mathrm{c}}(a+Q)\wedge\beta^{n-1}$, the local Lelong mass inequality and a bound for the mass of a fixed larger ball give $\mu(B(x,t)) \le Ct^{2n-2}$. The coefficients of $\partial\bar\partial(a+q_{x,t})$ are controlled in total variation by those of $\mathrm{dd}^{\mathrm{c}}(a+Q)$ plus a uniformly bounded smooth form. Write $|\partial\bar\partial(a+q_{x,t})|$ for the sum of the total variations of its coefficient measures. The rescaled averaging kernels are supported in $B(x,Ct)$ and bounded by a constant times t^{-2n}, so their integrals against this measure are bounded by

$$Ct^{-2n}|\partial\bar\partial(a+q_{x,t})|(B(x,Ct)) \le C't^{-2}.$$

Thus the terms of the expansion with a coefficient $O(t^3)$ contribute $O(t)$, and the remainder of the expansion of order two is $O(t)$ as well. The mixed and vertical contributions are bounded by $C(|\xi||\tau|+|\tau|^2)$. By the choice of A, the curvature term is bounded below by $-A\lambda(x,t)|\xi|^2$; here the radial term of the same expansion identifies the relevant mass with λ up to $O(t^2)$. Subtracting the regularization of $q_{x,t}$ restores $-\theta(x)$: its base Hessian differs from $\mathrm{dd}^{\mathrm{c}}q_{x,t}$ by $O(t)$, its mixed and vertical Hessians are bounded, and its radial logarithmic derivative is $O(t^2)$. The extra term $Bt\beta$ also costs only $O(t)$. For a real $(1,1)$-form α, write $\alpha[v]^2$ for its associated Hermitian quadratic form evaluated on v. Consequently, for a fixed constant $C_1>0$, the complex Hessian of $(x,w)\mapsto R_{|w|}a(x)$ satisfies

$$\mathrm{dd}^{\mathrm{c}}_{x,w}R_{|w|}a[\xi,\tau]^2 \ge -\theta_x[\xi]^2 - (A\lambda(x,t)+Ct)|\xi|^2 - C_1(|\xi||\tau|+|\tau|^2).$$

All constants are independent of x,t,c,δ and uniform for normalized a. In particular, setting $\xi=0$ in the same expansion gives a uniform lower bound for the vertical Hessian. Adding a fixed multiple of $|w|^2$ makes the function subharmonic in w, which gives the logarithmic convexity and monotonicity above with a uniform constant K_0.

Step 4: the minimum. Take $K\ge K_0$ and add $K(t^2+t)$ to the regularization. The positive vertical Hessian of $K|w|$ absorbs the mixed term by the inequality

$$C_1|\xi||\tau| \le C't|\xi|^2 + \frac{K}{8t}|\tau|^2,$$

and it absorbs the remaining bounded vertical error for small t. The logarithmic derivative of the corrected function is at least λ. The Kiselman minimum argument with an upper endpoint, as in the proof of Lemma 1.21.3, therefore gives the last inequality in (1.41), now with error $C\delta$. On compact subsets of Ω, local boundedness of a makes the term $-c\log(t/\delta)$ dominate uniformly as $t\downarrow 0$, so that the minimum is attained away from zero. As before, minimizers at the upper endpoint are handled without differentiating their radius.

Step 5: the remaining bounds. The other bounds in (1.41) follow from the monotonicity of $R_t a + Kt^2$ and from evaluation at $t=\delta$. In particular, the transform is bounded above near the analytic set $X\setminus\Omega$. The removable singularity theorem therefore extends it across this set, and local freezing and passage to the limit preserve the exact smooth lower bound for its Hessian. Its lower bound $a-K(\delta^2+\delta)$ also extends, since quasi-plurisubharmonic functions are determined by their values off an analytic set.

The adjoint computation in the proof of Lemma 1.21.2 gives $R_t^* 1 = 1 + O(t^2)$. It only needs $a \in L^1$, since

$$\left| \int_X (R_t a - a)\, \mathrm{dV} \right| \leq C t^2 \|a\|_1 .$$

Together with $R_t a - a \geq -K t^2$, this proves the stated L^1 estimate. Finally, near K_1 the smoothing kernel only samples a fixed larger compact subset of Ω, on which a is bounded. The kernel derivative estimate in the proof of Lemma 1.21.2 then gives the bound C_{K_1}/t. □

1.22 Pullback and descent

Pullback by a holomorphic map preserves the inequality $\theta + \mathrm{dd^c} u \geq 0$. Conversely, on a submersion with compact connected fibers, a potential that is positive with respect to a pulled-back background, which has no vertical component, must be constant on the fibers and therefore descends. For maps to a curve, descent also holds across critical fibers, and pullback preserves and reflects all-weight ideal types. If the fibers are disconnected, potentials descend to the curve of fiber components rather than the original base. Potentials also descend under modifications, and there a Jacobian factor accounts for the change in multiplier-ideal integrability.

1.22.1 Holomorphic disks

A smooth background form need not have local $\mathrm{dd^c}$-potentials, but its pullback to a disk does, since a real $(1,1)$-form on a disk is closed. Testing on holomorphic disks therefore characterizes the exact lower curvature bound in a way that is preserved by holomorphic maps.

Lemma 1.22.1 *Let θ be a smooth real $(1,1)$-form on a complex manifold M, and let u be quasi-plurisubharmonic on M. Then $\theta + \mathrm{dd^c} u \geq 0$ if and only if the following condition holds: for every holomorphic map $f : \Delta \to M$ from the unit disk such that $u \circ f$ is not identically $-\infty$, and for every smooth function a on an open subset of Δ with $\mathrm{dd^c} a = f^* \theta$, the function $u \circ f + a$ is subharmonic there.*

Proof Suppose first that $\theta + \mathrm{dd^c} u \geq 0$. On a coordinate ball, convolve u and θ with a smooth nonnegative radial kernel. The resulting smooth functions u_ϵ satisfy

$$\mathrm{dd^c} u_\epsilon \geq -\theta_\epsilon , \qquad \theta_\epsilon \longrightarrow \theta \quad \text{smoothly.}$$

Write $u = p - r$ locally, with p plurisubharmonic and r smooth. The convolutions p_ϵ decrease to p. On a smaller disk on which $u \circ f$ is not identically $-\infty$, $p_\epsilon \circ f$ therefore converges in L^1_{loc} to $p \circ f$, while $r_\epsilon \circ f$ converges smoothly. Pulling back

the smooth inequality and passing to the limit in the sense of distributions gives $\mathrm{dd}^{\mathrm{c}}(u \circ f) + f^{*}\theta \geq 0$. Since $u \circ f = p \circ f - r \circ f$ is the sum of a subharmonic and a smooth function, this distributional inequality makes $u \circ f + a$ subharmonic.

Conversely, test on affine complex lines in a coordinate ball. For a fixed nonzero constant direction ξ, local integrability of u implies that the restriction of u to almost every line parallel to ξ is not identically $-\infty$. Fubini's theorem, applied to nonnegative smooth test functions, then gives positivity of the scalar distribution obtained by evaluating the Hermitian coefficient matrix of $\theta + \mathrm{dd}^{\mathrm{c}}u$ on ξ. Positivity for a countable dense set of constant directions proves positivity of the Hermitian matrix of coefficient measures, which is the current inequality. □

Consequently, holomorphic pullback preserves the inequality $\theta + \mathrm{dd}^{\mathrm{c}}u \geq 0$ wherever the pulled-back function is not identically $-\infty$: apply the disk criterion to the compositions with the given map. We also use descent of subharmonicity under the finite map $\rho(t) = t^{k}$, $k \geq 1$, of the disk. If $h \circ \rho$ is subharmonic, local inverse branches of ρ show that h is subharmonic off zero. Moreover, h is bounded above near zero, and its value at zero is its upper limit there, since

$$h(0) = (h \circ \rho)(0) = \limsup_{t \to 0,\ t \neq 0} h(t^{k}) = \limsup_{z \to 0,\ z \neq 0} h(z).$$

By the removable-singularity theorem, h is subharmonic at zero as well.

1.22.2 Compact fibers

The connected components of the fibers of a submersion determine a finite covering of the base, and potentials first descend to this covering.

Lemma 1.22.2 *Let $p : M \to Y$ be a surjective holomorphic submersion between connected compact complex manifolds. There is a factorization*

$$M \xrightarrow{\pi} Y' \xrightarrow{r} Y, \qquad p = r \circ \pi,$$

where Y' is a connected compact complex manifold, r is a finite unramified holomorphic covering and π is a surjective holomorphic submersion with connected fibers. The points of $r^{-1}(y)$ correspond to the connected components of $p^{-1}(y)$, which are the fibers of π over those points.

Proof Fix a Hermitian metric on M. The orthogonal complement of $\ker \mathrm{d}p$ gives a smooth horizontal lift of tangent vectors on Y. Around $y_0 \in Y$ choose a coordinate ball B centered at y_0, with compact closure inside a larger coordinate ball. For $y \in B$, lift the straight segment from y_0 to y. The ordinary differential equation for horizontal transport has a solution along the whole segment, since its projection remains in the compact closure of B, whose inverse image is compact. Smooth dependence on the starting point and on y, together with transport along the reversed segment, gives a smooth trivialization

$$p^{-1}(B) \simeq B \times p^{-1}(y_0)$$

over B.

The compact manifold $p^{-1}(y_0)$ has finitely many connected components. The trivialization partitions $p^{-1}(B)$ into finitely many open and closed pieces, each of which meets every fiber in one connected component. On overlaps, two such local partitions identify the same fiber components, and their labels differ by locally constant permutations. Glue one copy of each base ball for every component, using these identifications. Equivalently, take the quotient of M that identifies points in the same connected component of a fiber. The local partitions make this quotient a Hausdorff covering space: distinct points over one base point lie on different sheets, and points over different base points are separated by their images in Y.

Call the quotient Y' and its projection r. Coordinates of Y on each sheet give holomorphic charts with holomorphic transition maps, so r is a local biholomorphism. It is a finite covering, and Y' is compact because a finite covering of a compact space is compact. Locally, the quotient map π is p restricted to one of the open pieces, so it is a holomorphic submersion with the asserted connected fibers. Surjectivity of π and connectedness of M make Y' connected. □

Proposition 1.22.1 *Let $\pi : Y \to X$ be a surjective holomorphic submersion between connected compact complex manifolds, with connected fibers. Let θ be a smooth real $(1,1)$-form on X. Pullback gives a bijection*

$$\mathrm{PSH}(X, \theta) \longrightarrow \mathrm{PSH}(Y, \pi^*\theta).$$

Every member on the right is constant on each fiber, with the value $-\infty$ allowed on an entire fiber.

Proof On a coordinate ball $V \subset X$, choose a smooth function ρ with $\mathrm{dd^c}\rho \geq \theta$. If $u \in \mathrm{PSH}(Y, \pi^*\theta)$, then $u + \rho \circ \pi$ is plurisubharmonic on $\pi^{-1}(V)$. Its restriction to a fiber is plurisubharmonic or identically $-\infty$, and since the fiber is compact and connected, the maximum principle shows that it is constant in either case. As $\rho \circ \pi$ is constant on fibers, $u = v \circ \pi$ for a uniquely defined function v on X.

A holomorphic submersion admits local holomorphic sections. Composing $u + \rho \circ \pi$ with such a section shows that $v + \rho$ is plurisubharmonic or identically $-\infty$ on a smaller ball. The latter alternative would make $u = -\infty$ on a nonempty open set, which is impossible for a quasi-plurisubharmonic function. Hence v is quasi-plurisubharmonic. Distributional differentiation in local product coordinates gives

$$\pi^*(\theta + \mathrm{dd^c}v) = \pi^*\theta + \mathrm{dd^c}u \geq 0.$$

Positivity of a pulled-back current of this form implies positivity on the base: test in product coordinates against products with a nonnegative compactly supported volume form of integral one in the fiber variables. It follows that $v \in \mathrm{PSH}(X, \theta)$.

Conversely, by Lemma 1.22.1, the pullback of a θ-plurisubharmonic function by π is $\pi^*\theta$-plurisubharmonic; in local product coordinates it is clearly not identically $-\infty$. The pullback map is injective because π is surjective. □

1.22.3 Maps to a curve

Let $p : X \to C$ be a surjective holomorphic map with connected fibers, where X is a connected compact complex manifold of dimension $n \geq 1$ and C is a connected compact Riemann surface. Critical fibers are allowed. Fix any smooth real $(1,1)$-form β on C.

Proposition 1.22.2 *Pullback gives a bijection*

$$\mathrm{PSH}(C,\beta) \longrightarrow \mathrm{PSH}(X, p^*\beta).$$

It preserves the supremum and the ordinary singularity order.

Proof The critical set is a proper compact analytic subset of X. It has finitely many irreducible components, and p is constant on each: its differential vanishes on the smooth locus of that component, and continuity extends the constant to the component. Thus the set $D \subset C$ of critical values is finite.

Let $U \in \mathrm{PSH}(X, p^*\beta)$. On a base coordinate disk choose a smooth a with $\mathrm{dd}^c a = \beta$. Over $C \setminus D$, the function $U + a \circ p$ restricts to a plurisubharmonic function, or the constant $-\infty$, on each compact connected fiber. The maximum principle makes it constant there. Local holomorphic sections then give a function v with $U = v \circ p$ and $a + v$ subharmonic. This is the local argument of Proposition 1.22.1; it uses compactness of the fibers, not compactness of the punctured total space.

The function v is bounded above by $\sup_X U$. The removable singularity theorem extends $a + v$ subharmonically across the finitely many punctures. The extensions glue, giving $v \in \mathrm{PSH}(C,\beta)$. Its pullback is $p^*\beta$-plurisubharmonic by Lemma 1.22.1. It agrees with U off the proper analytic set $p^{-1}(D)$, hence almost everywhere and everywhere by Lemma 1.3.3.

Conversely pullback preserves the curvature inequality by the disk criterion. It is not identically $-\infty$, because p is surjective. Surjectivity also proves uniqueness and preserves the supremum and every inequality $v \leq w + c$. □

Lemma 1.22.3 *Let $f : (\mathbb{C}^m, 0) \to (\mathbb{C}, 0)$ be a nonconstant holomorphic germ, with $m \geq 1$, and let $e = \mathrm{ord}_0 f$. For every quasi-subharmonic germ v at zero,*

$$\nu(v \circ f, 0) = e\nu(v, 0).$$

Proof A smooth correction of v pulls back to a smooth function, so we may assume that v is subharmonic. The Taylor expansion of f gives $|f(z)| \leq M|z|^e$ on a small ball. Choose a unit vector ξ on which the leading homogeneous term is nonzero. Then

$$f(\zeta\xi) = a\zeta^e + O(\zeta^{e+1}), \qquad a \neq 0.$$

For all small r, the remainder has modulus at most $|a|r^e/4$ on $|\zeta| = r$. If $|t| < |a|r^e/4$, Rouché's theorem shows that $f(\zeta\xi) - t$ has e zeros in $|\zeta| < r$. Consequently, with $c = |a|/4$,

$$\{|t| < cr^e\} \subset f(B(0,r)) \subset \{|t| < Mr^e\}.$$

The suprema of v on these three sets are ordered. Dividing by $\log r^2 < 0$, the two disk terms both tend to $e\nu(v,0)$ by the definition in Section 1.13. The middle term therefore has the same limit, proving the formula. □

Corollary 1.22.1 *For $v, w \in \mathrm{QPSH}(C)$, the inclusions $\mathcal{I}(tv) \subseteq \mathcal{I}(tw)$ for every $t > 0$ hold if and only if*

$$\mathcal{I}(t(v \circ p)) \subseteq \mathcal{I}(t(w \circ p)) \quad \textit{for every } t > 0.$$

In particular pullback preserves and reflects all-weight multiplier-ideal equivalence.

Proof On a smooth curve, local modifications are isomorphisms. By Theorem 1.16.1, the base inclusions are therefore equivalent to $\nu(v,s) \geq \nu(w,s)$ for every $s \in C$. Let π be any local modification of a neighborhood in X with smooth source, and let y be a point of its source. In a coordinate at $s = p(\pi(y))$, the germ $p \circ \pi - s$ is nonconstant. Indeed, a modification is an isomorphism on a dense open set, and a nonconstant holomorphic map cannot be constant on an open set. Its order e_y is positive and finite. The preceding lemma gives

$$\nu(v \circ p \circ \pi, y) = e_y \nu(v,s), \qquad \nu(w \circ p \circ \pi, y) = e_y \nu(w,s).$$

The base inequalities thus imply all inequalities upstairs, and the same valuative theorem gives the ideal inclusions. Conversely the upstairs inclusions give the inequalities for the identity modification at any $x \in p^{-1}(s)$. Dividing by $\mathrm{ord}_x(p-s) > 0$ recovers the base inequalities. Apply this argument in both directions for equality.□

Lemma 1.22.4 *If $v_j, v \in \mathrm{PSH}(C,\beta)$ and $v_j \to v$ in $L^1(C)$, then $v_j \circ p \to v \circ p$ in $L^1(X)$ for every smooth positive volume form on X.*

Proof Put $M_j = \sup_C v_j$ and $M = \sup_C v$. Hartogs' lemma applied at moving maximum points gives $\limsup M_j \leq M$. A subsequence with limiting suprema below M would give v below that limit almost everywhere, hence everywhere, a contradiction. Thus $M_j \to M$.

By surjectivity, $(v_j - M_j) \circ p$ has supremum zero. Normalized compactness, Theorem 1.4.1, makes these pullbacks precompact in $L^1(X)$. On every relatively compact product chart over $C \setminus D$, where D is the finite set of critical values, Fubini's theorem and bounded smooth volume densities give local L^1 convergence to $(v - M) \circ p$. Every subsequential limit therefore equals this pullback off $p^{-1}(D)$, and hence almost everywhere, because that analytic set has smooth volume zero. All subsequential limits agree, so the entire normalized sequence converges. Adding $M_j \to M$ proves the assertion. □

Lemma 1.22.5 *A function $v \in \mathrm{QPSH}(C)$ has analytic singularities if and only if $v \circ p$ has analytic singularities.*

Proof Composing a local analytic presentation with p proves the forward implication. The pulled-back generators are not all identically zero, since a nonconstant map to a curve is open.

Conversely fix $s \in C$ and $x \in p^{-1}(s)$. In coordinates, choose a complex line through x on which $p - s$ has its finite order e and is nonconstant, as in the Lelong lemma. On that line write

$$(p - s)(\zeta) = h(\zeta)^e,$$

where h is a local biholomorphism fixing zero; take an analytic eth root of the nonvanishing factor of the germ. The restriction of $v \circ p$ to the line is not identically $-\infty$, since v is finite almost everywhere and this map is open. By Proposition 1.13.1, it has analytic singularities. In one variable its presentation is $r \log|\zeta|^2 + O(1)$ with $r \in \mathbb{Q}_{\geq 0}$, obtained by taking the least order of its finitely many generators. Changing to $w = h(\zeta)$ gives

$$v(s + w^e) = r \log|w|^2 + O(1).$$

Every sufficiently small t has an eth root w, so $v(s + t) = (r/e) \log|t|^2 + O(1)$. This is an analytic presentation on the base, including a bounded one when $r = 0$. □

1.22.4 The curve of fiber components

Dropping the connected-fiber hypothesis requires replacing the base by the curve of fiber components. The following construction is the curve case of Stein factorization. It also identifies the multiplicities needed when pulling back curvature measures.

Proposition 1.22.3 *Let $p : X \to C$ be a surjective holomorphic map, where X is a connected compact complex manifold of dimension $n \geq 1$ and C is a connected compact Riemann surface. There is a factorization*

$$X \xrightarrow{q} C' \xrightarrow{r} C, \qquad p = r \circ q,$$

where C' is a connected compact Riemann surface, q is surjective and holomorphic with connected fibers, and r is a finite holomorphic map. The points of $r^{-1}(s)$ correspond to the connected components of $p^{-1}(s)$, which are the fibers of q over those points. The factorization is unique up to a unique isomorphism commuting with q and r.

If $t \in r^{-1}(s)$ has ramification index e_t, then, as effective divisors with multiplicities,

$$[p^{-1}(s)] = \sum_{t \in r^{-1}(s)} e_t [q^{-1}(t)].$$

The degree of r is the number of components of a regular fiber of p.

Proof We first construct the covering over the regular values, complete it across the critical values, and then extend its component quotient to X.

The critical values form a finite set $D \subset C$, by the critical-set argument in the proof of Proposition 1.22.2; that argument does not use connectedness of the fibers. Over $C^\circ = C \setminus D$, the map p is a proper submersion. The local construction in Lemma 1.22.2 applies there: horizontal transport over a disk has compact inverse image over its closure. Compact fibers have finitely many components, and the resulting local labels are glued by locally constant permutations. We obtain

$$X^\circ \xrightarrow{q^\circ} C'^\circ \xrightarrow{r^\circ} C^\circ, \qquad X^\circ = p^{-1}(C^\circ),$$

with q° a holomorphic submersion with connected fibers and r° a finite unramified covering of degree d. The complement of a proper analytic subset in a connected complex manifold is connected, so X° and its image C'° are connected. Here only the fiber divisor is removed. Locally, the complement of the zero set of a nonzero holomorphic function in a ball is path connected: join two outside points through an outside intermediate point by two complex-line disks. Each restriction is nonzero because it contains an outside endpoint, and its isolated zeros can be avoided. Applying this local argument along a chain of balls proves the required global connectedness.

For each $s \in D$, take a small coordinate disk centered at s and disjoint from the other critical values. A connected component of the covering over its puncture is a finite connected covering of a punctured disk, of some degree e. It has a coordinate w in which $r^\circ(w) = w^e$: the universal cover of the punctured disk is a half-plane with projection $z = \exp \zeta$, and the index-e subgroup of its deck group is generated by $\zeta \mapsto \zeta + 2\pi i e$. The coordinate $w = \exp(\zeta/e)$ gives the asserted form. Attach one point $w = 0$ to each such component. There are finitely many, with their degrees summing to d. Gluing these disks to C'° gives a connected Riemann surface C' and a finite holomorphic map $r : C' \to C$. The new points have disjoint disk neighborhoods, so this gluing is Hausdorff. The inverse image of a small closed base disk is a finite union of closed disks; over the complement of their interiors, the original finite covering is proper. Thus C' is compact.

We extend q°. Fix $x \in p^{-1}(s)$, $s \in D$. On a small coordinate ball B about x, the image of p lies in the chosen disk. The complement $B \setminus p^{-1}(s)$ is connected. Its image under q° therefore lies in a single punctured disk just attached to C', since those disks are the connected components of r^{-1} of the punctured base disk. In its coordinate w, the function $w \circ q^\circ$ is holomorphic and bounded, and

$$(w \circ q^\circ)^e = p - s.$$

The bounded holomorphic removable-singularity theorem extends it across $p^{-1}(s) \cap B$. To see this without assuming that the divisor is smooth, first extend at its smooth points by the one-variable theorem in transverse coordinates. The singular locus of the reduced divisor has complex codimension at least two in the ambient manifold, so Hartogs extension across that locus completes the extension. In dimension one there are only isolated points. Its eth power remains $p - s$ by the identity theorem,

and hence its value is zero on that fiber. This defines a holomorphic map from B to the attached disk. The local extensions agree on their dense common regular locus and therefore glue to $q : X \to C'$ with $p = r \circ q$. Its image is closed, by compactness, and contains the dense set C'°, so q is surjective.

Every fiber of q is connected. Otherwise write one fiber as a union of two disjoint nonempty compact subsets and put them in disjoint open neighborhoods U_1, U_2. Properness gives a disk V about their base point t such that

$$q^{-1}(V) \subset U_1 \cup U_2.$$

The map q is open: at any point, a complex line on which the nonconstant germ $q - t$ has its first nonzero term gives an open one-variable restriction. Consequently both $q(U_i)$ contain a neighborhood of t. A nearby point of C'° then has a fiber meeting both neighborhoods, contradicting connectedness of the regular fibers.

The fibers of p are the disjoint union of these connected q-fibers over the finitely many points of $r^{-1}(s)$. They are its components. Locally at t, the formula for a finite map is $r(w) - s = w^{e_t}$ after changing the coordinate by a holomorphic root of a nonvanishing factor. Pulling back this equality by q gives the divisor multiplicities stated above. Over C°, r is unramified and each sheet is one component, proving the degree assertion.

Finally, any factorization with the stated properties has over C° precisely this covering of fiber components. It is unramified there: a critical point of its finite map, together with surjectivity of its first factor, would make p critical over that base point. Thus the component identification is holomorphic on C'°. On every punctured disk it identifies two completions of the same finite covering, and the coordinates w^e above extend it biholomorphically across the added point. It gives a global isomorphism; density and surjectivity make it unique and give commutation with both maps. □

1.22.5 Finite maps between curves

Let $r : C' \to C$ be a finite surjective holomorphic map of degree d between connected compact Riemann surfaces. Write e_x for its local degree at $x \in C'$, so that $\sum_{r(x)=s} e_x = d$ for every $s \in C$. Fix a smooth real $(1,1)$-form β on C and put $\sigma = r^*\beta$. Potentials in background σ need not descend to C. Taking the maximum on each fiber nevertheless gives a base potential that dominates the original potential after pullback. Its Lelong numbers are the smallest ramification-adjusted Lelong numbers on the fiber.

Lemma 1.22.6 *For $h \in \mathrm{PSH}(C', \sigma)$, the function*

$$m_h(s) = \max_{r(x)=s} h(x)$$

belongs to $\mathrm{PSH}(C, \beta)$ *and satisfies $h \le m_h \circ r$. For every $s \in C$,*

$$\nu(m_h, s) = \min_{r(x)=s} \frac{\nu(h,x)}{e_x}.$$

If $v \in \mathrm{PSH}(C, \beta)$, then $h \preceq v \circ r$ implies $m_h \preceq v$. The analogous implication holds for the all-weight ideal order.

Proof On a base disk choose a smooth function a with $\mathrm{dd}^{\mathrm{c}} a = \beta$. Off the branch values, $m_h + a$ is the maximum of finitely many subharmonic functions obtained from $h + a \circ r$ by inverse branches. It is subharmonic there and locally bounded above. The removable-singularity theorem extends it across the branch values. This extension has the stated value: upper semicontinuity and properness give the upper bound at the fiber, while the genuine upper limits of $h + a \circ r$ at its points give the reverse bound. Thus the extensions glue. The function is not identically $-\infty$, since h is finite at some point. This proves the curvature inequality and $h \le m_h \circ r$.

Choose coordinates in the disjoint disks over s so that the map on the disk centered at x is $t = z^{e_x}$. Then

$$\sup_{|t|<\delta} m_h(t) = \max_{r(x)=s} \sup_{|z|<\delta^{1/e_x}} h(z).$$

Divide by $\log \delta^2 < 0$ and use the supremum definition of Lelong number. Each quotient on the right tends to $\nu(h,x)/e_x$, and the maximum becomes the minimum after division. Smooth local corrections do not affect these limits.

An ordinary bound $h \le v \circ r + c$ gives $m_h \le v + c$ on every fiber. On a curve, the all-weight ideal order is equivalent to the pointwise Lelong inequalities, by Theorem 1.16.1. The pullback formula Lemma 1.22.3 makes $h \preceq_{\mathcal{I}} v \circ r$ equivalent to $\nu(h,x) \ge e_x \nu(v, r(x))$ at every x. The minimum formula gives the required base inequalities. □

Finite pullback of measures includes ramification at atoms. For a continuous real function f on C', put

$$(\mathrm{Tr}_r\, f)(s) = \sum_{r(x)=s} e_x f(x).$$

This function is continuous: in the local description $t = z^e$, the e values tend to the same value at the branch point. For a finite positive measure μ on C, define $r^*\mu$ by

$$\int_{C'} f\, \mathrm{d}(r^*\mu) = \int_C \mathrm{Tr}_r\, f\, \mathrm{d}\mu,$$

and extend the definition to signed measures by linearity. Positivity and the bound $|\mathrm{Tr}_r\, f| \le d\|f\|_\infty$ give a finite measure by the Riesz representation theorem.

Lemma 1.22.7 *For every finite signed measure μ and Borel set $B \subset C$,*

$$r_* r^*\mu = d\mu, \qquad \|r^*\mu\|_{\mathrm{TV}} = d\|\mu\|_{\mathrm{TV}},$$
$$r^*(\mathbf{1}_B \mu) = \mathbf{1}_{r^{-1}(B)} r^*\mu, \qquad r^*\delta_s = \sum_{r(x)=s} e_x \delta_x.$$

For $v \in \mathrm{PSH}(C, \beta)$, writing $T_v = \beta + \mathrm{dd}^{\mathrm{c}} v$ and $\mu_v = \mathbf{1}_{\{v=-\infty\}} T_v$, one has

$$T_{v\circ r} = r^* T_v, \qquad \mu_{v\circ r} = r^* \mu_v.$$

Images and inverse images of polar sets under r are polar. Pullback and pushforward of positive measures commute with taking the atomic part.

Proof The trace of $g \circ r$ is dg, giving the pushforward identity. The same weighted fiber formula for Borel test functions follows from the monotone-class theorem and gives the restriction and atom formulas. The positive and negative Jordan parts of a signed measure have disjoint Borel carriers; their pullbacks are positive with disjoint inverse-image carriers. Each has d times its original mass, which proves the total-variation identity.

Choose a local smooth a with $\mathrm{dd}^{\mathrm{c}} a = \beta$; then $v + a$ is a subharmonic potential of T_v. Its Riesz representation is a logarithmic potential plus a harmonic function. In coordinates $t = z^e$, the identity

$$\mathrm{dd}^{\mathrm{c}}_z \log|z^e - t|^2 = \sum_{z^e=t} \mathrm{ord}_z(z^e - t)\delta_z$$

shows that pulling back this potential gives the weighted measure above. Fubini's theorem applies locally: factorization of $z^e - t$ into its e linear factors gives a uniform local L^1 bound for these logarithmic kernels as t varies on a smaller disk. The harmonic term has zero Hessian after pullback. This proves $T_{v\circ r} = r^* T_v$. The pole set of $v \circ r$ is exactly $r^{-1}\{v = -\infty\}$, so the restriction formula proves the polar identity.

Inverse images of polar sets are polar by composition of local subharmonic witnesses. For images, take local witnesses on the finitely many inverse-image disks of a small base disk. Off the branch values, the sum of their values over the inverse branches is subharmonic and is $-\infty$ wherever any witness has a pole. It is locally bounded above and is not identically $-\infty$. Its extension across the branch values is

subharmonic. Adding the finitely many branch values to the resulting polar set still gives a polar set. This proves the image assertion locally, hence globally.

The pullback of a nonatomic measure has no atoms by the atom formula. The pushforward of a nonatomic measure has no atoms because every fiber is finite. Atomic measures pull back and push forward to atomic measures. Splitting a positive measure into these two parts proves the last assertion. □

1.22.6 Modifications

Proposition 1.22.4 *Let $\pi : Y \to X$ be a modification of connected compact complex manifolds, and let θ be a smooth real $(1,1)$-form on X. Pullback gives a bijection*

$$\mathrm{PSH}(X,\theta) \longrightarrow \mathrm{PSH}(Y,\pi^*\theta).$$

Proof Let $S \subset X$ be a proper analytic subset over whose complement π is an isomorphism, and put $D = \pi^{-1}(S)$. By Lemma 1.22.1, pullback preserves the curvature inequality, and the pullback of a θ-plurisubharmonic function is not identically $-\infty$, since π is an isomorphism off D. The pullback map is injective because π is surjective.

To prove surjectivity, let $b \in \mathrm{PSH}(Y,\pi^*\theta)$, and define $u = b \circ \pi^{-1}$ off S. On a coordinate neighborhood in X, choose a smooth function ρ with $\mathrm{dd^c}\rho \geq \theta$. Then $b + \rho \circ \pi$ is plurisubharmonic on the inverse image of this neighborhood. By properness, its local upper bounds give a local upper bound for $u + \rho$ near S, so the removable-singularity theorem extends $u + \rho$ plurisubharmonically across S. The resulting quasi-plurisubharmonic extensions of u agree almost everywhere on overlaps, hence everywhere, and glue to a function on X.

The current $\theta + \mathrm{dd^c}u$ is positive off S. Locally it is the sum of the positive current $\mathrm{dd^c}(u + \rho)$ and the smooth form $\theta - \mathrm{dd^c}\rho$. The smooth form gives S zero mass, so the restriction of $\theta + \mathrm{dd^c}u$ to S is positive as well. Thus $u \in \mathrm{PSH}(X,\theta)$. The plurisubharmonic functions $b + \rho \circ \pi$ and $(u + \rho) \circ \pi$ agree off D, hence almost everywhere, hence everywhere. Therefore $b = u \circ \pi$. □

Pullback by a modification preserves L^1 convergence within a family with a common lower curvature bound. Compactness controls the pullbacks near the exceptional locus, where a direct change of variables would involve a vanishing Jacobian.

Lemma 1.22.8 *Let $\pi : Y \to X$ be a modification between connected complex manifolds, and let θ be a smooth real $(1,1)$-form on X. If $v_j \to v$ in $L^1_{\mathrm{loc}}(X)$ and all v_j, v belong to $\mathrm{PSH}(X,\theta)$, then*

$$v_j \circ \pi \longrightarrow v \circ \pi \quad \text{in } L^1_{\mathrm{loc}}(Y).$$

In particular, on compact manifolds this is convergence in L^1.

Proof By Lemma 1.4.1, the functions v_j are uniformly bounded above on relatively compact subsets of X. The pullbacks are therefore locally uniformly bounded above and have the common smooth lower curvature bound $-\pi^*\theta$. After a smooth local correction, the compactness theorem for plurisubharmonic functions shows that every subsequence has a further subsequence that either converges in L^1_{loc} or tends locally uniformly to $-\infty$ on each connected coordinate region in Y.

Every such region meets the complement of the exceptional locus. There π is a biholomorphism, and change of variables gives L^1_{loc} convergence to $v \circ \pi$, which excludes convergence to $-\infty$. Each subsequential limit agrees with $v \circ \pi$ off the exceptional locus, hence almost everywhere, since this analytic set has smooth volume zero. Thus the limit is unique, and applying this argument on a countable cover by coordinate regions proves convergence of the whole sequence in $L^1_{\mathrm{loc}}(Y)$. □

Convergence in capacity is also preserved by modifications. The comparison takes place away from small neighborhoods of the exceptional sets, so no uniform comparison of capacities on the whole manifolds is needed.

Lemma 1.22.9 *Let $\pi : Y \to X$ be a modification between connected compact complex manifolds, equipped with Hermitian forms ω_Y, ω_X. Write $\mathrm{Cap}_Y = \mathrm{Cap}_{\omega_Y}$ and $\mathrm{Cap}_X = \mathrm{Cap}_{\omega_X}$ for the Hermitian capacities of Section 1.8. For quasi-plurisubharmonic functions v_j, v on X,*

$$v_j \longrightarrow v \text{ in capacity on } X \quad \Longleftrightarrow \quad v_j \circ \pi \longrightarrow v \circ \pi \text{ in capacity on } Y.$$

Proof Choose a proper analytic subset $S \subset X$ such that π is an isomorphism outside $D = \pi^{-1}(S)$. Both S and D have capacity zero. For $\epsilon > 0$, choose an open neighborhood V of D of capacity less than ϵ. By properness, there is a neighborhood U_0 of S with $\pi^{-1}(U_0) \subset V$; shrink it to an open set U with $\mathrm{Cap}_X(U) < \epsilon$. The inverse of π is biholomorphic near the compact set $X \setminus U$. A finite cover by nested coordinate charts and the comparison of local and global capacities in Section 1.8 give a constant C_ϵ such that, for every Borel set $E \subset X$,

$$\mathrm{Cap}_Y(\pi^{-1}E) \le \epsilon + C_\epsilon \, \mathrm{Cap}_X(E),$$
$$\mathrm{Cap}_X(E) \le \epsilon + C_\epsilon \, \mathrm{Cap}_Y(\pi^{-1}E).$$

Apply these inequalities to $E = \{|v_j - v| > \delta\}$ for each fixed $\delta > 0$, omitting the pluripolar pole sets, and let first $j \to \infty$ and then $\epsilon \downarrow 0$. □

1.22.7 Multiplier ideals under modifications

Throughout this subsection, $\pi : Y \to X$ is a modification of connected compact complex manifolds of dimension n. There is an analytic subset $S \subset X$ of codimension at least two such that π is an isomorphism over $X \setminus S$. Let K_X and K_Y be the canonical line bundles. Set $D = \pi^{-1}(S)$ and

$$R_\pi = K_Y \otimes \pi^* K_X^{-1}.$$

The determinant of the differential of π is a canonical holomorphic section J_π of R_π; in local coordinates its coefficient is the holomorphic Jacobian determinant $\operatorname{Jac}\pi$, and its zeros are contained in D. These standard facts about modifications of complex manifolds include the case $n = 1$, in which every modification is an isomorphism.

Lemma 1.22.10 *Let a be quasi-plurisubharmonic on X. Pullback followed by multiplication with J_π induces an isomorphism*

$$\pi_*\big(R_\pi \otimes \mathcal{I}(a \circ \pi)\big) = \mathcal{I}(a).$$

More precisely, for every holomorphic line bundle M on X, the map

$$s \longmapsto J_\pi\, \pi^* s$$

is an isomorphism

$$H^0\big(X, M \otimes \mathcal{I}(a)\big) \simeq H^0\big(Y, \pi^* M \otimes R_\pi \otimes \mathcal{I}(a \circ \pi)\big).$$

Proof The assertion is local on X. In coordinates and local frames, the map sends a holomorphic coefficient f to $(f \circ \pi)\operatorname{Jac}\pi$. By the change-of-variables formula, local integrability of

$$|f|^2 \mathrm{e}^{-a} \quad \text{and} \quad |f \circ \pi|^2 |\operatorname{Jac}\pi|^2 \mathrm{e}^{-a\circ\pi}$$

are equivalent. For the implication from integrability on Y to integrability near a point of X, take a smaller relatively compact neighborhood of the point; by properness, its inverse image has compact closure, so finitely many charts on which the integrability holds suffice. Smooth positive coordinate densities are comparable on these charts, and analytic exceptional sets have smooth volume zero, so they do not change the integrals.

It remains to show that every section on Y is of the form $J_\pi \pi^* s$. Divide it by J_π off D and use the inverse of π there; this gives a holomorphic section of M off S. Since S has codimension at least two, Hartogs' extension theorem gives a holomorphic section s on X. Its image $J_\pi \pi^* s$ agrees with the given section off D, hence everywhere by the identity theorem. The integrability equivalence then places s in the required multiplier ideal. The same argument on each open set proves the sheaf identity as well as the global identification. □

Note that the lemma does not identify $\pi^*\mathcal{I}(a)$ with $\mathcal{I}(a\circ\pi)$: the Jacobian is part of the holomorphic coefficient on Y and cannot be removed from the integrability test.

We also need the invariance of the ideal order $\preceq_{\mathcal{I}}$ of Section 1.12, which involves all positive weights. The proof is local, so that we never have to extend a modification of a small open subset of Y to a global one.

Lemma 1.22.11 *For quasi-plurisubharmonic a, b on X,*

$$a \preceq_{\mathcal{I}} b \quad\Longleftrightarrow\quad a\circ\pi \preceq_{\mathcal{I}} b\circ\pi.$$

The assertion is local on X and also holds for a proper bimeromorphic map between noncompact smooth complex manifolds.

Proof The reverse implication follows at every positive weight from the sheaf identity in Lemma 1.22.10: tensor the inclusion of ideals on Y with R_π and apply the left-exact direct image functor. The proof of that sheaf identity is local on the target, since properness makes each fiber compact and gives the required finite cover by integrability charts; compactness of the manifolds themselves is not needed.

For the forward implication, fix a coordinate neighborhood $W \subset Y$, a local modification $\sigma : Z \to W$ with smooth source, and a prime divisor E on Z. After shrinking W around the point under consideration, its image is contained in a coordinate neighborhood $U \subset X$. Put $F = \pi\circ\sigma$ and

$$A_F(E) = 1 + \operatorname{ord}_E \operatorname{Jac} F.$$

The map F is holomorphic, and it is injective and biholomorphic off a proper analytic subset; it need not be a proper modification of U.

Let m be a positive integer, and let ν_E and ord_E be the generic Lelong number and the generic vanishing order along E, as in Section 1.17. The proof of Lemma 1.17.7 applies to the map F on relatively compact coordinate patches and gives

$$\max\left\{\nu_E(a\circ F) - \frac{A_F(E)}{m}, 0\right\} \le \frac{1}{m}\operatorname{ord}_E\big(\mathcal{I}(ma)\mathcal{O}_Z\big) \le \nu_E(a\circ F).$$

In more detail, the upper inequality follows by pulling back the local Bergman lower bound on U. For the lower one, a germ $f \in \mathcal{I}(ma)$ pulls back to a coefficient $(f\circ F)\operatorname{Jac} F$ that is square integrable against $\mathrm{e}^{-ma\circ F}$, because on a relatively compact patch of Z the change-of-variables integral is bounded by the integral over the image of the patch. Generic divisorial removal and the one-variable integral then give

$$\operatorname{ord}_E(f\circ F) + A_F(E) > m\nu_E(a\circ F).$$

This estimate only uses the injectivity of F off the exceptional set and the compactness of the patch, not properness of F over U. The same estimates hold for b.

The hypothesis gives $\mathcal{I}(ma) \subseteq \mathcal{I}(mb)$ for every $m > 0$, so the orders of the pulled-back ideals satisfy the reverse inequality. Letting $m \to \infty$ in the two estimates proves

$$\nu_E(a \circ F) \geq \nu_E(b \circ F).$$

This holds for every local divisor over Y. Blowing up a point on the source of any local modification recovers the Lelong number at that point as a generic Lelong number along the exceptional divisor; in dimension one the point already is a divisor. The local criterion in Theorem 1.16.1 now gives $a \circ \pi \preceq_{\mathcal{I}} b \circ \pi$. No extension of σ beyond its local domain was used. □

Lemma 1.22.12 *For a proper bimeromorphic map $\rho : Z \to Y$ between complex manifolds and quasi-plurisubharmonic functions a, b on Y,*

$$a \sim_{\mathcal{I}} b \quad \Longleftrightarrow \quad a \circ \rho \sim_{\mathcal{I}} b \circ \rho.$$

The statement is local on Y.

Proof Apply the local order equivalence of Lemma 1.22.11 to both (a, b) and (b, a). Together, the two order relations are equivalent to equality of the multiplier ideals at every positive weight. □

1.22.8 Restriction of analytic approximants

A quasi-plurisubharmonic function with zero generic Lelong number along a submanifold may still restrict to the function identically equal to $-\infty$ (Section 1.13). Analytic regularization removes this obstruction: the restrictions of the analytic approximants are quasi-plurisubharmonic, and a fixed lower curvature bound controls their generic Lelong numbers along divisors on every fixed modification.

Corollary 1.22.2 *Let θ be a smooth real $(1,1)$-form and $u \in \mathrm{PSH}(X, \theta)$, and let u_m, with curvature errors ϵ_m, be the approximants of Corollary 1.15.1. Let $Y \subset X$ be a connected compact complex submanifold along which the generic Lelong number of u vanishes:*

$$\nu(u, Y) = \inf_{y \in Y} \nu(u, y) = 0.$$

Then each restriction $u_m|_Y$ is quasi-plurisubharmonic on Y; in particular, it is not identically $-\infty$. If $\pi : Z \to Y$ is a modification with smooth compact source and $E \subset Z$ is a prime divisor, then

$$\sup_m \nu\big((u_m|_Y) \circ \pi, E\big) < \infty.$$

Proof For each m, choose $y \in Y$ with $\nu(u, y) < 1/m$. Skoda's local integrability criterion gives $\mathcal{I}(mu)_y = \mathcal{O}_{X,y}$, so the image ideal $\mathcal{I}(mu)\mathcal{O}_Y$ does not vanish identically. Since u_m has analytic type $(1/m, \mathcal{I}(mu))$, Proposition 1.13.1 shows that $u_m|_Y$ is quasi-plurisubharmonic on Y. Its pullback to Z is quasi-plurisubharmonic as well, since π is biholomorphic off a proper analytic subset.

Restricting and pulling back the curvature inequality of Corollary 1.15.1, which is allowed by Lemma 1.22.1, gives

$$\pi^*(\theta|_Y) + \mathrm{dd}^{\mathrm{c}}\big((u_m|_Y)\circ\pi\big) \geq -\epsilon_m\pi^*(\omega|_Y).$$

Since the errors ϵ_m are bounded, a sufficiently large multiple of a single Hermitian form on Z dominates $\pi^*(\theta|_Y) + \epsilon_m\pi^*(\omega|_Y)$ for all m. Lemma 1.17.6, applied on Z in this fixed background, therefore bounds the generic Lelong numbers along E uniformly in m. □

1.23 Integration against non-pluripolar measures

For uniformly bounded potentials, L^1 convergence with respect to a smooth volume form can be transferred to any fixed finite measure that does not charge pluripolar sets. Passing to bounded exponentials extends this to families that are only bounded above. The same mechanism applies to moving mixed Monge–Ampère measures of bounded potentials and to smoothings of a fixed measure.

1.23.1 A fixed measure

Cegrell's fixed-measure convergence lemma states that a uniformly bounded sequence of plurisubharmonic functions converging in L^1_{loc} converges in $L^1(\nu)$ on compact subsets, for every finite non-pluripolar measure ν. The usual formulation, which allows passing to a subsequence, gives the same conclusion: apply it to every subsequence after extracting a further subsequence converging almost everywhere for the smooth volume, and use the subsequence criterion for convergence. This is the classical fixed-measure argument used in [GZ17, Section 11.1.2], and we use this local lemma as a standard input.

Lemma 1.23.1 *Let ν be a finite non-pluripolar measure on X. If uniformly bounded quasi-plurisubharmonic functions a_j, a have a common smooth lower curvature bound and $a_j \to a$ in $L^1(X)$, then*

$$\int_X |a_j - a|\, \mathrm{d}\nu \longrightarrow 0.$$

If instead $u_j, u \in \mathrm{PSH}(X,\theta)$ have a common upper bound and $u_j \to u$ in $L^1(X)$, then, for every $b > 0$,

$$\int_X |\mathrm{e}^{bu_j} - \mathrm{e}^{bu}|\, \mathrm{d}\nu \longrightarrow 0.$$

Proof For the first statement, add a fixed smooth strictly plurisubharmonic function on each of finitely many coordinate balls, so that the resulting functions are uniformly bounded and plurisubharmonic there. Apply the local lemma on smaller compact balls covering X and sum the integrals; the added functions cancel in the differences.

For the second statement, choose $A > 0$ with $A\omega \geq \theta$. If $u_j \leq C$, the convex chain rule gives $\mathrm{dd^c e}^{bu_j} \geq -bA\mathrm{e}^{bC}\omega$, also for unbounded u_j by bounded truncation; here the exponential is given the value zero at a pole. Thus the functions e^{bu_j} are uniformly bounded and quasi-plurisubharmonic, with a common lower curvature bound. They converge in $L^1(\mathrm{d}V)$, because the exponential is Lipschitz with constant $b\mathrm{e}^{bC}$ on $(-\infty, C]$. The first statement now applies. □

1.23.2 Vanishing exponents

Proposition 1.23.1 *Let $\varphi \in \mathrm{PSH}(X,\theta)$ be unbounded below, and for each $\lambda > 0$ let u_λ be a quasi-plurisubharmonic function with $u_\lambda \sim \varphi$. Then, for each $\lambda > 0$, the function λu_λ has infinite distance in $L^\infty(\mathrm{d}V)$ from every constant. In particular, λu_λ cannot converge uniformly on X to a finite constant as $\lambda \downarrow 0$.*

Proof Since $u_\lambda \leq \varphi + C$ for a constant C, the function u_λ is unbounded below. Every nonempty strict sublevel set $\{u_\lambda < t\}$ of the upper semicontinuous function u_λ is open, hence of positive smooth volume. Thus u_λ, and with it λu_λ, is essentially unbounded below, and both conclusions follow. □

A vanishing exponent gives convergence of the exponentials to one, even when the normalized potentials vary.

Lemma 1.23.2 *Let $v_j \in \mathrm{PSH}(X,\theta)$ satisfy $\sup_X v_j = 0$, and let $\lambda_j > 0$ decrease to zero. For every finite non-pluripolar measure μ,*

$$\int_X \left|\mathrm{e}^{\lambda_j v_j} - 1\right| \mathrm{d}\mu \longrightarrow 0.$$

If $f \in L^p(\mathrm{d}V)$ for some $p > 1$, then more precisely

$$\int_X \left|\mathrm{e}^{\lambda_j v_j} - 1\right| |f| \,\mathrm{d}V \leq C_p \lambda_j \|f\|_{L^p(\mathrm{d}V)}.$$

The constant depends on the fixed background, p and $\mathrm{d}V$.

Proof Choose a Hermitian form $\Omega \geq \theta$, so that $v_j \in \mathrm{PSH}(X,\Omega)$. By Lemma 1.8.1, for every $T > 1$,

$$\mathrm{Cap}_\Omega(\{v_j < -T\}) \leq C/T$$

uniformly in j. Since $v_j \leq 0$ and $1 - \mathrm{e}^{-x} \leq x$ for $x \geq 0$, splitting the integral at this sublevel set gives

$$\int_X (1 - \mathrm{e}^{\lambda_j v_j}) \,\mathrm{d}\mu \leq \lambda_j T \mu(X) + \mu(\{v_j < -T\}).$$

By Lemma 1.8.8, the second term is uniformly small when T is large, and for this fixed T the first term tends to zero as $j \to \infty$. This proves the general assertion; here the exponential is given the value zero at a pole, and pole sets have zero μ-measure.

For the quantitative assertion, Lemma 1.5.1, applied in the background Ω, gives a uniform L^q bound for $-v_j$, where $q = p/(p-1)$. Hölder's inequality and the bound

$$0 \leq 1 - \mathrm{e}^{\lambda_j v_j} \leq \lambda_j |v_j|$$

give the claimed estimate for every j. □

1.23.3 Measures with bounded potentials

The fixed measure can be replaced by moving mixed Monge–Ampère measures of uniformly bounded potentials, provided these potentials converge in capacity. Since ω need not be closed, the proof has to control the torsion terms that appear in integration by parts.

Lemma 1.23.3 *Let $a_j, a, w_j, w \in \mathrm{PSH}(X,\omega)$ be uniformly bounded, and write $\omega_v = \omega + \mathrm{dd^c} v$. If $a_j \to a$ in $L^1(X)$ and $w_j \to w$ in capacity, then, for $0 \leq k \leq n$,*

$$\int_X |a_j - a| \,\omega_{w_j}^k \wedge \omega^{n-k} \longrightarrow 0.$$

The same conclusion holds if, instead of $a_j, a \in \mathrm{PSH}(X,\omega)$, the uniformly bounded functions a_j, a have any fixed smooth lower curvature bound.

Proof By Lemma 1.4.1, the tail envelopes $A_j = (\sup_{\ell\geq j} a_\ell)^*$ decrease to a. Since $a \leq \max(a_j, a) \leq A_j$, monotone convergence in capacity of bounded potentials (Lemma 1.8.9) implies

$$\alpha_j := \max(a_j, a) \longrightarrow a \quad \text{in capacity.}$$

We split $|a_j - a| = (\alpha_j - a) + (\alpha_j - a_j)$. The integral of the first part against the moving products tends to zero by Lemma 1.8.6.

For the second part, put $h_j = \alpha_j - a_j \geq 0$. We compare its integrals against the measures with indices j and ℓ. The case $k = 0$ follows from the assumed L^1 convergence. For $k \geq 1$, put $z = w_j - w_\ell$ and

$$T = \sum_{s=0}^{k-1} \omega_{w_j}^s \wedge \omega_{w_\ell}^{k-1-s} \wedge \omega^{n-k}.$$

Factorization and Stokes' theorem on the compact manifold X give

$$\int_X h_j\big(\omega_{w_j}^k - \omega_{w_\ell}^k\big) \wedge \omega^{n-k} = \int_X h_j \mathrm{dd^c} z \wedge T = \int_X z\, \mathrm{dd^c}(h_j T).$$

Since ω is not assumed to be closed, T need not be closed, and the product rule reads

$$\mathrm{dd^c}(h_j T) = \mathrm{dd^c} h_j \wedge T + \mathrm{d}h_j \wedge \mathrm{d^c} T - \mathrm{d^c} h_j \wedge \mathrm{d}T + h_j \mathrm{dd^c} T. \tag{1.42}$$

None of the terms involving derivatives of T need vanish.

We estimate the four terms. Since $\mathrm{dd^c} h_j = \omega_{\alpha_j} - \omega_{a_j}$, the absolute contribution of the first is at most

$$\int_X |z|(\omega_{\alpha_j} + \omega_{a_j}) \wedge T.$$

It tends to zero as $j, \ell \to \infty$ by Lemma 1.8.6, since $w_j - w_\ell \to 0$ in capacity. Differentiating each factor shows that $\mathrm{d}T = \mathrm{d}\omega \wedge R$ and $\mathrm{d^c}T = \mathrm{d^c}\omega \wedge R$, where R is a positive linear combination of mixed products of bidegree $(n-2, n-2)$. Moreover, $\mathrm{dd^c}T$ is a sum of terms consisting of $\mathrm{dd^c}\omega$ times mixed products of degree $n-2$, or of $\mathrm{d}\omega \wedge \mathrm{d^c}\omega$ times mixed products of degree $n-3$; terms of negative degree are absent. These smooth torsion factors are bounded in absolute value by fixed multiples of ω^2 and ω^3, respectively. As h_j is uniformly bounded, the contribution of $h_j \mathrm{dd^c} T$ also tends to zero, by the same capacity estimate.

For the two gradient terms, the pointwise Cauchy–Schwarz inequality for a positive mixed product gives, for example,

$$\left|\int_X z\,\mathrm{d}h_j\wedge\mathrm{d}^{\mathrm{c}}\omega\wedge R\right|^2 \le C\left(\int_X |z|\,\mathrm{d}h_j\wedge\mathrm{d}^{\mathrm{c}}h_j\wedge\omega\wedge R\right)\left(\int_X |z|\,\omega^2\wedge R\right).$$

The second factor tends to zero, and the first is uniformly bounded. Indeed, if p is any of the uniformly bounded potentials and S any positive mixed product of degree $n-1$ occurring here, then

$$\int_X \mathrm{d}p\wedge\mathrm{d}^{\mathrm{c}}p\wedge S = \frac{1}{2}\int_X p^2\mathrm{dd}^{\mathrm{c}}S - \int_X p\,\mathrm{dd}^{\mathrm{c}}p\wedge S.$$

Expand $\mathrm{dd}^{\mathrm{c}}S$ with all its torsion terms as above, and write $\mathrm{dd}^{\mathrm{c}}p = \omega_p - \omega$. Boundedness of p and Lemma 1.8.6 bound both integrals uniformly. Finally, $\mathrm{d}h_j\wedge\mathrm{d}^{\mathrm{c}}h_j \le 2\mathrm{d}\alpha_j\wedge\mathrm{d}^{\mathrm{c}}\alpha_j + 2\mathrm{d}a_j\wedge\mathrm{d}^{\mathrm{c}}a_j$ as positive quadratic forms, which proves the asserted bound. The other gradient term is estimated in the same way. In dimension one, $T = 1$ and all torsion terms in (1.42) vanish.

These integration-by-parts and energy identities hold for smooth potentials. They extend to bounded potentials through smooth decreasing approximations in the Hermitian background, using the local Bedford–Taylor chain rule, its gradient products and quasi-continuity; equivalently, they follow from the bounded current calculus of Section 1.7. Only the common bound on the potentials enters the estimates.

We have shown that the difference between the integrals of h_j against the measures with indices j and ℓ tends to zero as $j,\ell\to\infty$. For a fixed index ℓ, the measure $\omega_{w_\ell}^k\wedge\omega^{n-k}$ is a fixed finite non-pluripolar measure, and Lemma 1.23.1, applied separately to $\alpha_j\to a$ and $a_j\to a$ in $L^1(X)$, gives

$$\int_X h_j\,\omega_{w_\ell}^k\wedge\omega^{n-k}\longrightarrow 0 \qquad \text{as } j\to\infty.$$

Choosing first ℓ large and then letting $j\to\infty$, we conclude that the integrals of h_j against $\omega_{w_j}^k\wedge\omega^{n-k}$ tend to zero. Together with the estimate for $\alpha_j - a$, this proves the result. If the a_j only have some other fixed lower curvature bound, choose a Hermitian form $\Omega\ge\omega$ such that they are Ω-plurisubharmonic. By Section 1.8, convergence in capacity is unchanged by this replacement. Apply the result just proved with Ω in place of ω; by positivity, the original mixed measures are bounded by their counterparts for Ω. □

1.23.4 Smoothing the measure

Convolution in coordinate charts gives smooth approximations of a finite measure. For a varying quasi-plurisubharmonic integrand, the submean inequality transfers the error to the original measure; this gives the additional control needed beyond weak convergence of the measures themselves.

For a smooth real $(1,1)$-form θ with $\mathrm{PSH}(X,\theta)\neq\varnothing$ and a non-pluripolar probability measure ν on X, put

$$A_\theta(\nu) = \sup\left\{\int_X (-w)\,\mathrm{d}\nu : w \in \mathrm{PSH}(X,\theta),\ \sup_X w = 0\right\}.$$

This number may be infinite. It is finite for Monge–Ampère measures of bounded potentials.

Lemma 1.23.4 *Let $\psi \in \mathrm{PSH}(X,\omega)$ be bounded, and put $\nu = (\omega + \mathrm{dd^c}\psi)^n$. There is a finite constant C, depending only on ω, θ, $\mathrm{d}V$ and $\|\psi\|_\infty$, such that*

$$\int_X (-w)\,\mathrm{d}\nu \le C \qquad (w \in \mathrm{PSH}(X,\theta),\ \sup_X w = 0).$$

Proof Choose finitely many pairs of concentric coordinate balls $B'_a \Subset B_a$ such that the B'_a cover X, and fixed smooth functions q_a, r_a on B_a with $\mathrm{dd^c} q_a \ge \omega$ and $\mathrm{dd^c} r_a \ge \theta$, with $r_a \le 0$. Then $\psi + q_a$ is bounded and plurisubharmonic, $w + r_a$ is negative and plurisubharmonic, and positivity of bounded products gives

$$\int_{B'_a} (-w)\,\mathrm{d}\nu \le \int_{B'_a} (-w - r_a)\big(\mathrm{dd^c}(\psi + q_a)\big)^n \le C_a\big(1 + \|w\|_{L^1(B_a)}\big).$$

The last step is the weighted Chern–Levine–Nirenberg estimate of Section 1.6. Summing over the cover and using the normalized L^1 bound of Theorem 1.4.1 proves the lemma. □

To construct the smoothings, choose finitely many coordinate balls B_a and smooth functions $\eta_a \ge 0$ with compact support in B_a and $\sum_a \eta_a = 1$. Let $\chi \ge 0$ be a smooth radial kernel of integral one supported in the unit ball of $\mathbb{C}^n$, and fix $\epsilon_j \downarrow 0$ so small that all convolutions below stay in the corresponding coordinate ball. For a function F, let $S_{a,j}F$ be its convolution, in the chart of B_a, with the kernel $\epsilon_j^{-2n}\chi(\cdot/\epsilon_j)$. For a probability measure ν on X, define a smooth probability measure ν_j by convolving each coordinate measure $\eta_a\nu$ with the same kernel and adding the extensions by zero. It is characterized by the identity

$$\int_X F\,\mathrm{d}\nu_j = \sum_a \int_X \eta_a S_{a,j} F\,\mathrm{d}\nu, \tag{1.43}$$

for Borel functions F; since the kernel is even, the same convolution occurs on the right. This identity first holds for nonnegative Borel functions and then for integrable signed functions. In particular, $\nu_j \rightharpoonup \nu$ weakly.

Lemma 1.23.5 *Let ν be a non-pluripolar probability measure with $A_\theta(\nu) < \infty$, and let ν_j be its smoothings defined by (1.43). Then*

$$\sup_j A_\theta(\nu_j) < \infty.$$

Moreover, let z_j, z be quasi-plurisubharmonic functions with a common upper bound and a common smooth lower curvature bound, and suppose that $z_j \to z$ both in $L^1(X)$ and in $L^1(\nu)$. Then

$$\int_X |z_j - z| \, \mathrm{d}\nu_j \longrightarrow 0. \tag{1.44}$$

Consequently, for every $\lambda > 0$,

$$\mathrm{e}^{\lambda z_j}\nu_j \rightharpoonup \mathrm{e}^{\lambda z}\nu.$$

Proof On each coordinate ball B_a choose a fixed smooth function q_a with $\mathrm{dd}^{\mathrm{c}} q_a \geq \theta$. If $w \in \mathrm{PSH}(X, \theta)$ and $\sup_X w = 0$, then $w + q_a$ is plurisubharmonic, and the submean inequality gives

$$-S_{a,j}w \leq -w + S_{a,j}q_a - q_a \leq -w + C,$$

with a constant independent of w and j. Integrating and using (1.43) proves $A_\theta(\nu_j) \leq A_\theta(\nu) + C$.

For the second assertion, the tail envelopes

$$H_j = \left(\sup_{k \geq j} z_k\right)^*$$

decrease to z by Lemma 1.4.1. Enlarge the functions q_a so that $H_j + q_a$, $z_j + q_a$ and $z + q_a$ are all plurisubharmonic. Since $H_j \geq z_j$ and $H_j \geq z$, we have $|z_j - z| \leq 2H_j - z_j - z$, and the identity (1.43) and the submean inequality imply

$$\begin{aligned}\int_X |z_j - z| \, \mathrm{d}\nu_j &\leq \sum_a \int_X \eta_a S_{a,j}(2H_j - z_j - z) \, \mathrm{d}\nu \\ &\leq 2\sum_a \int_X \eta_a \big(S_{a,j}(H_j + q_a) - (z + q_a)\big) \, \mathrm{d}\nu + \int_X (z - z_j) \, \mathrm{d}\nu.\end{aligned}$$

All these integrals are well defined: each function on the larger side of a submean inequality is bounded above, and its negative part is controlled by that of the integrable function on the smaller side plus a constant.

Radial averages of a plurisubharmonic function decrease when the radius decreases. Therefore $S_{a,j}(H_j + q_a)$ decreases to $z + q_a$ on the support of η_a: to identify the limit, fix an index k, use $H_j \leq H_k$ for $j \geq k$, let $j \to \infty$ in the radius, and then let $k \to \infty$; the reverse inequality is the submean inequality. The nonnegative integrand in the second line of the last display is dominated on this compact support by a

constant minus z, which is ν-integrable, so its integral tends to zero by dominated convergence. The final integral tends to zero by convergence in $L^1(\nu)$. This proves (1.44).

Since the exponential is Lipschitz on the common range of the functions, (1.44) also gives $\int_X |e^{\lambda z_j} - e^{\lambda z}|\,d\nu_j \to 0$. If $\zeta > 0$ is smooth, then $\zeta e^{\lambda z} = e^{\lambda z + \log \zeta}$ is bounded and quasi-plurisubharmonic. For any fixed bounded quasi-plurisubharmonic function F, the same local submean argument and dominated convergence in (1.43) give

$$\int_X F\,d\nu_j \longrightarrow \int_X F\,d\nu.$$

Applying this to $F = \zeta e^{\lambda z}$ gives $\int_X \zeta e^{\lambda z_j}\,d\nu_j \to \int_X \zeta e^{\lambda z}\,d\nu$ for every smooth $\zeta > 0$. Since every smooth function is a difference of two positive smooth functions, the convergence holds for all smooth test functions, and uniformly bounded masses together with uniform approximation of continuous functions by smooth ones prove weak convergence. □

1.24 Curvature of line bundles

Let M be a complex manifold and let θ be a smooth real $(1,1)$-form on M. To relate potentials to holomorphic sections, we ask when a current $\theta + dd^c u$, with u locally integrable, can be the curvature current of a metric on a line bundle. The transition law for the local weights of such a metric forces a closedness condition on the background.

Proposition 1.24.1 *The curvature current of a singular Hermitian metric with locally integrable weights on a holomorphic line bundle is closed. In particular, a nonclosed form θ cannot itself be the curvature current of such a metric, and $\theta + dd^c u$ is not closed on any neighborhood of a point where $d\theta \neq 0$.*

Proof Let h be a singular Hermitian metric on a holomorphic line bundle $L \to M$. Choose a local holomorphic frame e of L and write its squared norm as $|e|_h^2 = e^{-\varphi}$; the curvature current is then locally $dd^c\varphi$. If $e' = ge$ is another frame, with g holomorphic and nowhere zero, the new weight is $\varphi - \log|g|^2$. Since $\log|g|^2$ is pluriharmonic, these local currents agree on overlaps and glue to a global current, which is closed because $ddd^c = 0$. The final assertion follows from the identity

$$d(\theta + dd^c u) = d\theta$$

of currents. □

Accordingly, when we study sections subject to multiplier-ideal conditions, we specify both the line bundle, whose curvature is closed, and any auxiliary Hermitian form on M. An algebraic interpretation then requires relating the invariants of the line bundle to this analytic background.

1.25 Polar curvature

For $u \in \mathrm{PSH}(X, \theta)$, the restriction of the current $\theta + \mathrm{dd}^{\mathrm{c}} u$ to the pole set $\{u = -\infty\}$ is called the *polar curvature* of u. A bounded change of the potential preserves more than its Lelong numbers: it preserves the whole polar curvature. Indeed, a local energy estimate puts the bounded difference of two potentials in a Sobolev space, while pole sets admit smooth test functions of arbitrarily small energy, and these test functions show that no coefficient measure of the Hessian of the difference charges the pole set. Polar curvature is closed even when the pole set is not closed, so a local elliptic equation recovers it from its scalar Hermitian trace.

Lemma 1.25.1 *Let $U \subset \mathbb{R}^d$ be open and let $w \in L^\infty_{\mathrm{loc}}(U)$. If Δw is a locally finite signed Radon measure, then $w \in W^{1,2}_{\mathrm{loc}}(U)$.*

Proof Fix a smooth function $0 \le \psi \le 1$ with compact support in U, and a relatively compact open neighborhood V of its support. Mollify w inside V with a standard mollifier ρ_ε, writing $w_\varepsilon = w * \rho_\varepsilon$ and $\nu_\varepsilon = (\Delta w) * \rho_\varepsilon$. For small ε, integration by parts and Young's inequality give

$$\begin{aligned}\int \psi^2 |\nabla w_\varepsilon|^2 &= -\int \psi^2 w_\varepsilon \nu_\varepsilon - 2\int \psi w_\varepsilon \nabla\psi \cdot \nabla w_\varepsilon \\ &\le \|w\|_{L^\infty(V)} |\Delta w|(V) + \tfrac{1}{2}\int \psi^2 |\nabla w_\varepsilon|^2 + 2\int w_\varepsilon^2 |\nabla\psi|^2.\end{aligned}$$

Absorbing the middle term on the right, we obtain a bound for $\int \psi^2 |\nabla w_\varepsilon|^2$ that is independent of ε. Taking $\psi = 1$ on a prescribed smaller compact set, weak compactness in $W^{1,2}$ and convergence of the mollifications in L^2 identify the weak limit with w. This proves the assertion. □

Lemma 1.25.2 *Let v be quasi-plurisubharmonic on a complex manifold, let U be a coordinate ball with compact closure in a larger chart, and let $K \subset U \cap \{v = -\infty\}$ be compact. For every open $O \subset U$ containing K, there are real $\varphi_j \in C^\infty_c(O)$ with $0 \le \varphi_j \le 1$, equal to one near K, such that $\|\varphi_j\|_{W^{1,2}(U)} \to 0$. The norm uses the Euclidean coordinates.*

Proof Adding a smooth quadratic function and subtracting a constant, we obtain a negative plurisubharmonic function h on U with the same pole set as v. Put $h_M = \max(h, -M)$ for $M \ge 1$, and choose $\psi \in C^\infty_c(O)$ with $0 \le \psi \le 1$ and $\psi = 1$ near K. On a fixed compact neighborhood of $\operatorname{supp}\psi$, the positive measures Δh_M have uniformly bounded mass: choose a nonnegative smooth function χ with compact support in U, equal to one on this neighborhood, and use

$$\int \chi\, \Delta h_M = \int h_M \Delta\chi, \qquad |h_M| \le |h| \in L^1_{\mathrm{loc}}(U).$$

Apply the integration-by-parts estimate of the preceding proof to mollifications of h_M. Their absolute values are at most M, and their squares are at most M times their

absolute values. The uniform bounds for the mass of the Laplacians and for the local L^1 norms therefore give, after passing to the weak limit in $W^{1,2}$,

$$\int \psi^2 |\nabla h_M|^2 \leq CM, \qquad \left\| \frac{-\psi h_M}{M} \right\|^2_{W^{1,2}(U)} \leq \frac{C}{M}.$$

Here C depends on the fixed cutoffs and the local L^1 norm of h, but not on M. The second inequality also uses $h_M^2 \leq M|h|$ in the terms containing ψ and $\nabla\psi$.

The Sobolev function $-\psi h_M/M$ takes values between zero and one. It equals one on a neighborhood of K, since h is upper semicontinuous and therefore $\{h < -M\}$ is an open neighborhood of K. Extend it by zero and mollify with a sufficiently small radius: the support stays in O, the function remains equal to one on a smaller neighborhood of K, and its Sobolev norm does not increase. Letting $M \to \infty$ gives the required smooth functions. □

For a current T of order zero and a Borel set B, we write $\mathbf{1}_B T$ for the restriction of T to B, taken coefficientwise on the Radon coefficient measures of T. These restrictions commute with smooth changes of coordinates.

Proposition 1.25.1 *Let u, v be quasi-plurisubharmonic functions on a complex manifold such that every point has a neighborhood on which $u - C \leq v \leq u + C$ for some constant C. Then u and v have the same pole set $S = \{u = -\infty\} = \{v = -\infty\}$, and*

$$\mathbf{1}_S \mathrm{dd}^{\mathrm{c}} u = \mathbf{1}_S \mathrm{dd}^{\mathrm{c}} v.$$

Consequently, for any smooth real $(1,1)$-forms θ, β,

$$\mathbf{1}_S(\theta + \mathrm{dd}^{\mathrm{c}} u) = \mathbf{1}_S(\beta + \mathrm{dd}^{\mathrm{c}} v).$$

Proof The two local inequalities show that the pole sets agree. Off S put $w = u - v$, and give w arbitrary bounded values on S. Since S has Lebesgue measure zero, this defines the locally bounded distribution $u - v$. The coefficient measures of $\mathrm{dd}^{\mathrm{c}} w$ are locally finite, since after a smooth correction the complex Hessians of u and v are positive currents of order zero. Taking the Euclidean trace shows that Δw is a signed Radon measure, so Lemma 1.25.1 gives $w \in W^{1,2}_{\mathrm{loc}}$.

Consequently, the real and imaginary parts of the coefficient measures of $\mathrm{dd}^{\mathrm{c}} w$ are continuous linear functionals on $W^{1,2}_0$ of a smaller ball, since a second distributional derivative of w is a first derivative of its L^2 gradient. Let ν be any one of these real signed measures, with Jordan decomposition $\nu = \nu^+ - \nu^-$. Choose a compact set K contained in the intersection of S with a positive set of a Hahn decomposition, so that $\nu^-(K) = 0$. For $\epsilon > 0$, take an open neighborhood O of K in the ball with $\nu^-(O) < \epsilon$. The test functions φ_j of Lemma 1.25.2, applied to u, satisfy

$$\nu^+(K) \leq \int \varphi_j \, \mathrm{d}\nu^+ = \langle \nu, \varphi_j \rangle + \int \varphi_j \, \mathrm{d}\nu^- \leq |\langle \nu, \varphi_j \rangle| + \epsilon.$$

By continuity on the Sobolev space, the first term tends to zero. Letting $\epsilon \downarrow 0$ and using inner regularity gives $\nu^+(S) = 0$ locally, and the same argument applied to $-\nu$ gives $\nu^-(S) = 0$. Thus all coefficient measures of $\mathrm{dd^c} w$ vanish on S, which proves the first identity. Since smooth forms also give S zero mass, the second identity follows.□

For closed positive currents, local potentials turn equality of the scalar traces into an elliptic equation. If both currents are carried by a Lebesgue null set, the resulting smooth difference vanishes.

Lemma 1.25.3 *Let T, S be closed positive $(1,1)$-currents on a complex manifold of dimension $n \geq 1$, both carried coefficientwise by a Borel set of Lebesgue measure zero. For any Hermitian form η,*

$$T \wedge \eta^{n-1} = S \wedge \eta^{n-1} \quad \Longrightarrow \quad T = S.$$

Proof On a small coordinate ball, take plurisubharmonic local potentials a, b with $T = \mathrm{dd^c} a$ and $S = \mathrm{dd^c} b$, by [Dem12, Chapter III, Proposition 1.19, p. 135]. Put $h = a - b \in L^1_{\mathrm{loc}}$. The trace identity gives $\mathrm{dd^c} h \wedge \eta^{n-1} = 0$ in the sense of distributions. Dividing by the smooth positive volume form η^n gives a scalar second-order operator with smooth coefficients whose principal matrix is a positive multiple of the inverse of the Hermitian matrix of η; it is uniformly elliptic on every smaller ball. Local elliptic regularity therefore makes h smooth. Thus $T - S = \mathrm{dd^c} h$ is smooth and carried by a Lebesgue null set, so its coefficient measures vanish. This proves equality locally, and hence globally. □

Pushforward by a proper map commutes with restriction to the inverse image of a Borel set. Hence polar curvature is compatible with modifications, even when the pole set is not closed.

Proposition 1.25.2 *Let $\pi : Y \to X$ be a modification of connected compact complex manifolds, let θ be a smooth real $(1,1)$-form on X, and let $u \in \mathrm{PSH}(X, \theta)$. Put $S = \{u = -\infty\}$ and*

$$T = \theta + \mathrm{dd^c} u, \qquad T_Y = \pi^*\theta + \mathrm{dd^c}(u \circ \pi).$$

Then

$$\pi_*\big(\mathbf{1}_{\pi^{-1}(S)} T_Y\big) = \mathbf{1}_S T. \tag{1.45}$$

Proof By Proposition 1.22.4, $u \circ \pi \in \mathrm{PSH}(Y, \pi^*\theta)$. Change of variables on the locus where π is an isomorphism, whose complement has Lebesgue measure zero in both manifolds, gives $\pi_*(u \circ \pi) = u$ as distributions and $\pi_*\pi^*\theta = \theta$ as currents. Since pushforward by a proper map commutes with $\mathrm{dd^c}$, we get $\pi_* T_Y = T$.

For any Borel set $B \subset X$, the coefficient measures of $\pi_* T_Y$ are pushforwards of the coefficient measures of T_Y, multiplied by the smooth coefficients that arise from pulling back a test form. Restriction therefore gives $\pi_*(\mathbf{1}_{\pi^{-1}(B)} T_Y) = \mathbf{1}_B \pi_* T_Y$. Applying this to the Borel set S proves (1.45); closedness of the restricted currents is not used. □

The restriction of a closed positive current to a closed complete pluripolar set is closed; the classical proof uses bounded cutoff functions. Since these cutoff functions converge pointwise to the indicator function of the complement of the pole set, the argument also applies to pole sets that are not closed.

Proposition 1.25.3 *Let X be a complex manifold of dimension $n \geq 1$, let u be quasi-plurisubharmonic on X, and let θ be a smooth real $(1,1)$-form. Then*

$$\mathrm{Pol}_\theta(u) := \mathbf{1}_{\{u=-\infty\}}(\theta + \mathrm{dd^c} u)$$

is a closed positive $(1,1)$-current.

Proof Locally, adding a smooth quadratic function to u and subtracting a constant gives a negative plurisubharmonic function a with pole set $S = \{u = -\infty\}$. Put $\Theta = \mathrm{dd^c} a$. Since smooth forms give S zero mass, the polar current equals $\mathbf{1}_S\Theta$ and is positive. In dimension one it is closed for degree reasons.

Now suppose that $n \geq 2$. Choose a smooth convex nondecreasing function χ on $\mathbb{R}$ with $\chi(t) = 0$ for $t \leq 1/2$ and $\chi(1) = 1$, and a smooth function $0 \leq \vartheta \leq 1$ that vanishes near zero and equals one near one. Set

$$w_k = \chi(\mathrm{e}^{a/k}), \qquad k \geq 1.$$

These functions are bounded and plurisubharmonic, with $0 \leq w_k \leq 1$. They vanish on S and tend to one at every point outside S. Hence $\vartheta(w_k)\Theta$ converges locally, coefficientwise in total variation, to $\mathbf{1}_{X\setminus S}\Theta$. Moreover, $\vartheta'(w_k)$ vanishes on S and tends to zero everywhere.

Fix a constant strongly positive $(n-2, n-2)$-form β and put $\Xi = \Theta \wedge \beta$. The bounded Bedford–Taylor chain rule gives

$$\mathrm{d}\big(\vartheta(w_k)\Xi\big) = \vartheta'(w_k)\,\mathrm{d}w_k \wedge \Xi.$$

Indeed, approximate w_k on a smaller ball by a decreasing sequence of smooth plurisubharmonic functions. Dominated convergence gives convergence of the corresponding ϑ-weighted currents, while the convergence of bounded Bedford–Taylor energies and the Cauchy–Schwarz inequality give convergence of the differentiated expressions; this proves the chain rule for w_k. For a smooth compactly supported test one-form α, choose a nonnegative smooth cutoff τ equal to one near its support. Since $w_k \geq 0$ and Ξ is closed and positive, bounded integration by parts gives

$$2\int \tau\,\mathrm{d}w_k \wedge \mathrm{d^c} w_k \wedge \Xi \leq \int \tau\,\mathrm{dd^c}(w_k^2) \wedge \Xi = \int w_k^2 \mathrm{dd^c}\tau \wedge \Xi \leq C.$$

Here C depends only on the local mass of Ξ and the fixed cutoff. The Cauchy–Schwarz inequality for a positive current now yields

$$\big|\langle \vartheta'(w_k)\,\mathrm{d}w_k \wedge \Xi, \alpha\rangle\big|^2 \leq C_\alpha \int_{\mathrm{supp}\,\alpha} |\vartheta'(w_k)|^2\,\Xi \wedge \kappa \longrightarrow 0,$$

where κ is the Euclidean form; the limit follows by dominated convergence with respect to the fixed locally finite trace measure. Hence $\mathrm{d}(\vartheta(w_k)\Xi) \to 0$, and $\mathbf{1}_{X\setminus S}\Theta \wedge \beta$ is closed. Since constant strongly positive forms span all constant forms of bidegree $(n-2, n-2)$, the current $\mathbf{1}_{X\setminus S}\Theta$ is closed. Subtracting it from Θ shows that $\mathbf{1}_S\Theta$ is closed. The local currents agree on overlaps and give the asserted global current. $\square$

Chapter 2
Torsion and the variation of mass

Throughout this chapter, ω is a Hermitian form on X. If ω were closed, Stokes' theorem would make the total Monge–Ampère mass $\int_X (\omega + \mathrm{dd^c} u)^n$ independent of the potential u. For a nonclosed Hermitian form this invariance can fail. Integration by parts expresses the mass of a smooth potential as a polynomial whose coefficients pair the potential with the complex Hessians of the powers of ω, and polarization shows that the vanishing of these Hessians is also necessary for invariance. When they do not vanish, even smooth potentials of the same singularity type can have different masses, and the usual global comparison principle fails. The masses may nevertheless remain bounded, and whether they do depends only on the manifold, not on the chosen Hermitian form.

2.1 Integration by parts with a nonclosed form

Integration by parts moves the complex Hessian of a function onto the form against which it is integrated. When that form is a power of a nonclosed $(1,1)$-form, its complex Hessian contains, besides the complex Hessian of the form itself, a quadratic term in its exterior derivative.

Lemma 2.1.1 *For a smooth real function f and a smooth form T of bidegree $(n-1, n-1)$,*

$$\int_X \mathrm{dd^c} f \wedge T = \int_X f \, \mathrm{dd^c} T.$$

Proof Since $\mathrm{d^c} f$ is a one-form, $\mathrm{d}(\mathrm{d^c} f \wedge T) = \mathrm{dd^c} f \wedge T - \mathrm{d^c} f \wedge \mathrm{d}T$, and Stokes' theorem gives the first equality in

$$\int_X \mathrm{dd^c} f \wedge T = \int_X \mathrm{d^c} f \wedge \mathrm{d}T = \int_X f \, \mathrm{dd^c} T.$$

For the second, recall that the integral of $\mathrm{d}^{\mathrm{c}}\sigma$ vanishes for every form σ of total degree $2n-1$, by Stokes' theorem for ∂ and $\bar{\partial}$. We apply this to $\sigma = f\,\mathrm{d}T$ and use $\mathrm{d}^{\mathrm{c}}\mathrm{d} = -\mathrm{d}\mathrm{d}^{\mathrm{c}}$. □

Lemma 2.1.2 *For a smooth real $(1,1)$-form θ and an integer $q \geq 1$,*

$$\mathrm{d}\mathrm{d}^{\mathrm{c}}(\theta^q) = q\,\theta^{q-1} \wedge \mathrm{d}\mathrm{d}^{\mathrm{c}}\theta + q(q-1)\,\theta^{q-2} \wedge \mathrm{d}\theta \wedge \mathrm{d}^{\mathrm{c}}\theta,$$

where the second term is omitted when $q = 1$.

Proof For $q = 1$ there is nothing to prove. For $q \geq 2$, since θ has even degree, $\mathrm{d}^{\mathrm{c}}(\theta^q) = q\,\theta^{q-1} \wedge \mathrm{d}^{\mathrm{c}}\theta$. Applying d and using again that θ^{q-1} has even degree, we obtain

$$\mathrm{d}\mathrm{d}^{\mathrm{c}}(\theta^q) = q(q-1)\,\theta^{q-2} \wedge \mathrm{d}\theta \wedge \mathrm{d}^{\mathrm{c}}\theta + q\,\theta^{q-1} \wedge \mathrm{d}\mathrm{d}^{\mathrm{c}}\theta.$$

Thus the quadratic torsion term $\mathrm{d}\omega \wedge \mathrm{d}^{\mathrm{c}}\omega$ can make the higher powers of ω fail to be $\mathrm{d}\mathrm{d}^{\mathrm{c}}$-closed even when $\mathrm{d}\mathrm{d}^{\mathrm{c}}\omega = 0$. The mass expansion below involves the complex Hessians of all these powers separately.

2.2 The mass polynomial

For a smooth real function u on X, write $\omega_u = \omega + \mathrm{d}\mathrm{d}^{\mathrm{c}}u$, and set

$$\mathcal{H}_\omega = \{u \in C^\infty(X,\mathbb{R}) : \omega + \mathrm{d}\mathrm{d}^{\mathrm{c}}u > 0\}, \qquad \mathrm{M}_\omega(u) = \int_X (\omega + \mathrm{d}\mathrm{d}^{\mathrm{c}}u)^n.$$

The set $\mathcal{H}_\omega$ of smooth strictly ω-plurisubharmonic functions is convex and open in the C^2 topology, while the mass $\mathrm{M}_\omega(u)$ is defined for every smooth real u. Expanding it along a smooth direction gives a polynomial whose nonconstant coefficients detect the complex Hessians of the powers of the background.

Theorem 2.2.1 *For every smooth real function u,*

$$\mathrm{M}_\omega(u) = \int_X \omega^n + \sum_{k=1}^{n-1} \binom{n}{k} \int_X u(\mathrm{d}\mathrm{d}^{\mathrm{c}}u)^{k-1} \wedge \mathrm{d}\mathrm{d}^{\mathrm{c}}(\omega^{n-k}). \tag{2.1}$$

Proof Expand $(\omega + \mathrm{d}\mathrm{d}^{\mathrm{c}}u)^n$ by the binomial theorem. The term with $k = n$ integrates to zero, since it is exact:

$$(\mathrm{d}\mathrm{d}^{\mathrm{c}}u)^n = \mathrm{d}\big(\mathrm{d}^{\mathrm{c}}u \wedge (\mathrm{d}\mathrm{d}^{\mathrm{c}}u)^{n-1}\big).$$

For $1 \leq k \leq n-1$, apply Lemma 2.1.1 with $f = u$ and $T = (\mathrm{d}\mathrm{d}^{\mathrm{c}}u)^{k-1} \wedge \omega^{n-k}$. Since both d and d^{c} annihilate $\mathrm{d}\mathrm{d}^{\mathrm{c}}u$,

$$\mathrm{d}\mathrm{d}^{\mathrm{c}}T = (\mathrm{d}\mathrm{d}^{\mathrm{c}}u)^{k-1} \wedge \mathrm{d}\mathrm{d}^{\mathrm{c}}(\omega^{n-k}),$$

which gives the kth term of (2.1). When $n = 1$, the sum is empty and the mass is constant. □

If every $\mathrm{dd^c}(\omega^j)$ with $1 \le j \le n-1$ vanishes, (2.1) shows that the mass is constant. Conversely, varying the potential in several independent directions recovers each of these forms by polarization.

Theorem 2.2.2 (Chiose) *Assume $n \ge 2$. The following conditions are equivalent:*

(1) $\int_X (\omega + \mathrm{dd^c} u)^n$ *is independent of* $u \in \mathcal{H}_\omega$;
(2) $\mathrm{dd^c}(\omega^j) = 0$ *for* $1 \le j \le n-1$;
(3) $\mathrm{dd^c}\omega = 0$ *and* $\mathrm{d}\omega \wedge \mathrm{d^c}\omega = 0$.

They are also equivalent to the condition that $\int_X (\omega + \mathrm{dd^c} u)^n$ be the same for all bounded ω-plurisubharmonic functions u, where $(\omega + \mathrm{dd^c} u)^n$ is the Bedford–Taylor product of Section 1.7. Under these conditions the common mass is $\int_X \omega^n$.

Proof *Step 1: the first condition implies the second.* Let u be a smooth real function. For $|t|$ small, tu belongs to $\mathcal{H}_\omega$ for both signs of t, so the polynomial $t \mapsto \int_X (\omega + t\mathrm{dd^c} u)^n$ is constant on an interval and its nonconstant coefficients vanish. For $1 \le j \le n-1$ this gives

$$\int_X \omega^j \wedge (\mathrm{dd^c} u)^{n-j} = 0.$$

Replace u by a linear combination of $n-j$ smooth real functions $u_1, \dots, u_{n-j}$ and compare the coefficients of the monomial in which every parameter appears once. We obtain

$$\int_X \omega^j \wedge \mathrm{dd^c} u_1 \wedge \cdots \wedge \mathrm{dd^c} u_{n-j} = 0.$$

Integrating by parts in the first factor and using that u_1 is arbitrary, we obtain the pointwise identity

$$\mathrm{dd^c}(\omega^j) \wedge \mathrm{dd^c} u_2 \wedge \cdots \wedge \mathrm{dd^c} u_{n-j} = 0$$

for every choice of the remaining functions. At a given point, the complex Hessians of these functions can be prescribed arbitrarily: multiply a quadratic polynomial in a coordinate chart by a cutoff function equal to one near that point. Since the identity is multilinear, we may complexify it and use the quadratic monomials $z_a \bar{z}_b$. Wedge products of their complex Hessians give all coordinate forms of the complementary bidegree, and pairing with these forms shows that every coefficient of $\mathrm{dd^c}(\omega^j)$ vanishes. When $j = n-1$ there are no remaining factors, and the same conclusion follows directly from the arbitrariness of u_1. This proves the second condition.

Step 2: the remaining equivalences for smooth potentials. The second condition implies the first by Theorem 2.2.1. For $n \ge 3$, the identities for $j = 1, 2$ and Lemma 2.1.2 give $\mathrm{dd^c}\omega = 0$ and

$$0 = \mathrm{dd^c}(\omega^2) = 2\omega \wedge \mathrm{dd^c}\omega + 2\mathrm{d}\omega \wedge \mathrm{d^c}\omega,$$

so the second condition implies the third. For $n = 2$, the second condition is $\mathrm{dd^c}\omega = 0$, while $\mathrm{d}\omega \wedge \mathrm{d^c}\omega$ vanishes for degree reasons; the implication is again immediate. Conversely, Lemma 2.1.2 derives all the identities of the second condition from the third.

Step 3: bounded potentials. Assume the first condition and let u be a bounded ω-plurisubharmonic function. By Theorem 1.11.1, there are uniformly bounded functions $u_j \in \mathcal{H}_\omega$ decreasing to u. Their masses all equal $\int_X \omega^n$, and the continuity of the bounded products of Section 1.7 along such sequences passes this common value to the limit. Conversely, every element of $\mathcal{H}_\omega$ is a bounded ω-plurisubharmonic function, so constancy for bounded potentials implies the first condition. The zero potential shows that the common mass is $\int_X \omega^n$. □

In particular, a closed background has invariant mass. Under the equivalent conditions above, (2.1) even gives $\mathrm{M}_\omega(u) = \int_X \omega^n$ for every smooth real u, not only for $u \in \mathcal{H}_\omega$. In dimension one the mass is always $\int_X \omega$.

Mass invariance can also hold in a nonclosed background. In Theorem 26.17.3, a pluriclosed metric with nonzero exterior derivative satisfies all the lower-power identities above. Those identities fix its bounded-potential mass, even though a family of scalar perturbations can have its least relative eigenvalue tend to zero.

The first variation of the mass involves only the complex Hessian of the power ω_u^{n-1} of the perturbed form.

Proposition 2.2.1 *For smooth real functions u, v on X,*

$$\left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} \mathrm{M}_\omega(u + tv) = n \int_X v\,\mathrm{dd^c}(\omega_u^{n-1}). \tag{2.2}$$

If M_ω is constant on $\mathcal{H}_\omega$, then $\mathrm{dd^c}(\omega_u^{n-1}) = 0$ for every $u \in \mathcal{H}_\omega$.

Proof Since $\mathrm{M}_\omega(u + tv)$ is a polynomial in t, its derivative at $t = 0$ is

$$n \int_X \mathrm{dd^c} v \wedge \omega_u^{n-1},$$

and Lemma 2.1.1 turns this into the right-hand side of (2.2). For the second assertion, fix $u \in \mathcal{H}_\omega$. For every smooth real direction v, the segment $u + tv$ lies in $\mathcal{H}_\omega$ when $|t|$ is sufficiently small, so the right-hand side of (2.2) vanishes for all smooth real v. Hence the smooth top-degree form $\mathrm{dd^c}(\omega_u^{n-1})$ vanishes. □

Corollary 2.2.1 *If $n = 2$, then for every smooth real function u on X,*

$$\mathrm{M}_\omega(u) = \int_X \omega^2 + 2 \int_X u\,\mathrm{dd^c}\omega.$$

Consequently, M_ω is constant on $\mathcal{H}_\omega$ if and only if $\mathrm{dd^c}\omega = 0$.

Proof The formula is the case $n = 2$ of (2.1), and it shows that $\mathrm{dd^c}\omega = 0$ implies constancy. Conversely, if the mass is constant, Proposition 2.2.1 at $u = 0$ gives $\mathrm{dd^c}\omega = 0$. □

The identity $\mathrm{dd^c}(\omega^{n-1}) = 0$ makes the first variation vanish at $u = 0$; Hermitian forms satisfying it are the Gauduchon metrics of Chapter 4. On a surface this identity already gives mass invariance. In dimension three, however, (2.1) reads

$$\mathrm{M}_\omega(u) = \int_X \omega^3 + 3\int_X u\,\mathrm{dd^c}(\omega^2) + 3\int_X u\,\mathrm{dd^c}u \wedge \mathrm{dd^c}\omega.$$

Vanishing of $\mathrm{dd^c}(\omega^2)$ removes the linear term, while $\mathrm{dd^c}\omega$ still governs the quadratic term. Thus stationarity of the mass at one potential must be distinguished from its invariance on $\mathcal{H}_\omega$; an explicit example is given in Example 4.8.1.

2.3 Mass variation on a complex torus

By Corollary 2.2.1, the mass on a surface varies precisely through the pairing $2\int_X u\,\mathrm{dd^c}\omega$ of the potential with the complex Hessian of the background. A product of elliptic curves gives an explicit background and a family of smooth potentials for which this pairing is nonzero.

Example 2.3.1 Let $X = (\mathbb{C}/(\mathbb{Z}+\mathrm{i}\mathbb{Z}))^2$. For $j = 1, 2$, let $z_j = x_j + \mathrm{i}y_j$ be the standard coordinates on the universal cover $\mathbb{C}^2$, with x_j, y_j real, and put

$$\beta_j = \frac{\mathrm{i}}{2\pi}\,\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j.$$

The forms β_j descend to X. For a real parameter t, define

$$b(x_1) = 2 + \cos(2\pi x_1), \qquad \omega = \beta_1 + b(x_1)\beta_2, \qquad u_t = t\cos(2\pi x_1).$$

Since $1 \le b \le 3$, the form ω is Hermitian. It is not closed, because $\mathrm{d}\omega = \mathrm{d}b \wedge \beta_2$ is not identically zero.

For a function f of x_1 alone, one has $\mathrm{dd^c}f = (f''/4)\beta_1$, where the prime denotes differentiation in x_1. Hence

$$\omega_{u_t} = \big(1 - \pi^2 t\cos(2\pi x_1)\big)\beta_1 + b\beta_2 > 0 \quad \text{if} \quad |t| < \pi^{-2}.$$

Writing $B = \int_X \beta_1 \wedge \beta_2 > 0$, we have

$$\mathrm{M}_\omega(u_t) = (4 - \pi^2 t)B. \tag{2.3}$$

Indeed,

$$\omega_{u_t}^2 = 2\big(1 - \pi^2 t\cos(2\pi x_1)\big)\big(2 + \cos(2\pi x_1)\big)\beta_1 \wedge \beta_2,$$

and over a period the average of $\cos(2\pi x_1)$ is zero while that of its square is $1/2$.

Although the complex torus is Kähler, the background ω chosen above is not closed, and this already allows the mass to vary. On non-Kähler manifolds even an upper bound for the mass can fail; the Hopf manifolds of Chapter 8 give examples.

Corollary 2.3.1 *In general, the total Monge–Ampère mass is not determined by the ordinary singularity type or by the multiplier ideals, even among smooth strictly ω-plurisubharmonic potentials.*

Proof The potentials u_t of Example 2.3.1 are smooth on the compact manifold X, so any two of them differ by a bounded function and have the same singularity type in the sense of Section 1.12. For the same reason, their multiplier ideals are the structure sheaf for every positive multiple of the weight. By (2.3), their masses differ. □

2.4 Comparison and mass invariance

The global comparison principle of Kähler geometry compares the Monge–Ampère measures of two potentials on the set where one lies below the other. Adding a constant to a potential leaves its Monge–Ampère measure unchanged, and after a large constant shift this set becomes the whole manifold. Such an inequality would therefore compare total masses, and the varying mass of Example 2.3.1 rules it out.

Proposition 2.4.1 *Suppose that every pair $u, v \in \mathcal{H}_\omega$ satisfies*

$$\int_{\{u<v\}} \omega_v^n \leq \int_{\{u<v\}} \omega_u^n. \tag{2.4}$$

Then M_ω is constant on $\mathcal{H}_\omega$.

Proof Fix $u, v \in \mathcal{H}_\omega$. By compactness there is a constant C such that $u < v + C$ everywhere. Since $\omega_{v+C} = \omega_v$, applying (2.4) to u and $v + C$ gives $\mathrm{M}_\omega(v) \leq \mathrm{M}_\omega(u)$. Exchanging the roles of u and v gives the opposite inequality. □

Corollary 2.4.1 *The inequality (2.4) does not hold for every Hermitian form on a compact complex manifold.*

Proof Let X, ω, u_t and $B = \int_X \beta_1 \wedge \beta_2$ be as in Example 2.3.1. For $-\pi^{-2} < t < 0$, set $u = 0$ and $v = u_t + C$ with $C > |t|$. Then $\{u < v\} = X$, but

$$\int_X \omega_v^2 = (4 - \pi^2 t)B > 4B = \int_X \omega_u^2.$$

Thus this pair violates (2.4). □

The modified comparison principle of Theorem 10.2.1 compensates for the derivatives of the background. Conversely, under the equivalent conditions of Theorem 2.2.2, the ordinary comparison principle holds for bounded potentials, by Theorem 11.5.2.

2.5 Uniform mass bounds

Although the mass varies, it may remain bounded. Set

$$\overline{\mathrm{v}}_{\mathrm{sm}}(\omega) = \sup_{u \in \mathcal{H}_\omega} \mathrm{M}_\omega(u) \in (0, +\infty],$$

the supremum of the masses of smooth strictly ω-plurisubharmonic potentials. Comparing two Hermitian forms and rescaling the potentials shows that the finiteness of this supremum depends only on X.

Proposition 2.5.1 *If η is another Hermitian form and $\omega \leq C\eta$ for a constant $C > 0$, then*

$$\overline{\mathrm{v}}_{\mathrm{sm}}(\omega) \leq C^n \overline{\mathrm{v}}_{\mathrm{sm}}(\eta).$$

In particular, finiteness of $\overline{\mathrm{v}}_{\mathrm{sm}}$ is independent of the Hermitian form.

Proof Let $u \in \mathcal{H}_\omega$. Since $C\eta + \mathrm{dd^c} u \geq \omega + \mathrm{dd^c} u > 0$, the function u/C belongs to $\mathcal{H}_\eta$. The top exterior power is monotone on positive $(1,1)$-forms: for positive Hermitian matrices $A \leq B$, all eigenvalues of $A^{-1/2} B A^{-1/2}$ are at least one, so $\det A \leq \det B$. Applying this pointwise gives

$$\int_X (\omega + \mathrm{dd^c} u)^n \leq C^n \int_X \big(\eta + \mathrm{dd^c}(u/C)\big)^n \leq C^n \overline{\mathrm{v}}_{\mathrm{sm}}(\eta).$$

Taking the supremum over u proves the inequality. Since any two Hermitian forms on the compact manifold X are comparable in both directions, the last assertion follows. □

The smooth supremum considered here is also the upper mass over all bounded ω-plurisubharmonic potentials: Proposition 6.5.1 proves this using approximation by smooth strict potentials and continuity of bounded products. In Chapter 6, we then pass to unbounded truncations. By Corollary 6.6.1, finiteness of this common supremum is equivalent to finiteness of the extended non-pluripolar mass of every ω-plurisubharmonic potential.

Chapter 3
Monge–Ampère energy and torsion

Throughout this chapter, ω is a Hermitian form on X, and $\omega_u = \omega + \mathrm{dd}^c u$ and the space $\mathcal{H}_\omega$ of smooth strictly ω-plurisubharmonic functions are as in Chapter 2.

For a Kähler form, the Monge–Ampère operator is the gradient of an energy: there is a functional on $\mathcal{H}_\omega$ whose derivative at u in every smooth real direction v is $\int_X v\,\omega_u^n$. For a Hermitian form, such a primitive exists exactly when ω is closed. Symmetry of its mixed second derivatives first forces $\mathrm{d}(\omega_u^{n-1}) = 0$, and varying the potential then forces $\mathrm{d}\omega = 0$; this is stronger than the mass invariance of Chapter 2. For a nonclosed background, integrating the Monge–Ampère one-form along radial segments still defines a functional, and its first variation shows which torsion terms enter the corresponding Euler equation. A different energy is available for Hermitian symplectic forms on fourfolds: along potential variations, this completion energy changes by minus the change of the volume. It is therefore constant along potential variations exactly when the mass is invariant, although even then the Monge–Ampère one-form has no primitive unless ω is closed.

3.1 Primitives of the Monge–Ampère one-form

On $\mathcal{H}_\omega$ consider the *Monge–Ampère one-form*

$$\alpha_u(v) = \int_X v\,\omega_u^n, \qquad v \in C^\infty(X, \mathbb{R}).$$

Let $U \subseteq \mathcal{H}_\omega$ be open in the C^2 topology on smooth functions. A *primitive* of α on U is a functional E on U such that, for every $u \in U$ and every smooth real direction v, the directional derivative

$$DE_u(v) = \left.\frac{\mathrm{d}}{\mathrm{d}t}\right|_{t=0} E(u + tv)$$

exists and equals $\alpha_u(v)$. Restrict E to the intersection of U with a finite-dimensional affine plane. Its first derivatives are values of α, which depend smoothly on the parameters, so its mixed second derivatives agree. The following integration-by-parts criterion identifies the differential condition imposed by this symmetry.

Lemma 3.1.1 *For a smooth real $(n-1,n-1)$-form Ω, the pairing $B(v,w) = \int_X w\,\mathrm{dd^c} v \wedge \Omega$ is symmetric on smooth real functions if and only if $\mathrm{d}\Omega = 0$.*

Proof By Lemma 2.1.1, $B(v,w) = \int_X v\,\mathrm{dd^c}(w\Omega)$. Since v is arbitrary, symmetry is therefore equivalent to the pointwise identity

$$\mathrm{dd^c}(w\Omega) - \mathrm{dd^c} w \wedge \Omega = w\,\mathrm{dd^c}\Omega + \mathrm{d}w \wedge \mathrm{d^c}\Omega - \mathrm{d^c} w \wedge \mathrm{d}\Omega = 0$$

for every smooth real w. Taking $w = 1$ gives $\mathrm{dd^c}\Omega = 0$. The remaining expression is linear in the first jet of w, so we may complexify the test functions. At a chosen point, take a holomorphic linear function multiplied by a cutoff function, so that $\partial w = \lambda$ is an arbitrary $(1,0)$-covector and $\bar\partial w = 0$ at that point. There the first-order expression equals

$$\frac{\mathrm{i}}{2\pi}\big(\partial w \wedge \bar\partial\Omega - \bar\partial w \wedge \partial\Omega\big).$$

It follows that $\lambda \wedge \bar\partial\Omega = 0$ for every $(1,0)$-covector λ. Since the wedge pairing between $(1,0)$-covectors and forms of bidegree $(n-1,n)$ is nondegenerate, $\bar\partial\Omega = 0$, and $\partial\Omega = 0$ because Ω is real. Conversely, if $\mathrm{d}\Omega = 0$, then $\partial\Omega = \bar\partial\Omega = 0$ by type, so $\mathrm{d^c}\Omega = 0$, and the same product formula proves symmetry. □

Lemma 3.1.2 *Let T be a form of type $(2,1)+(1,2)$ on a complex vector space of dimension $n \geq 2$. If $T \wedge A^{n-2} = 0$ for every real $(1,1)$-form A in an open neighborhood of a positive form, then $T = 0$.*

Proof For $n = 2$ the assertion is immediate. Otherwise the expression $T \wedge A^{n-2}$ is polynomial in the real coefficients of A, so it vanishes for every real $(1,1)$-form A. Polarization and then complexification give $T \wedge A_1 \wedge \cdots \wedge A_{n-2} = 0$ for arbitrary complex $(1,1)$-forms A_j, and such products span all forms of bidegree $(n-2,n-2)$.

Since these wedges preserve type, the identity holds separately for the two type components of T. Wedging the identity for $T^{2,1}$ with arbitrary $(0,1)$-covectors, we obtain test forms spanning bidegree $(n-2,n-1)$, which pairs perfectly with bidegree $(2,1)$ into top degree. Thus $T^{2,1} = 0$. The component $T^{1,2}$ is treated in the same way with $(1,0)$-covectors. □

Theorem 3.1.1 *For $n \geq 2$, the one-form α has a primitive on $\mathcal{H}_\omega$ if and only if $\mathrm{d}\omega = 0$. In fact, a primitive on a C^2-open neighborhood of 0 already forces $\mathrm{d}\omega = 0$.*

Proof Suppose that a primitive E exists on such a neighborhood U. For $u \in U$ and smooth real directions v, w, the mixed second derivatives of $(s,t) \mapsto E(u + sv + tw)$ at the origin agree. After division by n, this equality reads

$$\int_X w\,\mathrm{dd^c} v \wedge \omega_u^{n-1} = \int_X v\,\mathrm{dd^c} w \wedge \omega_u^{n-1}. \tag{3.1}$$

By Lemma 3.1.1,

$$0 = \mathrm{d}(\omega_u^{n-1}) = (n-1)\,\mathrm{d}\omega \wedge (\omega + \mathrm{dd^c} u)^{n-2}.$$

Fix a point x. A real quadratic polynomial in local coordinates, multiplied by a cutoff function equal to one near x, realizes any prescribed real $(1,1)$-form H as $\mathrm{dd^c} u(x)$. These functions can be chosen to depend linearly on H, with global C^2 norms bounded by a fixed constant times the coefficient norm of H. Thus every sufficiently small H is realized by a potential in U, and the preceding identity holds at x with $\omega(x) + H$ ranging over an open neighborhood of the positive form $\omega(x)$. Applying Lemma 3.1.2 with $T = \mathrm{d}\omega(x)$, we conclude that $\mathrm{d}\omega(x) = 0$.

Since x was arbitrary, $\mathrm{d}\omega = 0$. Conversely, Proposition 3.2.1 below constructs a primitive for a closed background. □

In dimension one every real $(1,1)$-form is closed, and Proposition 3.2.1 always gives a primitive. For $n \geq 2$, the symmetry condition at a single potential u is $\mathrm{d}(\omega_u^{n-1}) = 0$; the theorem uses it on an open set of potentials. Mass invariance alone does not suffice. Indeed, let X be a compact complex surface admitting no Kähler metric, and let ω be a Gauduchon form on X, that is, $\mathrm{dd^c}\omega = 0$ (Definition 4.1.1); such forms exist by Theorem 4.1.1. The mass of ω is constant by Corollary 2.2.1, but ω is not closed, so its Monge–Ampère one-form has no primitive.

3.2 Radial energy and closed backgrounds

Integrating the Monge–Ampère one-form along the segment from 0 to u defines a functional for an arbitrary background. Let θ be a smooth real $(1,1)$-form on X. For $u \in C^\infty(X, \mathbb{R})$, put $\theta_u = \theta + \mathrm{dd^c} u$ and define the *radial energy*

$$\begin{aligned} E_\theta(u) &= \int_0^1 \int_X u(\theta + t\,\mathrm{dd^c} u)^n \,\mathrm{d}t \\ &= \frac{1}{n+1} \sum_{j=0}^{n} \int_X u\,\theta_u^j \wedge \theta^{n-j}. \end{aligned} \tag{3.2}$$

To obtain the second expression, write $\theta + t\,\mathrm{dd^c} u = (1-t)\theta + t\theta_u$, expand, and use

$$\binom{n}{j} \int_0^1 t^j (1-t)^{n-j} \,\mathrm{d}t = \frac{1}{n+1}.$$

We write $DE_{\theta,u}(v)$ for the derivative of E_θ at u in the direction v. When θ is closed, integration by parts makes the derivatives of the mixed terms telescope.

Proposition 3.2.1 *If* $\mathrm{d}\theta = 0$*, then* $DE_{\theta,u}(v) = \int_X v\theta_u^n$ *for every pair of smooth real functions* u, v*.*

Proof Differentiate the finite sum in (3.2). The term indexed by j contributes

$$\int_X v\theta_u^j \wedge \theta^{n-j} + j \int_X u\mathrm{dd}^{\mathrm{c}} v \wedge \theta_u^{j-1} \wedge \theta^{n-j},$$

the second summand being absent for $j = 0$. For $j \geq 1$, the form $\theta_u^{j-1} \wedge \theta^{n-j}$ is closed, so by Lemma 3.1.1 we may interchange u and v in the second summand. Using $\mathrm{dd}^{\mathrm{c}} u = \theta_u - \theta$, we can then write the contribution of the term with $j \geq 1$ as

$$(j+1) \int_X v\theta_u^j \wedge \theta^{n-j} - j \int_X v\theta_u^{j-1} \wedge \theta^{n-j+1}.$$

Together with the contribution $\int_X v\theta^n$ of the term $j = 0$, these expressions telescope to $(n+1)\int_X v\theta_u^n$. Dividing by $n+1$ completes the proof. □

Thus, when $\mathrm{d}\omega = 0$, the restriction of E_ω to $\mathcal{H}_\omega$ is the primitive required in Theorem 3.1.1.

3.3 First variation in a nonclosed background

For the Hermitian background $\theta = \omega$, the functional (3.2) integrates α along the segment from 0 to $u \in \mathcal{H}_\omega$. When ω is not closed, the derivative of E_ω differs from α by the terms produced when integration by parts differentiates the background powers. Computing this difference gives the Euler equation of E_ω even when no primitive exists.

Proposition 3.3.1 *For* $u \in \mathcal{H}_\omega$ *and* $v \in C^\infty(X, \mathbb{R})$*, put* $\Omega_t = (\omega + t\mathrm{dd}^{\mathrm{c}} u)^{n-1}$ *for* $0 \leq t \leq 1$*. Then*

$$DE_{\omega,u}(v) - \int_X v\omega_u^n = n \int_0^1 t \int_X v\big(u\mathrm{dd}^{\mathrm{c}}\Omega_t + \mathrm{d}u \wedge \mathrm{d}^{\mathrm{c}}\Omega_t - \mathrm{d}^{\mathrm{c}} u \wedge \mathrm{d}\Omega_t\big)\,\mathrm{d}t. \tag{3.3}$$

Proof Differentiating the radial integral in (3.2) in the direction v gives

$$DE_{\omega,u}(v) = \int_0^1 \left(\int_X v(\omega + t\mathrm{dd}^{\mathrm{c}} u)^n + nt \int_X u\mathrm{dd}^{\mathrm{c}} v \wedge \Omega_t \right) \mathrm{d}t.$$

On the other hand,

$$\int_X v\omega_u^n = \int_0^1 \frac{\mathrm{d}}{\mathrm{d}t}\left(t\int_X v(\omega + t\mathrm{dd}^{\mathrm{c}}u)^n\right)\mathrm{d}t$$
$$= \int_0^1 \left(\int_X v(\omega + t\mathrm{dd}^{\mathrm{c}}u)^n + nt\int_X v\mathrm{dd}^{\mathrm{c}}u \wedge \Omega_t\right)\mathrm{d}t.$$

The terms without a factor nt cancel in the difference, leaving

$$DE_{\omega,u}(v) - \int_X v\omega_u^n = n\int_0^1 t\int_X (u\mathrm{dd}^{\mathrm{c}}v - v\mathrm{dd}^{\mathrm{c}}u)\wedge\Omega_t\,\mathrm{d}t$$
$$= n\int_0^1 t\int_X v\big(\mathrm{dd}^{\mathrm{c}}(u\Omega_t) - \mathrm{dd}^{\mathrm{c}}u\wedge\Omega_t\big)\,\mathrm{d}t.$$

The second equality is Lemma 2.1.1. Expanding the last parenthesis by the product rule in the proof of Lemma 3.1.1 gives (3.3). When $n = 1$, one has $\Omega_t = 1$ and the right-hand side vanishes. □

Proposition 3.3.2 *If $n = 2$, then every $u \in \mathcal{H}_\omega$ satisfies*

$$E_\omega(u) = \int_X u\omega^2 + \int_X u\omega\wedge\mathrm{dd}^{\mathrm{c}}u + \frac{1}{3}\int_X u(\mathrm{dd}^{\mathrm{c}}u)^2.$$

For every smooth real direction v, its differential satisfies

$$DE_{\omega,u}(v) - \int_X v\omega_u^2 = \int_X v\big(u\mathrm{dd}^{\mathrm{c}}\omega + \mathrm{d}u\wedge\mathrm{d}^{\mathrm{c}}\omega - \mathrm{d}^{\mathrm{c}}u\wedge\mathrm{d}\omega\big). \tag{3.4}$$

Proof Expanding the radial integral gives the first identity. For $n = 2$, one has $\Omega_t = \omega + t\mathrm{dd}^{\mathrm{c}}u$, and since d and d^{c} annihilate $\mathrm{dd}^{\mathrm{c}}u$, the derivatives $\mathrm{d}\Omega_t$, $\mathrm{d}^{\mathrm{c}}\Omega_t$ and $\mathrm{dd}^{\mathrm{c}}\Omega_t$ are those of ω. Formula (3.3) and $2\int_0^1 t\,\mathrm{d}t = 1$ give the second identity. □

Consequently, if $n = 2$ and μ is a fixed smooth real $(2,2)$-form on X, a critical point $u \in \mathcal{H}_\omega$ of the functional $E_\omega(u) - \int_X u\,\mu$ satisfies

$$\omega_u^2 + u\mathrm{dd}^{\mathrm{c}}\omega + \mathrm{d}u\wedge\mathrm{d}^{\mathrm{c}}\omega - \mathrm{d}^{\mathrm{c}}u\wedge\mathrm{d}\omega = \mu$$

rather than the Monge–Ampère equation $\omega_u^2 = \mu$. On a Gauduchon surface the term $u\mathrm{dd}^{\mathrm{c}}\omega$ vanishes, but the first-order torsion terms can persist. The radial Euler equation can therefore differ from the Monge–Ampère equation even when the total mass is invariant.

3.4 Symplectic completions and potential variations

The radial energy is built from the Monge–Ampère one-form, and its first variation exhibits the torsion of the background. When a Hermitian form is the $(1,1)$-part of a closed real two-form, there is another natural energy: the squared L^2 norm of the

smallest $(2,0)$-part needed to close it. In complex dimension four, adding a complex Hessian to the form changes this energy by minus the change of the volume. Its potential variations are therefore governed by the volume, and not by a primitive of the Monge–Ampère one-form.

Throughout this section we assume $n = 4$. A Hermitian form ω is *Hermitian symplectic* if there is a smooth $(2,0)$-form ρ, called a *completion* of ω, such that

$$\partial\rho = 0, \qquad \bar\partial\rho = -\partial\omega.$$

Equivalently, the real two-form $\omega + \rho + \bar\rho$ is closed. Applying $\bar\partial$ to the second equation shows that ω is pluriclosed, meaning $\mathrm{dd}^{\mathrm{c}}\omega = 0$. Two completions differ by a closed holomorphic $(2,0)$-form, so the completions of ω form an affine space over the finite-dimensional space of closed holomorphic $(2,0)$-forms. The quadratic norm

$$\|\rho\|^2_{L^2(\omega)} = \frac{1}{2}\int_X \rho\wedge\bar\rho\wedge\omega^2$$

is positive definite on $(2,0)$-forms, and minimizing it over this affine space gives a unique *canonical completion* ρ_ω. It is characterized by being orthogonal to every closed holomorphic $(2,0)$-form. Define the *completion energy* and the volume of ω by

$$F(\omega) = \|\rho_\omega\|^2_{L^2(\omega)}, \qquad V(\omega) = \frac{1}{4!}\int_X \omega^4.$$

The completion energy is nonnegative and vanishes exactly when ω is Kähler: a zero canonical completion forces $\partial\omega = 0$, while a closed ω has the zero completion.

Since ω is pluriclosed, it defines an Aeppli cohomology class, whose real $(1,1)$-representatives are the forms $\omega + \partial\bar\tau + \bar\partial\tau$, with τ a smooth $(1,0)$-form. We call a real form $\psi = \partial\bar\tau + \bar\partial\tau$ an *Aeppli variation*. If ρ completes ω and $\omega + t\psi$ is positive for a real t, then $\omega + t\psi$ has the completion $\rho + t\partial\tau$. In particular, the positive representatives $\omega + \partial\bar\tau + \bar\partial\tau > 0$ of the Aeppli class of ω are again Hermitian symplectic. Every positive potential variation $\omega + \mathrm{dd}^{\mathrm{c}}\varphi$ belongs to this class and has the same exterior derivative as ω. We write $DF_\omega(\psi)$ for the derivative of $t \mapsto F(\omega + t\psi)$ at $t = 0$.

Lemma 3.4.1 *Let ω be Hermitian symplectic, with canonical completion $\rho = \rho_\omega$. Every Aeppli variation $\psi = \partial\bar\tau + \bar\partial\tau$ satisfies*

$$DF_\omega(\psi) = \int_X \left(\mathrm{Re}(\partial\tau\wedge\bar\rho\wedge\omega^2) + \rho\wedge\bar\rho\wedge\psi\wedge\omega\right). \tag{3.5}$$

Proof The canonical completion of $\omega + t\psi$ is $\rho + t\partial\tau - h(t)$, where $h(t)$ is a closed holomorphic $(2,0)$-form and $h(0) = 0$. In a fixed basis of these holomorphic forms, the orthogonal projection defining $h(t)$ solves a positive definite Gram system whose coefficients are smooth in t. Since ρ is orthogonal to closed holomorphic $(2,0)$-forms, the contribution of $h'(0)$ to the first derivative of the squared norm vanishes. We may therefore differentiate using the completion $\rho + t\partial\tau$. Differentiating its two factors and the factor $(\omega + t\psi)^2/2$ gives the formula. □

Proposition 3.4.1 *Let ω be Hermitian symplectic. For every smooth real function φ with $\omega_\varphi = \omega + \mathrm{dd^c}\varphi > 0$, one has $\rho_{\omega_\varphi} = \rho_\omega$ and*

$$F(\omega_\varphi) + V(\omega_\varphi) = F(\omega) + V(\omega). \tag{3.6}$$

Moreover, $DF_\omega(\mathrm{dd^c}\varphi) = 0$ for every smooth real φ if and only if $\mathrm{dd^c}(\omega^3) = 0$. Thus a critical point of F in its Aeppli class is Gauduchon.

Proof Fix any completion ζ of ω and put $\Theta_\zeta = \omega + \zeta + \bar\zeta$. Expansion by type gives

$$\frac{1}{4!}\int_X \Theta_\zeta^4 = V(\omega) + \frac{1}{2}\int_X \zeta\wedge\bar\zeta\wedge\omega^2 + \frac{1}{4}\int_X \zeta^2\wedge\bar\zeta^2.$$

Since $\partial\omega_\varphi = \partial\omega$, the forms ω_φ and ω have the same completions. With ζ fixed, replacing ω by ω_φ changes the closed form Θ_ζ by an exact form, so the integral on the left is unchanged; so is the last integral on the right, which does not involve ω. Hence

$$\|\zeta\|^2_{L^2(\omega_\varphi)} - \|\zeta\|^2_{L^2(\omega)} = V(\omega) - V(\omega_\varphi).$$

This difference is independent of ζ, so the two norms have the same minimizer, which gives $\rho_{\omega_\varphi} = \rho_\omega$ and (3.6). Differentiating at $t = 0$ along $\omega + t\mathrm{dd^c}\varphi$ and using Lemma 2.1.1, we obtain

$$DF_\omega(\mathrm{dd^c}\varphi) = -\frac{1}{6}\int_X \varphi\mathrm{dd^c}(\omega^3).$$

Since φ is arbitrary, this proves the remaining assertions. □

The *positive index* of a real quadratic form on a real vector space is the supremum of the dimensions of the finite-dimensional subspaces on which it is positive definite; the *negative index* is defined in the same way. Thus the positive index is infinite when the form is positive definite on subspaces of arbitrarily large finite dimension.

Theorem 3.4.1 *Let ω be Hermitian symplectic, and let H_ω be the Hessian of F at ω along the affine space of real representatives of the Aeppli class of ω, so that $H_\omega(\psi,\psi)$ is the second derivative of $t \mapsto F(\omega + t\psi)$ at $t = 0$. If $\mathrm{dd^c}(\omega^2) \neq 0$, the restriction of H_ω to potential directions $\psi = \mathrm{dd^c}\varphi$ has infinite positive and negative index. If $\mathrm{dd^c}(\omega^2) = 0$, then $F(\omega + \mathrm{dd^c}\varphi) = F(\omega)$ whenever $\omega + \mathrm{dd^c}\varphi > 0$. Consequently, every local minimum of F in an Aeppli class satisfies $\mathrm{dd^c}(\omega^2) = 0$.*

Proof *Step 1: the Hessian formula.* Pluriclosedness and Stokes' theorem give $\int_X \omega\wedge(\mathrm{dd^c}\varphi)^3 = \int_X(\mathrm{dd^c}\varphi)^4 = 0$. Thus the volume and, by (3.6), the energy along a potential line $t \mapsto \omega + t\mathrm{dd^c}\varphi$ are polynomials of degree at most two in t. Differentiating twice and integrating by parts, we obtain

$$\begin{aligned} H_\omega(\mathrm{dd^c}\varphi, \mathrm{dd^c}\varphi) &= -\frac{1}{2}\int_X \omega^2\wedge(\mathrm{dd^c}\varphi)^2 \\ &= \frac{1}{2}\int_X \mathrm{dd^c}(\omega^2)\wedge\mathrm{d}\varphi\wedge\mathrm{d^c}\varphi. \end{aligned} \tag{3.7}$$

For the second equality, apply Lemma 2.1.1 once and then use the identity $\mathrm{dd^c}(\varphi^2/2) = \varphi\mathrm{dd^c}\varphi + \mathrm{d}\varphi \wedge \mathrm{d^c}\varphi$ against the closed form $\mathrm{dd^c}(\omega^2)$.

Step 2: both indices are infinite if $\mathrm{dd^c}(\omega^2) \neq 0$. Put $\Psi = \mathrm{dd^c}(\omega^2)$. At each point, $\xi \mapsto \Psi \wedge \mathrm{i}\xi \wedge \bar{\xi}$, divided by a positive volume form, is a Hermitian quadratic form in the $(1,0)$-covector ξ, and these quadratic forms determine Ψ. Their traces with respect to ω are positive multiples of the density $\Psi \wedge \omega$, whose integral vanishes by Stokes' theorem and $\mathrm{dd^c}\omega = 0$. If the quadratic forms took no strictly positive value, they would be negative semidefinite everywhere, with nonpositive traces of integral zero; the traces, and hence Ψ, would vanish identically. The same argument applies with the signs reversed. Therefore, if $\Psi \neq 0$, the quadratic forms take a strictly positive value somewhere and a strictly negative value somewhere.

Fix one of the two signs. Choose holomorphic coordinates on a ball such that, with $x = \operatorname{Re} z_1$, the density $\Psi \wedge \mathrm{d}x \wedge \mathrm{d^c}x$ has that sign on the ball; this is possible because $\mathrm{d}x \wedge \mathrm{d^c}x$ is a positive multiple of $\mathrm{i}\,\mathrm{d}z_1 \wedge \mathrm{d}\bar{z}_1$. For a nonzero real cutoff function a supported in the ball, set $\varphi_N = a\cos(Nx)$. Formula (3.7) gives

$$H_\omega(\mathrm{dd^c}\varphi_N, \mathrm{dd^c}\varphi_N) = \frac{N^2}{2}\int_X a^2 \sin^2(Nx)\Psi \wedge \mathrm{d}x \wedge \mathrm{d^c}x + O(N),$$

where the constant in $O(N)$ depends on Ψ, the chart and the cutoff, but not on N. By integration by parts in x, the integral tends to half the same integral without the factor $\sin^2(Nx)$. Hence the Hessian has the chosen sign for large N. For a positive integer k, apply this construction on k disjoint smaller balls in that region. By the local integral formula, the resulting nonzero directions are linearly independent and pairwise orthogonal for the Hessian, so their span is a k-dimensional subspace on which H_ω is definite of the chosen sign. Repeating the argument with the opposite sign proves that both indices are infinite. Each finite-dimensional span admits sufficiently small variations preserving positivity.

Step 3: flatness if $\mathrm{dd^c}(\omega^2) = 0$. If $\Psi = 0$, Lemma 2.1.2 and pluriclosedness give $\mathrm{dd^c}(\omega^3) = 3\omega \wedge \Psi = 0$. Both derivatives at $t = 0$ of the quadratic polynomial $t \mapsto F(\omega + t\mathrm{dd^c}\varphi)$ vanish, so it is constant on the interval of t for which $\omega + t\mathrm{dd^c}\varphi > 0$. This interval contains 0 and 1 whenever $\omega + \mathrm{dd^c}\varphi > 0$. Finally, a local minimum cannot have a potential direction along which the Hessian is negative, so it satisfies $\mathrm{dd^c}(\omega^2) = 0$ by Step 2. □

Corollary 3.4.1 *For a Hermitian symplectic form ω on X, the following conditions are equivalent:*

(1) *$F(\omega + \mathrm{dd^c}\varphi)$ is independent of the smooth real function φ with $\omega + \mathrm{dd^c}\varphi > 0$;*
(2) *$\mathrm{dd^c}(\omega^2) = 0$;*
(3) *$\int_X (\omega + \mathrm{dd^c}u)^4$ is independent of the bounded ω-plurisubharmonic function u.*

The common mass in the third condition is $24V(\omega)$. Every local minimum of F in an Aeppli class has these properties.

Proof By (3.6), the energy is constant along smooth positive potential variations if and only if their volume is. Since $\mathrm{dd^c}\omega = 0$, Lemma 2.1.2 and Theorem 2.2.2 show that this smooth mass invariance is equivalent to $\mathrm{dd^c}(\omega^2) = 0$ and to mass invariance for bounded potentials. The zero potential gives the common mass. The last assertion follows from Theorem 3.4.1. □

3.4.1 Completion energy on products of complex tori

Products of two complex two-tori give explicit Hermitian symplectic forms in both regimes of Theorem 3.4.1. Each factor carries a nonclosed form with an explicit completion. If both factors carry such a form, the product is critical for F under every Aeppli variation although its potential Hessian is indefinite. If only one factor does, the energy is constant along potential variations but varies in the Aeppli class.

Consider the square complex two-torus $S = \mathbb{C}^2/(\mathbb{Z} + \mathrm{i}\mathbb{Z})^2$. Let $z_j = x_j + \mathrm{i}y_j$ be the coordinates on its cover and put $\eta = \mathrm{i}\sum_{j=1}^2 \mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j$. For $0 < s < 1$, the periodic forms

$$v_s = \frac{s}{\pi}\mathrm{e}^{2\pi\mathrm{i}x_1}\mathrm{d}z_2, \qquad \alpha_s = \eta + \partial\bar{v}_s + \bar{\partial}v_s$$

are well defined on S. The Hermitian matrix of α_s with respect to the forms $\mathrm{i}\,\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_k$ is

$$\begin{pmatrix} 1 & -s\mathrm{e}^{-2\pi\mathrm{i}x_1} \\ -s\mathrm{e}^{2\pi\mathrm{i}x_1} & 1 \end{pmatrix},$$

with eigenvalues $1 - s$ and $1 + s$, so α_s is a Hermitian form. It has the completion $\rho_s = \partial v_s = \mathrm{i}s\mathrm{e}^{2\pi\mathrm{i}x_1}\mathrm{d}z_1 \wedge \mathrm{d}z_2$, and with $\mu_0 = \eta^2/2$,

$$\frac{\alpha_s^2}{2} = (1 - s^2)\mu_0, \qquad \rho_s \wedge \bar{\rho}_s = s^2\mu_0.$$

Example 3.4.1 On $X = S \times S$, let ω be the sum of the pullbacks of $\alpha_{1/\sqrt{2}}$ from the two factors. This form is Hermitian symplectic but not Kähler, and it is critical for F under every Aeppli variation, including those with mixed factor components. If $V_0 = \int_S \mu_0$, then $F(\omega) = V_0^2/2 > 0$. The potential Hessian of F at ω has infinite positive and negative index, even though potential variations preserve $\mathrm{d}\omega$.

Proof Denote the two factor forms by α_i, ρ_i, and put $\mu_i = \alpha_i^2/2$ and $\nu_i = \rho_i \wedge \bar{\rho}_i$; we suppress pullbacks from the notation. Every holomorphic form on a complex torus has

constant coefficients. On each factor, the L^2 pairing of $\rho_i = \partial v_i$ with a holomorphic two-form is a multiple of their wedge pairing, which vanishes by Stokes' theorem. On the product, pure and mixed two-forms are pointwise orthogonal, and the pairing with a pure-factor form is the vanishing pairing on that factor times the volume of the other factor. Thus $\rho = \rho_1 + \rho_2$ is the canonical completion of ω. Since $\mu_i = \nu_i$ is half the pullback of μ_0, expansion gives $F(\omega) = \int_X (\nu_1 \wedge \mu_2 + \mu_1 \wedge \nu_2) = V_0^2/2$.

Put $\Theta_i = \alpha_i + \rho_i + \bar\rho_i$ and let $\Theta = \Theta_1 + \Theta_2$, which is closed. For an arbitrary real $(1,1)$-form ψ and $(2,0)$-form σ on X, expansion on the two factors gives

$$\mathrm{Re}(\sigma \wedge \bar\rho \wedge \omega^2) + \rho \wedge \bar\rho \wedge \psi \wedge \omega = \frac{1}{12}(\psi + \sigma + \bar\sigma) \wedge \Theta^3.$$

Indeed, the mixed components of ψ and σ have odd degree on both factors and contribute zero. The pure components on the left give $(\psi+\sigma+\bar\sigma)\wedge(\Theta_1\wedge\mu_2+\Theta_2\wedge\mu_1)$, and since $\Theta_i^2 = 4\mu_i$, the cube on the right is twelve times the same complementary form. Apply Lemma 3.4.1 with $\psi = \partial\bar\tau + \bar\partial\tau$ and $\sigma = \partial\tau$. The derivative is $\frac{1}{12}\int_X \mathrm{d}(\tau+\bar\tau)\wedge\Theta^3 = 0$, since Θ is closed. This proves criticality under every Aeppli variation.

Each $\partial\alpha_i = -\bar\partial\rho_i$ is nonzero, so ω is not Kähler. In $\partial\omega \wedge \bar\partial\omega$, the terms coming from a single factor vanish for dimension reasons, while the two cross terms are nonzero and have different bidegrees on the factors, so they cannot cancel. Hence $\mathrm{d}\omega \wedge \mathrm{d}^c\omega \neq 0$, and since $\mathrm{dd}^c\omega = 0$, Lemma 2.1.2 gives $\mathrm{dd}^c(\omega^2) \neq 0$. It remains to apply Theorem 3.4.1. □

If only one factor carries a nonclosed form, the energy becomes constant along potential variations, while the same explicit family shows that it still varies in the Aeppli class.

Example 3.4.2 For $0 < s < 1$, let $\widehat\omega_s$ on $X = S \times S$ be the sum of the pullbacks of α_s from the first factor and of η from the second, and set $V_0 = \int_S \mu_0$. Then $\mathrm{d}\widehat\omega_s \neq 0$ and

$$F(\widehat\omega_s) = s^2 V_0^2, \qquad V(\widehat\omega_s) = (1 - s^2)V_0^2.$$

The energy is constant on all positive smooth potential variations of $\widehat\omega_s$, and every bounded $\widehat\omega_s$-plurisubharmonic function has mass $24(1 - s^2)V_0^2$. The form $\widehat\omega_s$ is not a critical point of F in its Aeppli class, and its Monge–Ampère one-form has no primitive on any C^2-open neighborhood of zero.

Proof The pullback of ρ_s from the first factor is a completion of $\widehat\omega_s$. It is canonical: pure and mixed holomorphic two-forms are orthogonal for the product metric, and its pairing with pure-factor forms vanishes by the Stokes argument in the proof of Example 3.4.1. The energy is therefore $\int_X \rho_s \wedge \bar\rho_s \wedge \eta^2/2 = s^2V_0^2$. The volume is the product of the two surface volumes, which gives the second formula.

The exterior derivatives of $\widehat\omega_s$ come entirely from the first factor. Their wedge product $\mathrm{d}\widehat\omega_s \wedge \mathrm{d}^c\widehat\omega_s$ vanishes for degree reasons, while $\mathrm{dd}^c\widehat\omega_s = 0$. Thus $\mathrm{dd}^c(\widehat\omega_s^2) = 0$ by Lemma 2.1.2, and Corollary 3.4.1 gives the constancy of the energy and the common bounded mass.

The forms $\widehat{\omega}_{(1+t)s}$ are positive for small $|t|$ and lie in the Aeppli class of $\widehat{\omega}_s$, since $v_{(1+t)s} = (1+t)v_s$. The derivative of their energy at $t = 0$ is $2s^2V_0^2 > 0$, so $\widehat{\omega}_s$ is not a critical point in its Aeppli class. Finally, $\partial\alpha_s = -\bar{\partial}\rho_s \neq 0$. Hence $\mathrm{d}\widehat{\omega}_s \neq 0$, and Theorem 3.1.1 shows that no primitive exists. □

Chapter 4
Gauduchon metrics and linear mass

Throughout this chapter, ω is a fixed Hermitian form on X, and $n \geq 2$ unless a section specifies another setting.

The mass variation in Chapter 2 leaves a linear conservation law. If γ is a Gauduchon metric, so that $\mathrm{dd}^{\mathrm{c}}(\gamma^{n-1}) = 0$, integration against γ^{n-1} annihilates every complex Hessian. Thus the trace mass $\int_X (\theta + \mathrm{dd}^{\mathrm{c}} u) \wedge \gamma^{n-1}$ of a positive current depends only on its smooth background θ, even when u is unbounded. Gauduchon's theorem produces such a metric in every conformal class, providing conserved pairings when the background is not closed.

These pairings determine positivity as well as mass. A smooth form θ admits a positive current $\theta + \mathrm{dd}^{\mathrm{c}} u$ exactly when all its Gauduchon degrees are nonnegative. Normalizing the degrees gives the largest lower curvature bound obtainable by adding a complex Hessian. This bound is always attained by a potential; a minimizing test exists in the weak closure of the normalized smooth Gauduchon forms, although a smooth minimizing metric generally does not exist. Applied to ω_u, the conformal construction also gives the adjoint probability of the linearized Monge–Ampère operator. It identifies the compatibility condition for that operator and explains the extra term in entropy dissipation for a nonclosed background.

For a holomorphic line bundle, the conserved pairing is the degree of its curvature, and a positive degree excludes a metric with nonpositive curvature. Fiber averaging extends this obstruction to plurisubharmonic norms near a direct sum of line bundles. Polar duality and homogeneous regularization then turn it into an obstruction to semipositive Finsler curvature. The stable ample bundles constructed on Hirzebruch surfaces show that ampleness alone does not remove the obstruction; their projective complements give a geometric way to measure it.

The same scalar equation can improve curvature when the mean curvature is nonnegative: a conformal change spreads directional positivity from a nonempty open set to the whole manifold. Ricci-flat Kähler surfaces illustrate the distinction between this directional condition and positivity on every tangent and fiber pair. On a projective manifold, positivity on every such pair admits another duality criterion, expressed by positive measures over the dual bundle.

4.1 Conformal Gauduchon metrics

By Proposition 2.2.1, the first variation of the mass at $u = 0$ vanishes exactly when $\mathrm{dd}^{\mathrm{c}}(\omega^{n-1}) = 0$. This condition can be achieved in every conformal class: finding a conformal factor amounts to finding a positive generator of the kernel of the adjoint of a scalar elliptic operator.

Definition 4.1.1 A Hermitian form γ is *Gauduchon*, or a *Gauduchon metric*, if

$$\mathrm{dd}^{\mathrm{c}}(\gamma^{n-1}) = 0.$$

It is *balanced* if $\mathrm{d}(\gamma^{n-1}) = 0$, and *pluriclosed* if $\mathrm{dd}^{\mathrm{c}}\gamma = 0$.

Theorem 4.1.1 (Gauduchon's theorem) *Every Hermitian form η has a conformal Gauduchon representative. More precisely, there is a smooth strictly positive function ρ, unique up to multiplication by a positive constant, such that*

$$\mathrm{dd}^{\mathrm{c}}(\rho\eta^{n-1}) = 0.$$

The associated Gauduchon form is $\gamma = \rho^{1/(n-1)}\eta$.

Proof For a smooth real function v on X, define

$$Lv = n\frac{\mathrm{dd}^{\mathrm{c}}v \wedge \eta^{n-1}}{\eta^n}.$$

This real second-order operator has positive definite principal symbol and no zeroth-order term. By the maximum principle, its kernel consists of the constants. Its index is zero, since the linear path joining it to a Laplace operator consists of elliptic operators. Fredholm theory and elliptic regularity therefore show that the formal adjoint L^* of L with respect to η^n has a one-dimensional kernel, generated by a nonzero smooth real function ρ.

We first prove that $\int_X \rho\eta^n \neq 0$. Otherwise the constant function 1 would be orthogonal to the kernel of L^*, and the Fredholm alternative would solve $Lv = 1$, which is impossible at a maximum point of v. We may therefore rescale so that $\int_X \rho\eta^n = 1$.

Next we show that $\rho \geq 0$. Suppose instead that ρ is negative somewhere. Choose a nonzero smooth function $h \geq 0$ supported where $\rho < 0$, and put $c = \int_X h\rho\eta^n < 0$. The function $h - c$ is strictly positive and orthogonal to the kernel of L^*, so the Fredholm alternative would solve $Lv = h - c > 0$, which is again impossible at a maximum point of v.

In real local coordinates $(x_1, \ldots, x_{2n})$, write $L^* = A^{ij}\partial_i\partial_j + B^i\partial_i + C$, where $\partial_i = \partial/\partial x_i$, the coefficients are smooth, and repeated indices are summed from 1 to $2n$. The leading symbol (A^{ij}) is positive definite. Since $\rho \geq 0$,

$$(L^* - \max(C, 0))\rho = -\max(C, 0)\rho \leq 0,$$

and the operator $L^* - \max(C, 0)$ has nonpositive zeroth-order term. By the strong minimum principle, a zero of ρ would force ρ to vanish identically on the connected manifold X. Hence $\rho > 0$.

Finally, integration by parts gives

$$\int_X \rho L v \, \eta^n = n \int_X v \, \mathrm{dd^c}(\rho \eta^{n-1}).$$

Thus the equation $L^*\rho = 0$ is precisely $\mathrm{dd^c}(\rho\eta^{n-1}) = 0$, and the one-dimensional adjoint kernel gives uniqueness up to positive scaling. Since $\gamma^{n-1} = \rho\eta^{n-1}$, the form γ is Gauduchon. □

A Kähler form, that is, a closed Hermitian form, is both balanced and pluriclosed, and every balanced form is Gauduchon. On surfaces, balanced forms are Kähler, and the Gauduchon and pluriclosed conditions coincide.

4.2 Conservation of the trace mass

The power γ^{n-1} of a Gauduchon metric annihilates every complex Hessian under integration. It therefore assigns to a positive current $\theta + \mathrm{dd^c}u$ a mass depending only on its smooth background θ, also when the potential u is unbounded.

Proposition 4.2.1 *Let θ be a smooth real $(1,1)$-form, let u be a θ-plurisubharmonic function, and let γ be a Gauduchon metric. Then*

$$\int_X (\theta + \mathrm{dd^c}u) \wedge \gamma^{n-1} = \int_X \theta \wedge \gamma^{n-1}. \tag{4.1}$$

Proof Since $\mathrm{dd^c}(\gamma^{n-1}) = 0$, distributional integration by parts gives

$$\langle \mathrm{dd^c}u, \gamma^{n-1} \rangle = \langle u, \mathrm{dd^c}(\gamma^{n-1}) \rangle = 0.$$

The product on the left of (4.1) is a positive measure, whose total mass is therefore the finite number on the right. □

We call $\int_X \theta \wedge \gamma^{n-1}$ the *Gauduchon degree* of θ with respect to γ. Here $\theta + \mathrm{dd^c}u$ is the full distributional current, including any mass carried by the pole set of u. The non-pluripolar Monge–Ampère measure of Chapter 6 discards this mass; Example 7.5.1 illustrates the difference on a curve.

Corollary 4.2.1 *There are constants $0 < a \le b < +\infty$, depending only on ω and a chosen Gauduchon metric, such that every $u \in \mathrm{PSH}(X, \omega)$ satisfies*

$$a \le \int_X (\omega + \mathrm{dd^c}u) \wedge \omega^{n-1} \le b.$$

Proof Fix a Gauduchon form γ on X and choose positive constants c, C with $c\gamma^{n-1} \le \omega^{n-1} \le C\gamma^{n-1}$. Wedging these inequalities with the positive current $\omega + \mathrm{dd^c}u$ and integrating, we obtain, by Proposition 4.2.1, the bounds cA and CA, where $A = \int_X \omega \wedge \gamma^{n-1} > 0$. □

The trace bound controls the mass of positive currents and hence their weak compactness. By itself it gives no bound for the Monge–Ampère mass, since a bound on the integral of a trace does not bound the integral of its nth power.

The pointwise arithmetic–geometric mean inequality relates the conserved trace to the density in a smooth Monge–Ampère equation. Fix a smooth positive volume form $\mathrm{d}V$ on X.

Proposition 4.2.2 *For any two Hermitian forms η, γ,*

$$\eta \wedge \gamma^{n-1} \ge \left(\frac{\eta^n}{\gamma^n}\right)^{1/n} \gamma^n \tag{4.2}$$

pointwise. Consequently, let θ be a smooth real $(1,1)$-form and f a smooth strictly positive function. If $u \in C^\infty(X, \mathbb{R})$ and $c > 0$ satisfy $(\theta + \mathrm{dd^c}u)^n = cf\,\mathrm{d}V$ with $\theta + \mathrm{dd^c}u > 0$, then

$$c^{1/n} \int_X \left(\frac{f\,\mathrm{d}V}{\gamma^n}\right)^{1/n} \gamma^n \le \int_X \theta \wedge \gamma^{n-1} \tag{4.3}$$

for every Gauduchon metric γ.

Proof In a frame where γ is the identity, let $\lambda_1, \dots, \lambda_n > 0$ be the eigenvalues of η. The ratios of the two sides of (4.2) to γ^n are $n^{-1}\sum_j \lambda_j$ and $(\prod_j \lambda_j)^{1/n}$, respectively, and their comparison is the arithmetic–geometric mean inequality.

For the second assertion, apply (4.2) with $\eta = \theta + \mathrm{dd^c}u$, integrate, and use (4.1).□

The corresponding density inequality for unbounded potentials in a Hermitian background is proved in Lemma 6.4.2.

4.3 The Gauduchon criterion for positivity

The trace identity gives a necessary condition for $\mathrm{PSH}(X, \theta)$ to be nonempty: every Gauduchon degree of θ must be nonnegative. The condition is also sufficient. A Hahn–Banach separation produces a positive current with the prescribed pairings, and a scalar elliptic equation shows that its difference from θ is $\mathrm{dd^c}$-exact.

Theorem 4.3.1 (The generalized Lamari criterion) *For a smooth real $(1,1)$-form θ, the following conditions are equivalent:*

(1) *There exists $u \in \mathrm{PSH}(X, \theta)$.*
(2) $\int_X \theta \wedge \gamma^{n-1} \ge 0$ *for every Gauduchon metric γ.*

To apply separation, we express the test in terms of smooth strictly positive dd^{c}-closed $(n-1,n-1)$-forms Γ. Every strictly positive $(n-1,n-1)$-form Γ has a unique strictly positive $(1,1)$-root γ, that is, $\Gamma = \gamma^{n-1}$. Indeed, in a frame in which Γ is diagonal, and with the same wedge normalization on both sides, the coefficients g_i of Γ are the products $\prod_{j\neq i}\lambda_j$ of the eigenvalues λ_j of γ. Hence

$$\lambda_i = \frac{(\prod_j g_j)^{1/(n-1)}}{g_i}.$$

This spectral formula uses only a positive determinant and a matrix inverse, so the root depends smoothly on the coefficients of Γ, also at repeated eigenvalues, and pointwise uniqueness makes the local roots agree on overlaps. Consequently, $\mathrm{dd}^{\mathrm{c}}\Gamma = 0$ says exactly that the root γ is Gauduchon.

Proof (of Theorem 4.3.1) Necessity is Proposition 4.2.1. For sufficiency, let F be the real vector space of smooth real $(n-1,n-1)$-forms, and let

$$E = \{\Gamma \in F : \mathrm{dd}^{\mathrm{c}}\Gamma = 0\}, \qquad \ell(\Gamma) = \int_X \theta\wedge\Gamma \quad (\Gamma \in E).$$

Fix a strictly positive $\Gamma_0 \in E$, which exists by Theorem 4.1.1. By the root calculation above, the hypothesis says that ℓ is nonnegative on the strictly positive elements of E. Adding $\epsilon\Gamma_0$ and letting $\epsilon \downarrow 0$, we see that ℓ is also nonnegative on the semipositive elements of E.

Step 1: a positive extension of ℓ. For $\Phi \in F$ put

$$p(\Phi) = \inf\{\ell(\Gamma) : \Gamma \in E,\ \Gamma \geq \Phi\}.$$

This is a finite sublinear function. To see finiteness, choose C with $-C\Gamma_0 \leq \Phi \leq C\Gamma_0$. The admissible element $C\Gamma_0$ gives an upper bound, while every admissible Γ satisfies $\Gamma + C\Gamma_0 \geq 0$ and hence $\ell(\Gamma) \geq -C\ell(\Gamma_0)$. Sublinearity follows by adding and rescaling competitors. For $\Phi \in E$, the nonnegativity of $\ell(\Gamma - \Phi)$ for admissible Γ shows that $p(\Phi) = \ell(\Phi)$.

The Hahn–Banach theorem gives a real linear extension T of ℓ to F with $T(\Phi) \leq p(\Phi)$ for all $\Phi \in F$. If $\Phi \geq 0$, the zero form is admissible for $p(-\Phi)$, so $T(-\Phi) \leq 0$, that is, $T(\Phi) \geq 0$. Moreover, the bounds by $C\Gamma_0$ show that T is continuous for the uniform norm. It is therefore a positive $(1,1)$-current, and the current $S = T - \theta$ annihilates E.

Step 2: S is dd^{c}-exact. To recover a potential from S, consider the scalar operator

$$Dv = \frac{\mathrm{dd}^{\mathrm{c}}(v\Gamma_0)}{\mathrm{d}V},$$

where $\mathrm{d}V$ is the smooth positive volume form fixed above. Since $\mathrm{dd}^{\mathrm{c}}\Gamma_0 = 0$, this is an elliptic scalar operator with no zeroth-order term. Its kernel consists of the constants and its index is zero, while Stokes' theorem gives $\int_X Dv\,\mathrm{d}V = 0$. Consequently its range is exactly the space of smooth functions of integral zero, and by elliptic

estimates its inverse on functions normalized by $\int_X v\,\mathrm{d}V = 0$ is continuous in the smooth topology.

For a smooth top-degree form ζ with $\int_X \zeta = 0$, solve $Dv = \zeta/\mathrm{d}V$ with this normalization and set $R\zeta = v\Gamma_0$. Then $\mathrm{dd^c} R\zeta = \zeta$, and R is continuous. Define a distribution u on such top-degree forms by

$$\langle u, \zeta \rangle = S(R\zeta),$$

and extend it to all top-degree forms by assigning an arbitrary value on one fixed volume form of integral one. For every $\Phi \in F$, the form $\Phi - R(\mathrm{dd^c}\Phi)$ belongs to E, and S annihilates it. It follows that

$$\langle \mathrm{dd^c} u, \Phi \rangle = S(R(\mathrm{dd^c}\Phi)) = S(\Phi).$$

Thus $\theta + \mathrm{dd^c} u = T \geq 0$, and Proposition 1.1.1 gives a representative of u in $\mathrm{PSH}(X, \theta)$. □

Applying the criterion to $\theta - a\omega$, for $a \in \mathbb{R}$, determines the largest lower curvature bound attainable in the background θ.

Corollary 4.3.1 *For a smooth real $(1,1)$-form θ, set*

$$\kappa_\omega(\theta) = \inf_{\gamma \text{ Gauduchon}} \frac{\int_X \theta \wedge \gamma^{n-1}}{\int_X \omega \wedge \gamma^{n-1}}.$$

This is a finite real number, and it is the largest real a for which there is a quasi-plurisubharmonic function u satisfying

$$\theta + \mathrm{dd^c} u \geq a\omega.$$

In particular, this largest value is attained, and θ is big, in the sense of Section 1.19, precisely when $\kappa_\omega(\theta) > 0$.

Proof Since θ is smooth, $-C\omega \leq \theta \leq C\omega$ for some C, so the infimum lies in $[-C, C]$. If $\theta + \mathrm{dd^c} u \geq a\omega$, the trace identity applied to the background $\theta - a\omega$ shows that a is at most each of the ratios in the definition, hence $a \leq \kappa_\omega(\theta)$. Conversely, for $a = \kappa_\omega(\theta)$, all Gauduchon degrees of $\theta - a\omega$ are nonnegative, and Theorem 4.3.1 applied to this smooth form gives the required u. The last assertion follows, since bigness means the existence of a θ-plurisubharmonic u with $\theta + \mathrm{dd^c} u \geq \delta\omega$ for some $\delta > 0$. □

Whether the infimum defining $\kappa_\omega(\theta)$ is attained by a smooth Gauduchon metric is decided by a rigidity property of the trace: a positive current $\theta + \mathrm{dd^c} u$ with vanishing Gauduchon degree is zero.

Lemma 4.3.1 *Let θ be a smooth real $(1,1)$-form with $\mathrm{PSH}(X,\theta) \neq \varnothing$. If*

$$\int_X \theta \wedge \gamma^{n-1} = 0$$

for one Gauduchon metric γ, then $\theta = \mathrm{dd}^{\mathrm{c}} f$ for a smooth real function f. Conversely, a form $\mathrm{dd}^{\mathrm{c}} f$ with f smooth has zero degree with respect to every Gauduchon metric. The same conclusions hold for $n = 1$, with $\gamma^{n-1} = 1$.

Proof Choose $u \in \mathrm{PSH}(X,\theta)$ and put $S = \theta + \mathrm{dd}^{\mathrm{c}} u \geq 0$. By Proposition 4.2.1, $\int_X S \wedge \gamma^{n-1} = 0$. Since the trace measure $S \wedge \gamma^{n-1}$ of the positive current S controls all its coefficient measures, $S = 0$. Taking the trace of the equation $\mathrm{dd}^{\mathrm{c}} u = -\theta$ with respect to ω gives an elliptic equation with smooth right-hand side, so u is smooth by elliptic regularity, and $f = -u$ has the required property. The converse is Stokes' theorem. For $n = 1$, the trace measure is S itself and the same argument applies. □

For a smooth real $(1,1)$-form θ, put $a = \kappa_\omega(\theta)$. By Corollary 4.3.1, the form $\theta - a\omega$ admits a positive current $\theta - a\omega + \mathrm{dd}^{\mathrm{c}} u$. A Gauduchon metric γ attains the infimum defining $\kappa_\omega(\theta)$ precisely when the Gauduchon degree of $\theta - a\omega$ with respect to γ vanishes. Hence Lemma 4.3.1 shows that the infimum is attained by a smooth Gauduchon metric if and only if

$$\theta - a\omega = \mathrm{dd}^{\mathrm{c}} f \quad \text{for some } f \in C^\infty(X,\mathbb{R}),$$

and in that case every Gauduchon metric attains it. Thus a positive current at the threshold always exists, whereas a smooth minimizing Gauduchon metric exists only in this exceptional situation.

4.4 Compactness and duality of Gauduchon currents

When no smooth Gauduchon metric attains the threshold, a minimizer can still be found among weak limits of normalized Gauduchon forms. The normalization bounds the coefficient measures and hence gives compactness. Let $\mathscr{G}_\omega$ be the set of positive $(n-1,n-1)$-currents T on X satisfying

$$\mathrm{dd}^{\mathrm{c}} T = 0, \qquad \int_X \omega \wedge T = 1.$$

We call them *normalized Gauduchon currents*. Let $\mathscr{C}_\omega$ be the weak closure of the set of smooth strictly positive members of $\mathscr{G}_\omega$. By the root calculation preceding the proof of Theorem 4.3.1, these smooth members are exactly the normalized powers $\gamma^{n-1} / \int_X \omega \wedge \gamma^{n-1}$ of Gauduchon metrics γ.

Proposition 4.4.1 *The sets $\mathcal{G}_\omega$ and $\mathcal{C}_\omega$ are nonempty, compact and convex. For every smooth real $(1,1)$-form θ,*

$$\kappa_\omega(\theta) = \min_{T \in \mathcal{C}_\omega} \int_X \theta \wedge T. \tag{4.4}$$

Moreover, a current $T \in \mathcal{G}_\omega$ belongs to $\mathcal{C}_\omega$ if and only if

$$\int_X \theta \wedge T \geq 0 \quad \text{for every smooth real } \theta \text{ with } \mathrm{PSH}(X,\theta) \neq \varnothing. \tag{4.5}$$

Proof Gauduchon's theorem gives a smooth strictly positive member of $\mathcal{G}_\omega$ after normalization. The fixed trace mass bounds the total variation of all coefficient measures in finitely many local frames, so weak compactness of finite measures gives compactness of the family of positive currents with this trace. Positivity, the trace normalization and the equation $\mathrm{dd^c} T = 0$ pass to weak limits. On this bounded set, testing against smooth forms or against forms with continuous coefficients gives the same topology, by uniform approximation, and this topology is metrizable since the space of continuous test forms is separable. Thus the compactness can also be used sequentially. The defining conditions of $\mathcal{G}_\omega$ are convex. Its smooth strictly positive members form a convex set, so their closure $\mathcal{C}_\omega$ is compact and convex as well.

Pairing with a fixed smooth θ is weakly continuous. Its minimum on the closure of the smooth members is therefore their infimum, which proves (4.4). The Lamari criterion shows that (4.5) holds for every smooth strictly positive member, and hence for every member of their weak closure.

Conversely, suppose that $T \in \mathcal{G}_\omega$ does not belong to $\mathcal{C}_\omega$, and separate this point from the compact convex set $\mathcal{C}_\omega$ in the space of currents with the weak topology. A continuous linear functional for that topology is evaluation against a smooth form. After changing its sign if necessary, we obtain a smooth real $(1,1)$-form β such that

$$\int_X \beta \wedge T < \min_{R \in \mathcal{C}_\omega} \int_X \beta \wedge R = \kappa_\omega(\beta).$$

By Corollary 4.3.1, the smooth form $\beta - \kappa_\omega(\beta)\omega$ admits a positive current. Its pairing with T is negative, because $\int_X \omega \wedge T = 1$. This contradicts (4.5) and proves the converse. □

Corollary 4.4.1 *The function κ_ω is concave, positively homogeneous and invariant under the addition of $\mathrm{dd^c} f$ for $f \in C^\infty(X,\mathbb{R})$. Let θ and η be smooth real $(1,1)$-forms and let $\varepsilon \geq 0$. If $-\varepsilon\omega \leq \theta - \eta \leq \varepsilon\omega$, then*

$$|\kappa_\omega(\theta) - \kappa_\omega(\eta)| \leq \varepsilon.$$

If smooth real $(1,1)$-forms θ_j converge uniformly to a smooth form θ and $T_j \in \mathcal{C}_\omega$ minimize their pairings, every weak cluster point of (T_j) minimizes the pairing with θ.

Proof By (4.4), κ_ω is an infimum of linear functionals, which proves concavity and positive homogeneity. Invariance under the addition of $\mathrm{dd^c} f$ follows from $\mathrm{dd^c} T = 0$. The normalization of the trace gives

$$\left| \int_X (\theta - \eta) \wedge T \right| \le \varepsilon \quad (T \in \mathscr{C}_\omega),$$

and taking infima proves the estimate. For the last assertion, pass to a subsequence $T_j \rightharpoonup T \in \mathscr{C}_\omega$. The estimate and the uniform convergence of the backgrounds give

$$\int_X \theta \wedge T = \lim_j \int_X \theta_j \wedge T_j = \lim_j \kappa_\omega(\theta_j) = \kappa_\omega(\theta).$$

Thus T is a minimizer. □

In general, the closure $\mathscr{C}_\omega$ cannot be replaced by all of $\mathscr{G}_\omega$: the exceptional-curve example in Example 28.8.1 separates the two sets by a smooth closed form. Testing against all of $\mathscr{G}_\omega$ instead detects smooth positivity and nefness, as shown in Theorem 26.20.1.

4.5 Transverse concentration of Gauduchon tests

Let $\mathcal{T}_\omega$ be the smooth strictly positive members of the normalized current cone $\mathscr{G}_\omega$ of Section 4.4. Thus every $\Theta \in \mathcal{T}_\omega$ satisfies $\mathrm{dd^c}\Theta = 0$ and $\int_X \omega \wedge \Theta = 1$. These tests form a weakly relatively compact family, but their pairings with a form concentrating transversely to a hypersurface need not stay bounded. A uniform bound would, by duality, produce a potential whose curvature charges the local hypersurface. Analyticity of Lelong level sets then forces a global hypersurface.

Choose a product coordinate chart $(z, \zeta) \in U \times \Delta_r$, with $z \in \mathbb{C}^{n-1}$, and a smooth compactly supported $0 \le \chi \le 1$ on U, equal to one on a nonempty connected smaller polydisk U'. Put $\sigma_\zeta = (\mathrm{i}/(2\pi))\, \mathrm{d}\zeta \wedge \mathrm{d}\bar{\zeta}$. Fix $p \in C_c^\infty(\mathbb{C})$, nonnegative and supported in the closed unit disk, with $\int p\, \sigma_\zeta = 1$. For small $\delta > 0$ extend

$$B_\delta = \chi(z) \delta^{-2} p(\zeta/\delta) \sigma_\zeta$$

by zero to X, and set

$$C_\delta = \sup_{\Theta \in \mathcal{T}_\omega} \int_X B_\delta \wedge \Theta.$$

The form B_δ is smooth and semipositive. For fixed δ it is bounded above by a finite multiple of ω, so $C_\delta < \infty$.

Theorem 4.5.1 *If C_{δ_j} stays bounded along a sequence $\delta_j \downarrow 0$, then some global analytic hypersurface contains $U' \times \{0\}$. In particular, on a manifold without analytic hypersurfaces, $C_\delta \to \infty$ as $\delta \downarrow 0$.*

Proof Suppose $C_{\delta_j} \le M$ and put $\kappa = (M+1)^{-1}$. Normalizing any smooth strictly positive $\mathrm{dd^c}$-closed complementary form gives

$$\int_X (\omega - \kappa B_{\delta_j}) \wedge \Theta \ge 0.$$

The generalized Lamari criterion, Theorem 4.3.1, supplies v_j with

$$\omega + \mathrm{dd^c} v_j \ge \kappa B_{\delta_j}, \qquad \sup_X v_j = 0.$$

Since $B_{\delta_j} \ge 0$, the potentials belong to the fixed normalized ω-plurisubharmonic family. By Theorem 1.4.1, a subsequence converges in L^1 to $v \in \mathrm{PSH}(X, \omega)$. The transverse approximate identity converges to $\chi[\zeta = 0]$, so passing in distributions gives

$$\omega + \mathrm{dd^c} v \ge \kappa \chi[\zeta = 0].$$

On a smaller chart meeting the inner hypersurface, add a smooth ρ with $\mathrm{dd^c}\rho \ge \omega$. The closed positive current $\mathrm{dd^c}(v + \rho)$ dominates $\kappa[\zeta = 0]$ where $\chi = 1$. Hence the Lelong number of v is at least κ at every point of $U' \times \{0\}$. By Siu's theorem in Section 1.13.1, the set $Z = \{\nu(v, \cdot) \ge \kappa\}$ is analytic and has dimension at most $n-1$. Smooth local corrections do not change its definition. The compact analytic set Z has finitely many global irreducible components. Their intersections with the connected inner hypersurface are analytic subsets covering it. At least one intersection is the whole hypersurface, since finitely many proper analytic subsets cannot cover an open polydisk. That component has dimension $n-1$ and is the required global hypersurface. If no such hypersurface exists, there is no bounded sequence C_{δ_j} with $\delta_j \downarrow 0$, which proves the asserted divergence. □

Proposition 4.5.1 *Suppose an effective Cartier divisor agrees, with multiplicity one, with $\{\zeta = 0\}$ throughout the chosen coordinate chart. Then C_δ is uniformly bounded for all sufficiently small δ.*

Proof Let s be the canonical section of its divisor line bundle. In the chart write $s = \zeta e$ with e a nonvanishing holomorphic frame. Choose a smooth Hermitian metric h with $|e|_h = 1$ on a neighborhood of $\operatorname{supp}\chi \times \{|\zeta| \le \delta_0\}$ for a fixed small $\delta_0 > 0$. The smooth global functions $\psi_\delta = \log(|s|_h^2 + \delta^2)$ satisfy $\mathrm{dd^c}\psi_\delta \ge -C\omega$ with one $C \ge 1$. Off the divisor their Hessians are a bounded scalar multiple of the negative curvature of h, plus a semipositive gradient term; continuity gives the same lower bound at the divisor. Fix $0 < \epsilon \le (2C)^{-1}$, so $\omega + \epsilon\mathrm{dd^c}\psi_\delta \ge \omega/2$. On the flat-frame region,

$$\mathrm{dd^c}\psi_\delta = \frac{\delta^2}{(|\zeta|^2 + \delta^2)^2}\sigma_\zeta \ge \frac{1}{4\delta^2}\sigma_\zeta \quad (|\zeta| \le \delta).$$

If $P = \|p\|_\infty$, then $B_\delta \le P\delta^{-2}\sigma_\zeta$ on its support. Therefore

$$\omega + \epsilon \mathrm{dd}^{\mathrm{c}}\psi_\delta \ge \frac{\epsilon}{4P} B_\delta$$

globally for $\delta \le \delta_0$. Every $\Theta \in \mathcal{T}_\omega$ gives, by smooth Stokes,

$$1 = \int_X (\omega + \epsilon \mathrm{dd}^{\mathrm{c}}\psi_\delta) \wedge \Theta \ge \frac{\epsilon}{4P} \int_X B_\delta \wedge \Theta.$$

Taking the supremum proves $C_\delta \le 4P/\epsilon$. □

The uniform bound requires the divisor to agree on the entire cutoff chart. A global hypersurface supplied by the preceding theorem can have further branches there, so the theorem does not provide this converse at arbitrary intersections. Divergence of the transverse pairing alone also gives no lower bound for the volume of the positive root of a test.

4.6 Convex norms and Gauduchon degrees

For holomorphic line bundles, the trace identity of Proposition 4.2.1 becomes a statement about curvature. Let F be a holomorphic line bundle on X and k a smooth Hermitian metric on F. In a local holomorphic frame e of F we identify k with the positive function $|e|_k^2$, and the curvature form of k is $R_k = -\mathrm{dd}^{\mathrm{c}} \log k$. Let Θ be a smooth strictly positive real $(n-1, n-1)$-form with $\mathrm{dd}^{\mathrm{c}}\Theta = 0$; by the root calculation preceding the proof of Theorem 4.3.1, $\Theta = \gamma^{n-1}$ for a unique Gauduchon metric γ. The *degree* of F with respect to Θ is

$$\deg_\Theta F = \int_X R_k \wedge \Theta.$$

Two metrics on F differ by a factor e^{-u} with u smooth, which adds $\mathrm{dd}^{\mathrm{c}}u$ to the curvature, so the degree is independent of k by Lemma 2.1.1. It is the Gauduchon degree of the curvature form with respect to γ; the form Θ need not be d-closed.

The squared norm $v \mapsto |v|_k^2$ is plurisubharmonic on the total space of F off the zero section exactly when $\log k$ is plurisubharmonic, that is, when $R_k \le 0$; this follows from the Levi form computation in the proof of Lemma 4.6.6 below. A line bundle of positive degree therefore admits no metric with plurisubharmonic squared norm. This section extends the obstruction to direct sums of line bundles of positive degree, to all holomorphic structures sufficiently close to such a direct sum, and to norms that need not be Hermitian. The mechanism is again integration against Θ: averaging the horizontal complex Hessians of a norm near the line summands produces a negative multiple of the degrees, and this negativity is stable under small changes of the holomorphic structure.

For a smooth complex vector bundle F, a *smooth complex norm* is a continuous function $p : F \to [0, +\infty)$, positive away from the zero section and smooth there, such that

$$p(\lambda v) = |\lambda| p(v), \qquad p(v + w) \le p(v) + p(w)$$

for $\lambda \in \mathbb{C}$ and vectors v, w in the same fiber. Its square $G = p^2$ satisfies $G(\lambda v) = |\lambda|^2 G(v)$. Near each line summand of a direct sum, the triangle inequality controls the fiber derivatives of G, and these estimates control the averaged horizontal complex Hessians.

Lemma 4.6.1 *Fix a smooth positive volume form μ on X. Every holomorphic line bundle F has a Hermitian metric k satisfying*

$$R_k \wedge \Theta = \lambda \mu, \qquad \lambda = \frac{\deg_\Theta F}{\int_X \mu}.$$

Proof Start with any metric k^0, and put $\mathcal{L}u = (\mathrm{dd^c} u \wedge \Theta)/\mu$. This scalar operator is uniformly elliptic, has no zeroth-order term, and its kernel consists of the constants by the maximum principle. On Hölder spaces, the homotopy to a Laplace operator used in the proof of Theorem 4.1.1 shows that its index is zero, so its cokernel is one-dimensional. Since $\mathrm{dd^c}\Theta = 0$, integration by parts gives $\int_X \mathcal{L}u \, \mu = 0$, and therefore its image consists exactly of the smooth functions of zero μ-mean. Hence we can solve

$$\mathrm{dd^c} u \wedge \Theta = \lambda \mu - R_{k^0} \wedge \Theta,$$

whose right-hand side has integral zero, and elliptic regularity makes u smooth. Then $k = k^0 \mathrm{e}^{-u}$ has the required curvature. □

Let $F_0 = \bigoplus_{s=1}^{r} F_s$ be a direct sum of holomorphic line bundles, with $r \ge 2$. Choose Hermitian metrics k_s on F_s and write $k = \bigoplus_s k_s$. Let P_s be the orthogonal projection onto F_s, and let

$$\Sigma = \{v \in F_0 : |v|_k = 1\}$$

be the unit sphere bundle, with fibers Σ_x. On each fiber sphere Σ_x we use the rotation-invariant probability measure $\mathrm{d}\sigma_x$. Fix a nonnegative smooth function χ supported in $(-1, 1)$ and positive near zero. For $0 < \varepsilon < 1/2$, define weights ρ_s on Σ by

$$\rho_s(v) = c_\varepsilon \chi\left(\frac{|(I - P_s)v|_k^2}{\varepsilon^2}\right), \qquad \int_{\Sigma_x} \rho_s \, \mathrm{d}\sigma_x = 1.$$

In unitary frames respecting the splitting, these weights and the normalizing constant c_ε are independent of the base point and of the index s. Independent phase rotations of the summands preserve them, so they are globally defined. The support of ρ_s lies within distance ε of the unit circle of F_s.

Lemma 4.6.2 *For a smooth complex norm on F_0 with square G, put*

$$a_s(x) = G(e_s), \qquad N(x) = \sum_s a_s(x), \qquad D_j G(v) = \mathrm{d}_v G(P_j v),$$

where e_s is any k_s-unit vector in the fiber of F_s at x; complex homogeneity makes a_s well defined. Then

$$G(v) \le N|v|_k^2, \qquad |\mathrm{d}_v G(w)| \le 2N|v|_k|w|_k.$$

On the support of ρ_s,

$$|D_j G| \le 2\varepsilon N \quad (j \ne s), \qquad |D_s G - 2a_s| \le 10\varepsilon N.$$

Proof The triangle inequality and the Cauchy–Schwarz inequality give $p(v) \le \sum_s |v_s|_k \sqrt{a_s} \le \sqrt{N}|v|_k$. Differentiating $|p(v+tw) - p(v)| \le |t|p(w)$ in the real variable t gives $|\mathrm{d}_v p(w)| \le p(w)$, and both global bounds follow.

For v in the support of ρ_s, set $w = (I - P_s)v$ and $e_s = P_s v/|P_s v|_k$. Then $|w|_k < \varepsilon$ and $|v - e_s|_k \le |w|_k + 1 - |P_s v|_k < 2\varepsilon$. The segment from e_s to v stays in the unit ball and avoids zero, so integrating the derivative bound along it gives $|G(v) - a_s| \le 4\varepsilon N$. For $j \ne s$, we have $|P_j v|_k < \varepsilon$, which gives the first axis bound. Euler's identity $\mathrm{d}_v G(v) = 2G(v)$ yields

$$D_s G - 2a_s = 2(G(v) - a_s) - \sum_{j \ne s} D_j G.$$

The sum on the right is $\mathrm{d}_v G(w)$, whose absolute value is at most $2\varepsilon N$. This proves the second axis bound. □

Write $\pi : F_0 \to X$ for the bundle projection. For $v \in F_0$ with $\pi(v) = x$, let $H_{0,v} : T_x X \to T_v F_0$ be the horizontal lift for the Chern connection of k. It is complex linear, and at unit vectors it is tangent to Σ, since the Chern connection preserves k. For a smooth real function G on $F_0 \setminus \{0\}$, define a $(1,1)$-form $\beta_s(G)$ and functions U_s, V_{sj} on X by

$$\beta_s(G) = \int_{\Sigma_x} \rho_s H_{0,v}^*(\mathrm{dd^c} G)\, \mathrm{d}\sigma_x,$$
$$U_s = \int_{\Sigma_x} G\rho_s\, \mathrm{d}\sigma_x,$$
$$V_{sj} = \int_{\Sigma_x} D_j G \rho_s\, \mathrm{d}\sigma_x.$$

Lemma 4.6.3 *With R_j the curvature of k_j,*

$$\beta_s(G) = \mathrm{dd^c} U_s - \frac{1}{2}\sum_j R_j V_{sj}.$$

Proof At a fixed base point, choose holomorphic frames of the line bundles with $k_j = e^{-\varphi_j}$ and $d\varphi_j = 0$ at that point. There the horizontal lift has zero vertical component. Write the smooth unitary fiber coordinates as $\zeta_j = e^{-\varphi_j/2} v_j$ and $G(z, v) = g(z, \zeta)$. At the base point, the first base derivatives of ζ_j vanish, and its mixed second base derivatives are $-\frac{1}{2}(\varphi_j)_{\alpha\bar\beta}\zeta_j$ and their conjugates. The chain rule therefore gives

$$G_{\alpha\bar\beta} = g_{\alpha\bar\beta} - \frac{1}{2}\sum_j (\varphi_j)_{\alpha\bar\beta}(\zeta_j g_{\zeta_j} + \bar\zeta_j g_{\bar\zeta_j}).$$

The expression in parentheses is $D_j G$. Both the spherical measure and ρ_s are independent of z in unitary coordinates, so averaging the identity gives the result, since $R_j = dd^c\varphi_j$. □

Theorem 4.6.1 *Suppose that for each s there is a smooth strictly positive real $(n-1, n-1)$-form Θ_s satisfying*

$$dd^c\Theta_s = 0, \qquad \deg_{\Theta_s} F_s > 0.$$

Then there is a C^4 neighborhood of the split Dolbeault operator on the underlying smooth bundle of F_0 such that no integrable Dolbeault operator in this neighborhood admits a smooth complex norm whose square is plurisubharmonic off the zero section.

Proof *Step 1: the split structure.* Fix μ and use Lemma 4.6.1 to choose k_s with $R_s \wedge \Theta_s = \lambda_s \mu$, where $\lambda_s > 0$. Put

$$\lambda_* = \min_s \lambda_s, \qquad C = 5\sum_s \lambda_s + \sum_s \sum_{j\neq s} \sup_X \left| \frac{R_j \wedge \Theta_s}{\mu} \right|.$$

For a squared norm G, define $I_0(G) = \sum_s \int_X \beta_s(G) \wedge \Theta_s$. By Lemma 4.6.3, the term $dd^c U_s$ integrates to zero against Θ_s, and the axis estimates of Lemma 4.6.2 then give

$$I_0(G) = -\frac{1}{2}\sum_{s,j} \int_X V_{sj} R_j \wedge \Theta_s \le -(\lambda_* - \varepsilon C)\int_X N\mu.$$

Choose ε so that $\varepsilon C < \lambda_*/2$, and keep all weights fixed.

Step 2: nearby holomorphic structures. Write a nearby operator as $\bar\partial_A = \bar\partial_0 + A$, with $\bar\partial_A^2 = 0$. Its Chern connection for k is $D_A = D_0 + A - A^{*k}$, where the adjoint changes the type from $(0,1)$ to $(1,0)$. Let J_A be the corresponding complex structure on the total space and $H_{A,v}$ the horizontal lift of D_A. These depend smoothly on A, and $H_{A,v}$ is complex linear and tangent to the fixed sphere bundle Σ.

For $g \in C^\infty(\Sigma, \mathbb{R})$, define its homogeneous extension by

$$(\mathcal{E}g)(v) = |v|_k^2 g(v/|v|_k),$$

and define a real differential operator on Σ by

$$(\mathcal{P}_A g)(v) = \sum_s \rho_s(v) \frac{H^*_{A,v}(\mathrm{dd}^{\mathrm{c}}_{J_A} \mathcal{E} g)_v \wedge \Theta_s(x)}{\mu(x)}, \qquad x = \pi(v).$$

It has order at most two. By the identity $\mathrm{d}^{\mathrm{c}}_J f = -(4\pi)^{-1} \mathrm{d} f \circ J$, its coefficients depend on A and its first derivatives, as well as on the fixed smooth data. Consequently they converge in C^2 as $A \to 0$ in C^4.

Step 3: the adjoint operator. Take the formal adjoint $\mathcal{P}^*_A$ for the fixed density $\mathrm{d}\nu = \mathrm{d}\sigma_x \, \mu(x)$ on the compact sphere bundle, and put $b_A = \mathcal{P}^*_A 1$. Locally, if $\mathrm{d}\nu = m(y)\,\mathrm{d}y$ and $\mathcal{P}_A = \sum_{|\alpha| \le 2} c_{\alpha,A} \partial^\alpha$, then

$$b_A = m^{-1} \sum_{|\alpha| \le 2} (-1)^{|\alpha|} \partial^\alpha (m c_{\alpha,A}).$$

Thus $\|b_A - b_0\|_{C^0} \to 0$ as $A \to 0$ in C^4. For $g = G|_\Sigma$, homogeneity gives $\mathcal{E} g = G$ and

$$I_A(G) := \int_\Sigma \mathcal{P}_A g \, \mathrm{d}\nu = \int_\Sigma g b_A \, \mathrm{d}\nu.$$

Since $0 < g \le N \circ \pi$ and the spherical measures have mass one,

$$|I_A(G) - I_0(G)| \le \|b_A - b_0\|_{C^0} \int_X N \mu.$$

Choose the neighborhood so that $\|b_A - b_0\|_{C^0} < \lambda_*/4$ in it. Then $I_A(G) \le -\frac{1}{4}\lambda_* \int_X N\mu < 0$ for every smooth squared complex norm G. If G were plurisubharmonic for J_A, all horizontal pullbacks of $\mathrm{dd}^{\mathrm{c}}_{J_A} G$ would be semipositive, and their pairings with Θ_s, weighted by $\rho_s \ge 0$, would give $I_A(G) \ge 0$, a contradiction.□

The neighborhood depends on the bundle and on the test forms Θ_s, and different line summands may require different tests. Its size is independent of all derivatives of the candidate norms: integration over the fixed sphere bundle transfers those derivatives to the coefficients of the adjoint operator.

To apply Theorem 4.6.1 to norms obtained by duality, we first need to regularize continuous norms while preserving a strict convexity margin. Polar duality then turns the obstruction into a failure of semipositive Kobayashi curvature on the dual bundle. Stable ample bundles on Hirzebruch surfaces provide concrete examples, and a fixed Stein hypersurface detects the failure for every Finsler metric on such a bundle.

Dual support norms also connect this obstruction with the geometry of neighborhoods of the zero section. This leads to bounds for the convexity of a projective complement. Curvature supplies a second way to study these complements, through explicit exhaustions. A uniformly negative bundle over a Kähler base with a proper psh exhaustion instead gives logarithmic weights and a complete metric on its punctured total space (Section 4.6.10). The distinction between these spaces matters: the final flat and Hopf examples use restrictions and topology to obtain further bounds for the projective complement.

4.6.1 Homogeneous convex regularization

Theorem 4.6.1 concerns smooth norms, whereas the norms produced by duality later in this section are in general only continuous. We show that a continuous homogeneous function with strict positivity margins can be approximated by smooth ones with the same margins, so the obstruction applies to it as well. The local step is Wu's convolution in projective coordinates, written as an average of holomorphic linear shears; the local approximations are glued by the argument of Greene and Wu. We give both steps in order to keep track of strict plurisubharmonicity and of strong convexity in the fibers; see Section 34.3 for attribution.

Let $\pi : F \to X$ be a holomorphic vector bundle, and write $F^\times$ for the complement of its zero section. A continuous real function Q on F is *complex homogeneous of degree two* if

$$Q(\lambda v) = |\lambda|^2 Q(v) \qquad (\lambda \in \mathbb{C}).$$

We call Q *locally strongly convex in the fibers* if, in a local bundle frame and near every point of $F^\times$, there is a constant $c > 0$ such that $Q(z, v) - c|v|^2$ is convex on sufficiently small real fiber balls. For continuous functions, strict plurisubharmonicity means that subtracting a sufficiently small positive multiple of the Euclidean squared norm in local coordinates of the total space leaves a plurisubharmonic function. Both conditions are local, and on compact subsets of $F^\times$ they hold with uniform positive margins.

The strong convexity required here holds with one constant on a neighborhood in the total space. Strong convexity of every fixed fiber is weaker, even for a plurisubharmonic squared complex norm.

Example 4.6.1 On the trivial bundle $D \times \mathbb{C}^2$, where $D = \{z \in \mathbb{C} : |z| < 1/2\}$, put

$$Q(z, v) = \max\left\{ |v_1|^2 + |v_2|^2,\ \frac{|v_1|^2}{1 - |z|^2} + |z|^2 |v_2|^2 \right\}.$$

This is a continuous plurisubharmonic function, positive off the zero section and complex homogeneous of degree two. Its square root is a complex norm on every fiber, and for each fixed z, the real function $Q(z, \cdot)$ is strongly convex. Nevertheless, Q is not locally strongly convex in the fibers near $(z, v) = (0, (1, 0))$ in the sense defined above.

Proof Write $t = |z|^2$. Both branches are continuous, positive semidefinite Hermitian quadratic forms in v, and the first is positive definite. Their square roots satisfy the triangle inequality and complex homogeneity; their maximum therefore is a complex norm. In particular Q is positive off zero and continuous, also on the zero section.

The first branch is plurisubharmonic on the total space. For the second, the locally uniformly convergent expansion

$$\frac{|v_1|^2}{1 - |z|^2} + |z|^2 |v_2|^2 = \sum_{k=0}^{\infty} |z^k v_1|^2 + |z v_2|^2$$

expresses it as a limit of sums of squared moduli of holomorphic functions. Thus it too is plurisubharmonic, and so is their maximum.

For $0 < t < 1/4$, subtracting $t|v|^2$ gives

$$Q(z,v) - t|v|^2 = \max\left\{(1-t)|v|^2, \left(\frac{1}{1-t} - t\right)|v_1|^2\right\},$$

which is convex. At $z = 0$, one has $Q(0,v) = |v|^2$. Hence each fixed fiber has a positive strong convexity margin.

To test a margin on a neighborhood of $(0,(1,0))$, fix any $c > 0$ and choose a nonzero z arbitrarily close to zero with $t < c$. At $v = (1,0)$ the second branch is strictly larger than the first, so it remains the maximum on a small fiber ball. Along the real line $v = (1,s)$ in this ball,

$$Q(z,(1,s)) - c|(1,s)|^2 = \frac{1}{1-t} - c + (t-c)s^2.$$

Its second derivative is negative. Thus no positive c makes $Q - c|v|^2$ convex on the fiber balls in any such total-space neighborhood. A fiber-linear change of smooth frame and its inverse are uniformly bounded on a smaller base neighborhood, so a positive quadratic margin in another frame would give one in this frame. This proves the failure of the local margin. □

Lemma 4.6.4 *Let M be a compact smooth manifold and let $\mathcal{S}$ be a sheaf of germs of continuous real functions on M, whose elements we call sections. Suppose that $\mathcal{S}$ is closed under maxima and has the following two properties.*

Stability: *if f is a section near a compact set K, then $f + u$ is a section near K whenever u is smooth and sufficiently small in the C^∞ topology on a neighborhood of K.*

Local approximation: *every point has a neighborhood U such that, for every compact $K \Subset U$, a section near K can be approximated uniformly on K by smooth sections near K, with arbitrarily small errors in any prescribed finite collection of derivative norms on compact subsets where the section is already smooth.*

Then every global section can be approximated uniformly on M by smooth global sections.

Proof We first describe a gluing step. Let f be a global section that is smooth near a compact set L_1, and let L_2 be a compact subset of one of the neighborhoods U in the statement. Choose relatively compact open sets W_3, W_4 with $L_1 \subset W_3$, f smooth near $\overline{W}_3$, and $L_2 \subset W_4 \Subset U$. Choose a smooth function $0 \le \rho \le 1$ equal to one near $\overline{W}_3$, with compact support in the region where f is smooth. Put $V = W_3 \cup W_4$, and choose a smooth function $-1 \le \psi \le 1$ equal to one near $L_1 \cup L_2$ and equal to minus one near $M \setminus V$.

By stability, for sufficiently small $\xi > 0$ the function $f_\xi = f + \xi\psi$ is still a global section. Approximate f_ξ on $\overline{W}_4$ by a smooth section g, with uniform error less than $\delta < \xi/2$, and with arbitrarily small derivative errors near the compact set $\overline{W}_4 \cap \operatorname{supp}\rho$, where f_ξ is smooth. On V define

$$h = f_\xi \quad \text{on } W_3, \qquad h = \rho f_\xi + (1-\rho)g \quad \text{on } W_4.$$

These definitions agree on the overlap, and h is smooth. Where ρ vanishes, h is the section g. Where ρ can be nonzero, $h - f_\xi = (1-\rho)(g - f_\xi)$, and stability applied to the smooth section f_ξ makes h a section if the derivative errors of $g - f_\xi$ are sufficiently small. Moreover, $|h - f_\xi| < \delta$.

Define $f_1 = \max\{f, h\}$ on V and $f_1 = f$ outside V. Near $L_1 \cup L_2$ we have $h > f$, and near the boundary of V we have $h < f$. Thus f_1 is continuous, it is a section because $\mathcal{S}$ is closed under maxima, and it is smooth near $L_1 \cup L_2$. Also $\|f_1 - f\|_{C^0} < \xi + \delta$. Near L_1 it equals $f + \xi$, so the previous smoothness is preserved.

Now cover M by finitely many compact sets L_2 of this kind and repeat the step, starting with L_1 empty and then taking for L_1 the union of the previously treated compact sets. At every step choose ξ and δ so small that the sum of the finitely many uniform errors is below the prescribed tolerance. The final section is smooth everywhere and has the required uniform error. □

Lemma 4.6.5 *In a holomorphic bundle chart, write $v = (v', v_r)$ and use the affine projective coordinate $w = v'/v_r$ on the cone $v_r \neq 0$. Suppose that a positive continuous complex homogeneous function Q of degree two is strictly plurisubharmonic and locally strongly convex in the fibers on this cone, and put $q(z, w) = Q(z, (w, 1))$. For a nonnegative smooth approximate identity $\eta_\delta(s, t)$ of integral one, define*

$$q_\delta(z, w) = \int q(z - s, w - t)\eta_\delta(s, t)\, \mathrm{d}s\, \mathrm{d}t, \qquad Q_\delta(z, v) = |v_r|^2 q_\delta(z, v'/v_r).$$

On every relatively compact projective subchart, for sufficiently small δ, Q_δ is a smooth positive complex homogeneous function of degree two that is strictly plurisubharmonic and locally strongly convex in the fibers. As $\delta \to 0$, it converges to Q uniformly on compact subsets of the cone consisting of vectors of norm one, and in every finite derivative norm wherever Q is already smooth.

Proof Complex homogeneity gives the identity

$$Q_\delta(z, v) = \int Q(z - s, T_t v)\eta_\delta(s, t)\, \mathrm{d}s\, \mathrm{d}t, \qquad T_t(v', v_r) = (v' - v_r t, v_r).$$

For fixed (s, t), the map $(z, v) \mapsto (z - s, T_t v)$ is holomorphic and invertible, and its restriction to each fiber is linear. On a compact subset of the cone consisting of vectors of norm one, all these maps with (s, t) sufficiently small stay in a fixed compact subset of the original cone, and their differentials and inverses are uniformly bounded there. A positive local lower bound for the Levi form of Q, interpreted through quadratic barriers, therefore gives a positive lower bound for every pullback and for their average. The same argument with real quadratic barriers in the fibers preserves local strong convexity. Only fiber segments contained in the local cone neighborhood are used here.

Ordinary convolution makes q_δ smooth, and the formula for Q_δ makes it smooth on the cone and complex homogeneous. Uniform convergence, derivative convergence

on compact regions where Q is smooth, and positivity for small δ follow from the corresponding properties of convolution and from the positive minimum of Q on compact sets of vectors of norm one. □

Theorem 4.6.2 *Let $Q : F \to [0, +\infty)$ be continuous, positive on $F^\times$, complex homogeneous of degree two, strictly plurisubharmonic on $F^\times$, and locally strongly convex in the fibers. Then there are continuous complex homogeneous functions Q_j of degree two, smooth on $F^\times$, strictly plurisubharmonic there and locally strongly convex in the fibers, which converge to Q uniformly on the unit sphere bundle of any fixed smooth Hermitian metric. Each $p_j = \sqrt{Q_j}$ is a smooth complex norm.*

Proof Fix a smooth Hermitian squared norm G on F, and let $M = \mathbb{P}(F)$ be the bundle of complex lines in F. The quotient $m = Q/G$ is a positive continuous function on the compact manifold M. Define a sheaf $\mathcal{S}$ on M by requiring that the corresponding function Gm on the cone be positive, strictly plurisubharmonic, and locally strongly convex in the fibers.

This sheaf is closed under maxima. Indeed, multiplication by $G > 0$ commutes with maxima. Near a point of the cone, subtract a common positive quadratic barrier from both functions; their maximum remains plurisubharmonic, and on sufficiently small fiber balls it remains convex. Positivity is also preserved.

For stability on a compact subset K of M, restrict to vectors of norm one lying over K, and to a fixed compact annulus around them. Finitely many bundle charts provide positive common lower bounds for both barriers. If u is a smooth function on M that is sufficiently small in C^2 near K, the Levi form and the real fiber Hessian of Gu are smaller than half these bounds on that annulus. The perturbed function is therefore still positive and has both strict margins. Homogeneity transports the local conditions to the rest of the cone over K. This proves the stability required in Lemma 4.6.4.

On a sufficiently small projective coordinate chart, Lemma 4.6.5 gives local approximation, including derivative control on compact subsets where m is smooth; dividing its regularizations by G gives local smooth sections of $\mathcal{S}$. By Lemma 4.6.4, there are smooth positive global sections $m_j \to m$ uniformly. Put $Q_j = Gm_j$ off the zero section and $Q_j = 0$ on the zero section. Homogeneity gives continuity at zero, uniformly over the compact base, as well as the asserted convergence on a fixed unit sphere bundle.

It remains to see that p_j is a norm. Local convexity in the fibers away from zero implies convexity on the whole fiber. Indeed, the restriction of Q_j to a real line avoiding zero is locally convex and hence convex, while on a real line through zero, homogeneity gives $Q_j(tv) = t^2 Q_j(v)$ for real t, which is convex including at zero. Thus the set $B_x = \{v : Q_j(v) \leq 1\}$ is convex, balanced and absorbing, and its gauge is $\sqrt{Q_j}$. If v, w are nonzero, convexity applied to $v/p_j(v)$ and $w/p_j(w)$, with weights proportional to $p_j(v)$ and $p_j(w)$, gives the triangle inequality; the cases with a zero vector follow directly. Positivity, smoothness off zero and complex homogeneity give the remaining properties of a smooth complex norm. □

Proposition 4.6.1 *Suppose that F admits a smooth positive complex homogeneous function H of degree two that is strictly plurisubharmonic on $F^\times$. If a positive continuous complex homogeneous function Q of degree two is plurisubharmonic on $F^\times$ and locally strongly convex in the fibers, then F admits a smooth complex norm with strictly plurisubharmonic square on $F^\times$.*

Proof For $\tau > 0$, set $Q_\tau = Q + \tau H$; it is positive, complex homogeneous and strictly plurisubharmonic. On a compact annulus of vectors of norm close to one, local strong convexity of Q in the fibers gives a positive uniform margin in finitely many frames, while the real fiber Hessian of H is uniformly bounded there. Choose τ so small that the possible negative part of τ times this Hessian consumes less than half the margin. Homogeneity then gives local strong convexity of Q_τ in the fibers everywhere off zero. Apply Theorem 4.6.2 to Q_τ and take one of its smooth regularizations; its square root is the required smooth complex norm. □

Corollary 4.6.1 *For every holomorphic structure in the neighborhood of Theorem 4.6.1, there is no positive continuous complex homogeneous function of degree two that is both strictly plurisubharmonic off zero and locally strongly convex in the fibers. If that structure admits a function H as in Proposition 4.6.1, there is also no positive continuous complex homogeneous function of degree two that is plurisubharmonic off zero and locally strongly convex in the fibers.*

Proof For the first assertion, Theorem 4.6.2 would produce a smooth complex norm with plurisubharmonic square, contrary to Theorem 4.6.1. For the second, use Proposition 4.6.1 and the same obstruction. □

The second assertion requires the strictly plurisubharmonic homogeneous function H, which need not exist for an arbitrary holomorphic bundle; Section 4.6.2 shows that it exists when the dual bundle is ample. Without a strong convexity margin in the fibers, the regularization gives no obstruction for continuous fiber norms.

4.6.2 Strict positivity from the tautological metric

The second part of Corollary 4.6.1 requires a smooth strictly plurisubharmonic function on $F^\times$ that is complex homogeneous of degree two. Such a function is the squared norm of a vector, viewed as a point of the tautological line it spans, for a suitable metric on the tautological line bundle. Its Levi form is strictly positive exactly when the dual tautological metric is positively curved, so the function exists when F^* is ample.

Let $F \to X$ be a holomorphic vector bundle of positive rank. In this subsection, $\mathbb{P}(F)$ parametrizes complex lines in F, $\mathcal{O}_{\mathbb{P}(F)}(-1)$ is the tautological line bundle whose fiber over a line is that line, and

$$L = \mathcal{O}_{\mathbb{P}(F)}(1) = \mathcal{O}_{\mathbb{P}(F)}(-1)^*.$$

The map $v \mapsto ([v], v)$ identifies $F^\times$ holomorphically with the complement of the zero section in $\mathcal{O}_{\mathbb{P}(F)}(-1)$. We use the curvature convention $R_h = -\mathrm{dd^c} \log h$ of Section 4.6.

Lemma 4.6.6 *A smooth Hermitian metric h on L determines a positive smooth complex homogeneous function H of degree two on $F^\times$: the squared norm of v in the dual metric on the tautological line $\mathcal{O}_{\mathbb{P}(F)}(-1)_{[v]}$. The function H is strictly plurisubharmonic if and only if R_h is strictly positive on $\mathbb{P}(F)$.*

Proof Take local holomorphic coordinates y on $\mathbb{P}(F)$ and a holomorphic frame e of the tautological line bundle, and write the metric of the dual frame as $h = \mathrm{e}^{-\varphi}$. The dual metric gives

$$H(y, \lambda e) = |\lambda|^2 \mathrm{e}^{\varphi(y)}, \qquad R_h = \mathrm{dd^c}\varphi.$$

Let $\mathcal{L}$ denote the complex Hessian, without the factor $\mathrm{i}/(2\pi)$ of the curvature normalization. Differentiating at a point with $\lambda \neq 0$ gives

$$\mathcal{L}H(u,t) = H\left(\mathcal{L}\varphi(u) + \left|\frac{t}{\lambda} + \partial\varphi(u)\right|^2\right), \qquad (u,t) \in T^{1,0}_y\mathbb{P}(F) \oplus \mathbb{C}.$$

If $\mathcal{L}\varphi$ is positive definite, the right-hand side is positive for every nonzero (u,t): the first term detects $u \neq 0$, and the second detects $t \neq 0$ when $u = 0$. Conversely, for $u \neq 0$, set $t = -\lambda\partial\varphi(u)$; strict positivity of $\mathcal{L}H$ then forces $\mathcal{L}\varphi(u) > 0$. This is exactly positivity of R_h. The squared tautological norm is independent of the chosen frame and is complex homogeneous, so the local functions define the asserted global function H. □

A line bundle is very ample when its complete linear system defines a holomorphic embedding, and ample when some positive tensor power is very ample. With the convention above, a vector bundle F^* is called ample when L is ample.

Proposition 4.6.2 *If F^* is ample, there is a positive complex homogeneous function H of degree two on $F^\times$ that is smooth and strictly plurisubharmonic there and, after extension by zero, continuous on F.*

Proof Choose $m \geq 1$ such that L^m is very ample. Its complete linear system gives an embedding $\iota : \mathbb{P}(F) \to \mathbb{P}^N$ with $L^m = \iota^*\mathcal{O}_{\mathbb{P}^N}(1)$. Pull back the Fubini–Study metric to a metric k on L^m, and take its positive mth root h on L: in a local frame $h = k^{1/m}$, and the transformation law for L^m makes these local roots a metric on L. Its curvature is

$$R_h = \frac{1}{m}\iota^*\omega_{\mathrm{FS}} > 0,$$

because the differential of the embedding is injective. Apply Lemma 4.6.6. Since the base is compact, the resulting H is bounded on the unit sphere bundle of a fixed Hermitian metric. Homogeneity then gives $0 < H(v) \leq C|v|^2$ off zero, which proves continuity of the extension by zero. □

Corollary 4.6.2 *Let F carry a holomorphic structure in the neighborhood of Theorem 4.6.1. If F^* is ample, there is no positive continuous complex homogeneous function of degree two on F that is plurisubharmonic off zero and locally strongly convex in the fibers.*

Proof By Proposition 4.6.2, ampleness of F^* gives the function H required in Proposition 4.6.1. A function Q as in the statement would therefore give a smooth complex norm on F with strictly plurisubharmonic square, contradicting Theorem 4.6.1. □

The function H is not the square of a Hermitian norm in general, since the metric on the tautological line may vary with the line. It provides the strict plurisubharmonicity on the total space needed for regularization, whereas local strong convexity in the fibers remains a separate hypothesis in the continuous obstruction.

4.6.3 Polar norms of semipositive Finsler metrics

For a holomorphic vector bundle that is not assumed to carry a positively curved Hermitian metric, positivity can be measured by Finsler metrics and their Kobayashi curvature. Polar duality converts a Finsler metric on E with semipositive Kobayashi curvature into a continuous norm on E^* whose square is plurisubharmonic and uniformly convex in the fibers. With the regularization of Section 4.6.1, Theorem 4.6.1 therefore excludes such Finsler metrics on an ample bundle whose dual is close to a split bundle with positive Gauduchon degrees.

Let $E \to X$ be a holomorphic vector bundle of positive rank; in this subsection $n \geq 1$. Write $E^\times$ for the complement of its zero section. A *squared Finsler metric* on E is a positive smooth function G on $E^\times$ with

$$G(x, tv) = |t|^2 G(x, v), \qquad t \in \mathbb{C} \setminus \{0\},$$

extended continuously by zero to the zero section. It is *strongly pseudoconvex* if its vertical complex Hessian $(G_{i\bar{j}})$ is positive definite; this does not require convexity in the real fiber variables.

In local holomorphic base and fiber coordinates (z, v), with Greek indices for base coordinates, Latin indices for fiber coordinates and summation over repeated indices, put

$$S_{\alpha\bar{\beta}} = G_{\alpha\bar{\beta}} - G_{\alpha\bar{j}} G^{\bar{j}i} G_{i\bar{\beta}},$$
$$\mathcal{K}_G = -\frac{\mathrm{i}}{2\pi G} S_{\alpha\bar{\beta}}\, \mathrm{d}z^\alpha \wedge \mathrm{d}\bar{z}^\beta,$$

where $(G^{\bar{j}i})$ is the inverse of the vertical Hessian. We use this convention for the *Kobayashi curvature* $\mathcal{K}_G$, a horizontal $(1,1)$-form at each point of $E^\times$. Thus $\mathcal{K}_G \geq 0$ means $S \leq 0$, and $\mathcal{K}_G > 0$ means that S is negative definite.

Lemma 4.6.7 *Let G be a strongly pseudoconvex squared Finsler metric. If $\mathcal{K}_G > 0$, then for every $v_0 \in E^{\times}_{x_0}$ there is a local holomorphic section σ with $\sigma(x_0) = v_0$ and*

$$G(z, \sigma(z)) \le G(x_0, v_0)$$

near x_0. Moreover, without any curvature assumption, on a coordinate ball, for $\varphi = |z|^2$ and $\varepsilon > 0$, the metric $G_\varepsilon = \mathrm{e}^{-\varepsilon\varphi} G$ is strongly pseudoconvex and satisfies

$$\mathcal{K}_{G_\varepsilon} = \mathcal{K}_G + \varepsilon \mathrm{dd}^{\mathrm{c}} \varphi.$$

Proof Since the vertical Hessian is positive, the Levi-orthogonal complement $H_{G,v}$ of the vertical tangent space at v projects isomorphically onto the base tangent space. The Levi form of G on $H_{G,v}$ is the Schur complement S, which is negative definite when $\mathcal{K}_G > 0$. For the vertical radial vector $R = v_i \partial_{v_i}$, complex homogeneity gives

$$\partial G(R) = G, \qquad \mathcal{L}_G(a, \bar{R}) = \partial G(a)$$

for every tangent vector a, where $\mathcal{L}_G$ is the Levi form. Since R is vertical, the second identity implies $\partial G|_{H_{G,v}} = 0$.

Choose a holomorphic section σ_0 through v_0 whose tangent space at x_0 is H_{G,v_0}. In coordinates centered at x_0, the function $G \circ \sigma_0$ has zero first derivative and Taylor expansion

$$G(x_0, v_0) + P(z) + \overline{P(z)} + S_{\alpha\bar{\beta}} z^\alpha \bar{z}^\beta + O(|z|^3),$$

where P is a homogeneous holomorphic quadratic polynomial. The identity $\partial_v G(v_0)(v_0) = G(v_0) > 0$ gives a vertical vector b with $\partial_v G(v_0)(b) = 1$. Set $\sigma = \sigma_0 - bP$ in the local frame. This changes only the pure quadratic terms and cancels $P + \bar{P}$. The remaining quadratic form is negative definite, and therefore dominates the cubic remainder on a sufficiently small ball. The section stays nonzero there and satisfies the asserted inequality.

For the last assertion, differentiate $\mathrm{e}^{-\varepsilon\varphi} G$ in the Schur complement. Euler's identities give $G_{\bar{j}} = v_i G_{i\bar{j}}$ and $G_\alpha = G_{\alpha\bar{j}} \bar{v}_j$. Hence the terms containing $\partial\varphi$, including its square, cancel between the base Hessian and the mixed block product, leaving

$$S(G_\varepsilon) = \mathrm{e}^{-\varepsilon\varphi} \big(S(G) - \varepsilon G(\varphi_{\alpha\bar{\beta}}) \big).$$

Dividing by G_ε gives the curvature formula. The vertical Hessian of G_ε is the positive multiple $\mathrm{e}^{-\varepsilon\varphi}(G_{i\bar{j}})$, so G_ε is again strongly pseudoconvex. □

Proposition 4.6.3 *Let G be a strongly pseudoconvex squared Finsler metric with $\mathcal{K}_G \geq 0$. Its* polar square

$$Q(x,\xi) = \max_{[v]\in\mathbb{P}(E_x)} \frac{|\xi(v)|^2}{G(x,v)}, \qquad \xi \in E_x^*,$$

is continuous and plurisubharmonic on the total space of E^*, positive off the zero section and complex homogeneous of degree two. The function $\log Q$ is plurisubharmonic off the zero section, and $\sqrt{Q}$ is a complex norm on each fiber.

Proof The ratio is invariant under complex rescaling of v, so the maximum can be taken over the compact unit sphere in a local frame, which proves continuity. Positive upper and lower bounds for G on that sphere compare Q with a Hermitian squared dual norm; this gives positivity off zero and continuity at zero, and complex homogeneity is clear. Moreover,

$$\sqrt{Q(x,\xi)} = \sup_{v\neq 0} \frac{|\xi(v)|}{\sqrt{G(x,v)}}.$$

Each term satisfies the triangle inequality in ξ, and so does their supremum.

On a coordinate ball, set $G_\varepsilon = \mathrm{e}^{-\varepsilon|z|^2} G$. By Lemma 4.6.7, its Kobayashi curvature is strictly positive, and its polar square is $Q_\varepsilon = \mathrm{e}^{\varepsilon|z|^2} Q$. At a point (x_0,ξ_0) with $\xi_0 \neq 0$, choose a maximizing line and a vector v_0 on it. The lemma, applied to G_ε, gives a holomorphic section σ such that

$$\log Q_\varepsilon(z,\xi) \geq \log|\xi(\sigma(z))|^2 - \log G_\varepsilon(x_0,v_0),$$

with equality at (x_0,ξ_0). The pairing $\xi(\sigma(z))$ is nonzero near that point, so the right-hand side is pluriharmonic there. Restriction to sufficiently small holomorphic disks centered at the point therefore gives the submean inequality for $\log Q_\varepsilon$. This argument applies at every point off the zero section, and together with continuity it shows that $\log Q_\varepsilon$ is plurisubharmonic there.

As $\varepsilon \downarrow 0$, the functions $\log Q_\varepsilon = \log Q + \varepsilon|z|^2$ converge locally uniformly off the zero section. Passing to the limit in the submean inequalities on disks proves that $\log Q$ is plurisubharmonic off the zero section. Since the exponential is increasing and convex, Jensen's inequality shows that $Q = \exp(\log Q)$ is plurisubharmonic there. At a point of the zero section, $Q = 0$ and $Q \geq 0$, so every centered disk satisfies the submean inequality there. Together with continuity and the submean inequalities at nonzero points, this proves plurisubharmonicity on the whole total space of E^*. □

Lemma 4.6.8 *Let k be a smooth Hermitian metric on E, and let G be a positive smooth complex homogeneous function of degree two on $E^\times$, extended by zero. Then its polar square Q, defined as in Proposition 4.6.3, has a constant $c > 0$ such that*

$$Q(x,\xi) - c|\xi|_{k^*}^2$$

is real convex on every dual fiber. Neither strong pseudoconvexity nor real convexity of G is required here.

Proof The real fiber Hessian of G is bounded above by $2L$ times k on the compact unit sphere bundle of k, for some $L > 0$, and homogeneity extends this bound to every nonzero vector. Also, G is C^1 at zero with derivative zero, since its value is $O(|v|^2)$ and its first fiber derivative is $O(|v|)$, uniformly over the base. Integrating the Hessian estimate along a segment gives

$$G(v+w) \le G(v) + \mathrm{d}_v G(w) + L|w|_k^2; \tag{4.6}$$

a segment passing through zero is handled by splitting it there and using the continuity of the first derivative.

Complex homogeneity and completing the square on each complex line give the identity

$$Q(x,\xi) = \max_{v \in E_x} \{2\operatorname{Re}\xi(v) - G(x,v)\}. \tag{4.7}$$

The maximum exists because $G(v) \ge a|v|_k^2$ for a uniform constant $a > 0$. Fix a maximizer v_0 for ξ_0. Differentiation, including the case $\xi_0 = v_0 = 0$, gives $\mathrm{d}G(v_0) = 2\operatorname{Re}\xi_0$. Evaluate the expression in (4.7) for $\xi_0 + \zeta$ at $v_0 + w$ and apply (4.6). The terms involving $\xi_0(w)$ cancel, and we obtain

$$Q(\xi_0+\zeta) \ge Q(\xi_0) + 2\operatorname{Re}\zeta(v_0) + 2\operatorname{Re}\zeta(w) - L|w|_k^2.$$

Taking the supremum over w yields

$$Q(\xi_0+\zeta) \ge Q(\xi_0) + 2\operatorname{Re}\zeta(v_0) + L^{-1}|\zeta|_{k^*}^2.$$

Set $c = L^{-1}$ and $\Phi = Q - c|\cdot|_{k^*}^2$. After subtracting the square, this inequality gives a real affine function on the whole dual fiber that lies below Φ and equals Φ at ξ_0. Hence Φ is the supremum of such affine functions, and therefore convex. Neither uniqueness of the maximizer nor real convexity of G has been used. □

Corollary 4.6.3 *If E is ample and has a strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature, then E^* admits a smooth complex norm whose square is strictly plurisubharmonic off zero and locally strongly convex in the real fibers.*

Proof By Proposition 4.6.3, the polar square is a positive continuous plurisubharmonic complex homogeneous function of degree two, and by Lemma 4.6.8 it has

the strong convexity in the fibers required in Proposition 4.6.1. Applying Proposition 4.6.2 to $F = E^*$, whose dual $F^* = E$ is ample, gives the positive smooth strictly plurisubharmonic homogeneous function H on E^*. Hence Proposition 4.6.1 applies. Its proof uses Theorem 4.6.2, which preserves strong convexity in the fibers, and the square root of the resulting function is the asserted smooth norm. □

Corollary 4.6.4 *Let F be the underlying smooth bundle of F_0 in Theorem 4.6.1, with a holomorphic structure in the neighborhood given there. If F^* is ample, then F^* admits no strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature.*

Proof Apply Corollary 4.6.3 to $E = F^*$. Such a metric would produce a smooth complex norm on F with plurisubharmonic square, contrary to Theorem 4.6.1. □

The corollary applies only near a split bundle whose line summands have positive Gauduchon degrees, and it is not vacuous only if such a neighborhood contains holomorphic structures with ample dual. On Hirzebruch surfaces, Theorem 4.6.3 gives stable ample bundles whose duals lie in this neighborhood. Since the polar square need not be smooth, the regularization of Section 4.6.1 is an essential step of the argument.

4.6.4 Ample comparison quotients on Hirzebruch surfaces

To apply Corollary 4.6.4, we need ample vector bundles whose duals are close to a split bundle $F_1 \oplus F_2$ with $\deg_{\Theta_s} F_s > 0$ for suitable test forms Θ_s. The split bundle $F_1^* \oplus F_2^*$ is not ample itself: otherwise its quotient line bundles F_s^* would be ample, hence carry positively curved metrics, and each F_s would have negative degree for every test form. The ample bundles must therefore be obtained by deformation. On a Hirzebruch surface we choose a split bundle $E_0 = L_1 \oplus L_2$ whose dual summands have positive degree for suitable Kähler forms, and we construct an ample bundle E_{amp} with the same Chern classes as a quotient of a trivial bundle. Both bundles belong to the family of bundles with these Chern classes that are prioritary for the ruling. This family is irreducible, which will allow us to find ample bundles in every neighborhood of E_0.

Let $e \geq 0$ be an integer, and let

$$X = \mathbb{F}_e = \mathbb{P}_{\mathbb{P}^1}(\mathcal{O} \oplus \mathcal{O}(e)), \qquad \pi : X \longrightarrow \mathbb{P}^1,$$

be the Hirzebruch surface, where the projective bundle parametrizes lines. Write S for the section defined by the subbundle $\mathcal{O}(e)$ and f for a fiber of π, called a ruling fiber; we identify line bundles with divisor classes and write $\mathcal{O}_X(aS + bf)$. The normal bundle of S is $\mathcal{O}(-e)$, so

$$S^2 = -e, \qquad S \cdot f = 1, \qquad f^2 = 0.$$

The dual of the tautological line bundle is $\mathcal{O}_X(S)$. A line bundle of degree zero on the ruling fibers is pulled back from $\mathbb{P}^1$: its direct image has rank one, and the evaluation map from the pullback of the direct image is an isomorphism on each fiber. Consequently $\mathrm{Pic}(X) = \mathbb{Z}S \oplus \mathbb{Z}f$.

Lemma 4.6.9 *For integers $a \geq 0$ and b,*

$$\pi_*\mathcal{O}_X(aS + bf) = \bigoplus_{i=0}^{a} \mathcal{O}_{\mathbb{P}^1}(b - ie), \qquad R^1\pi_*\mathcal{O}_X(aS + bf) = 0.$$

A class $aS + bf$ is effective exactly when $a, b \geq 0$. If $a \geq 1$ and $b > ae$, its line bundle is very ample. In particular,

$$H = S + (3e + 1)f, \qquad H^2 = 5e + 2, \qquad h^0(X, \mathcal{O}_X(H)) = 5e + 4.$$

The canonical class is $K_X = -2S - (e + 2)f$.

Proof Over a trivializing chart of the base, sections of $\mathcal{O}_X(aS)$ are homogeneous polynomials of degree a in the fiber coordinates. Their transition law gives

$$\pi_*\mathcal{O}_X(aS) = \mathrm{Sym}^a(\mathcal{O} \oplus \mathcal{O}(-e)),$$

and twisting by the base gives the formula. The first cohomology of $\mathcal{O}_{\mathbb{P}^1}(a)$ on each fiber vanishes, which gives the assertion on the higher direct image. If $a < 0$, restriction to a general ruling fiber excludes a nonzero section. For $a \geq 0$, the direct-image formula gives a nonzero section exactly when $b \geq 0$.

Suppose that $a \geq 1$ and $b > ae$. All line bundles in the direct image then have degree at least one. Fiber polynomials of degree a separate points and tangent directions within a fiber. To separate points over different base points, choose a fiber monomial that is nonzero at the first point and a coefficient section vanishing at the second base point but not at the first. At any point, choose such a nonzero monomial and a coefficient section with a simple zero at its base point; the resulting global section vanishes there, has nonzero derivative in a prescribed base direction and has zero vertical derivative. The complete linear system therefore separates points and first jets, so it defines an embedding. The formulas for H^2 and $h^0(H)$ follow from the intersection numbers and from the direct image $\mathcal{O}(3e + 1) \oplus \mathcal{O}(2e + 1)$. Finally, the relative Euler sequence gives $K_{X/\mathbb{P}^1} = -2S - ef$, and adding the pullback of the canonical class of $\mathbb{P}^1$ proves the last identity. □

Put

$$L_1 = \mathcal{O}_X(5S - f), \qquad L_2 = \mathcal{O}_X(-S + (12e + 5)f), \qquad E_0 = L_1 \oplus L_2.$$

Their Chern classes satisfy

$$c_1(E_0) = 4H, \qquad c_2(E_0) = 65e + 26 = 13H^2.$$

An ample bundle with these Chern classes can be constructed as a quotient of a trivial bundle. The main point of the proof is to make the fibers of the associated map to projective space finite, which requires excluding common curves of the defining sections uniformly over the projective parameter.

Proposition 4.6.4 *There exist linearly independent sections $a_0, \dots, a_3$ of $\mathcal{O}_X(H)$ with no common zero. For any such quadruple and a general quadruple $b_0, \dots, b_3$ of sections of $\mathcal{O}_X(3H)$, the sequence*

$$0 \longrightarrow \mathcal{O}_X(-H) \oplus \mathcal{O}_X(-3H) \xrightarrow{(a,b)} \mathcal{O}_X^{\oplus 4} \longrightarrow E_{\mathrm{amp}} \longrightarrow 0$$

has a locally free ample cokernel E_{amp} of rank two, with $c_1(E_{\mathrm{amp}}) = 4H$ and $c_2(E_{\mathrm{amp}}) = 13H^2$. Here general *means outside a proper Zariski-closed subset of the space of quadruples.*

Proof *Step 1: the quadruple a.* Since $\mathcal{O}_X(H)$ is globally generated, a common zero at a fixed point imposes four independent linear conditions on a quadruple a. The incidence variety of quadruples with a common zero at some point of the surface therefore has codimension at least two in the space of quadruples, and its image there is closed by properness. Linear independence is also a nonempty open condition, because $h^0(H) \geq 4$, and the two open conditions intersect. Fix such an a and write

$$V = H^0(X, \mathcal{O}_X(3H))^{\oplus 4}, \qquad N = \dim V.$$

Step 2: local freeness. At a fixed point x, the map (a, b) drops rank exactly when $b(x)$ is proportional to the nonzero vector $a(x)$. Since evaluation on V is surjective, this is a condition of codimension three. Its incidence over X has dimension at most $N - 1$, and its image in V is closed. Outside that image the cokernel is locally free of rank two.

Step 3: the map to projective space. Dualizing the sequence identifies E_{amp}^* with a subbundle of $(\mathbb{C}^4)^* \otimes \mathcal{O}_X$. This inclusion defines a proper morphism

$$q_b : \mathbb{P}(E_{\mathrm{amp}}^*) \longrightarrow \mathbb{P}((\mathbb{C}^4)^*), \qquad \mathcal{O}_{\mathbb{P}(E_{\mathrm{amp}}^*)}(1) = q_b^* \mathcal{O}_{\mathbb{P}^3}(1).$$

For $w = [w_0 : \cdots : w_3]$, its fiber is the common zero scheme of

$$s_w = \sum_i w_i a_i \in H^0(X, \mathcal{O}_X(H)), \qquad t_w = \sum_i w_i b_i \in H^0(X, \mathcal{O}_X(3H)).$$

Linear independence of a gives $s_w \neq 0$ for every w.

Step 4: no common curves. A nonzero effective subdivisor D of $\mathrm{div}(s_w)$ has class $uS + vf$, where

$$u \in \{0, 1\}, \qquad 0 \leq v \leq 3e + 1, \qquad (u, v) \neq (0, 0).$$

Write $|D| = \mathbb{P}H^0(X, \mathcal{O}_X(D))$ for the complete linear system. For each of these finitely many classes D_0, let T_{D_0} parametrize the triples $(w, [\sigma], [\tau])$ with

$$[\sigma] \in |D_0|, \qquad [\tau] \in |H - D_0|, \qquad [s_w] = [\sigma\tau].$$

Since products of nonzero sections are nonzero, this is a closed projective parameter scheme. Its fiber over w consists of the finitely many effective subdivisors of the fixed divisor $\operatorname{div}(s_w)$, counted with their possible multiplicities. Thus $\dim T_{D_0} \le 3$.

Vanishing on a nonzero effective divisor D imposes at least four independent conditions on $H^0(X, O_X(3H))$. Indeed, choose an integral curve C in its support. Very ampleness gives sections r_0, r_1 of $O_X(H)$ with nonconstant ratio on C. The four cubic monomials in their restrictions are linearly independent, since a linear relation would make the nonconstant ratio algebraic over $\mathbb{C}$, hence constant.

For fixed $(w, [\sigma], [\tau])$, the map $V \to H^0(X, O_X(3H))$, $b \mapsto t_w$, is surjective. The condition that t_w vanish on $D = \operatorname{div}(\sigma)$ therefore has codimension at least four in V. This condition is closed in families: the universal multiplication map

$$H^0(X, O_X(3H - D_0)) \otimes O_{|D_0|}(-1) \longrightarrow H^0(X, O_X(3H)) \otimes O_{|D_0|}$$

is injective on fibers, so its image is a subbundle, and the condition is the vanishing of the image of t_w in the quotient bundle. Its incidence over T_{D_0} has dimension at most $N - 1$, and its image in V is closed.

Step 5: conclusion. Choose b outside these finitely many proper closed images and outside the image of Step 2. Then s_w and t_w have no common curve for any w, so every fiber of q_b is finite. A proper morphism with finite fibers is finite, and the pullback of $O_{\mathbb{P}^3}(1)$ by a finite morphism is ample; hence E_{amp} is ample. Finally, the Whitney formula gives

$$c(E_{\mathrm{amp}}) = \frac{1}{(1 - H)(1 - 3H)} = 1 + 4H + 13H^2.$$

A vector bundle E on X is called *prioritary for the ruling* if $\operatorname{Ext}^2_X(E, E(-f)) = 0$. Since all ruling fibers are linearly equivalent, this condition does not depend on the chosen fiber, and by Serre duality it is equivalent to

$$\operatorname{Hom}_X(E, E(K_X + f)) = 0.$$

Prioritary bundles of fixed rank and Chern classes form an irreducible family, by the theorem of Walter recalled in Section 4.6.6.

Lemma 4.6.10 *Both E_0 and E_{amp} are prioritary for the ruling.*

Proof Write $D = K_X + f = -2S - (e + 1)f$. The summands of $\operatorname{End}(E_0)(D)$ have classes

$$D, \quad D, \quad 4S - (13e + 7)f, \quad -8S + (11e + 5)f.$$

Each has a negative coefficient in the basis S, f, so by Lemma 4.6.9 none of them has a nonzero section. This proves the required vanishing of Hom for E_0.

Precomposition with the surjection $O_X^4 \to E_{\mathrm{amp}}$ gives an injection

$$\operatorname{Hom}(E_{\mathrm{amp}}, E_{\mathrm{amp}}(D)) \hookrightarrow H^0(X, E_{\mathrm{amp}}(D))^4.$$

Twist the defining sequence by D. Its middle term has no sections. For $j = 1, 3$, Serre duality and the formula of Lemma 4.6.9 give

$$H^1(X, \mathcal{O}_X(D - jH)) = H^1(X, \mathcal{O}_X(jH - f))^*,$$
$$\pi_* \mathcal{O}_X(jH - f) = \bigoplus_{i=0}^{j} \mathcal{O}_{\mathbb{P}^1}(j(3e + 1) - 1 - ie).$$

The higher direct image vanishes, and every degree in this sum is at least $j(2e+1)-1 \geq 0$. Hence all these first cohomology groups vanish, and the long exact sequence of the twisted sequence gives $H^0(X, E_{\mathrm{amp}}(D)) = 0$. This proves the vanishing of Hom for E_{amp}. □

Proposition 4.6.5 *For $F_s = L_s^*$, $s = 1, 2$, there are Kähler forms η_s with $\deg_{\eta_s} F_s = 1$. Consequently, the split bundle $E_0^* = F_1 \oplus F_2$ satisfies the hypotheses of Theorem 4.6.1.*

Proof The integral classes

$$A_1 = 6S + (6e + 1)f, \qquad A_2 = S + (13e + 6)f$$

are very ample by Lemma 4.6.9. Pullbacks of normalized Fubini–Study forms under the corresponding embeddings give Kähler forms η_s representing $c_1(\mathcal{O}_X(A_s))$. A direct computation of intersection numbers gives

$$c_1(L_1) \cdot A_1 = -1, \qquad c_1(L_2) \cdot A_2 = -1,$$

so the degrees of the duals are equal to one. Since $n = 2$, the closed positive $(1, 1)$-forms η_s are admissible test forms Θ_s in Theorem 4.6.1. □

4.6.5 Stable extensions approaching the split comparison bundle

The bundles near E_0 that we construct will also be slope-stable for a fixed polarization. The split bundle E_0 is unstable, and the ample bundle E_{amp} need not be stable. Nonsplit extensions of L_2 by L_1 have the same Chern classes as E_0, are stable, and converge to E_0 as the extension class tends to zero; they are not ample, however. The next subsection combines them with E_{amp}.

Keep the Hirzebruch surface $X = \mathbb{F}_e$, its ruling and the line bundles of Section 4.6.4. Thus

$$L_1 = \mathcal{O}_X(5S - f), \qquad L_2 = \mathcal{O}_X(-S + (12e + 5)f), \qquad E_0 = L_1 \oplus L_2.$$

We use the very ample polarization $P = 4H - f = 4S + (12e + 3)f$. For a torsion-free coherent sheaf E of positive rank on X, put

$$\deg_P E = c_1(E) \cdot P, \qquad \mu_P(E) = \frac{\deg_P E}{\operatorname{rank} E}.$$

A vector bundle V is *μ_P-stable* if $\mu_P(M) < \mu_P(V)$ for every coherent subsheaf $M \subset V$ with $0 < \operatorname{rank} M < \operatorname{rank} V$. Since $\mu_P(L_2) > \mu_P(E_0)$ by the computation below, the split bundle E_0 is not μ_P-stable.

Proposition 4.6.6 *The extension space has dimension*

$$\dim \operatorname{Ext}^1_X(L_2, L_1) = 105e + 35.$$

Every nonsplit extension

$$0 \longrightarrow L_1 \longrightarrow V \xrightarrow{q} L_2 \longrightarrow 0$$

is a locally free, μ_P-stable bundle with $c_1(V) = 4H$ and $c_2(V) = 13H^2$.

Proof Extensions of line bundles are locally free: the quotient is free on a small trivializing neighborhood, so the sequence splits there. Their classes form

$$\operatorname{Ext}^1_X(L_2, L_1) = H^1(X, \mathcal{O}_X(6S - (12e + 6)f)).$$

By Lemma 4.6.9, the higher direct image of this line bundle vanishes and its direct image is the sum of the seven line bundles $\mathcal{O}_{\mathbb{P}^1}(-12e - 6 - ie)$, $0 \le i \le 6$. Their first cohomology groups have total dimension

$$\sum_{i=0}^{6} (12e + 5 + ie) = 105e + 35 > 0.$$

The Chern classes follow from the extension sequence. Direct computations of intersection numbers give

$$\mu_P(L_1) = 40e + 11, \qquad \mu_P(V) = 40e + 14, \qquad \mu_P(L_2) = 40e + 17.$$

It suffices to test line-bundle subsheaves $M \hookrightarrow V$. Indeed, a rank-one torsion-free subsheaf on a smooth surface has a line bundle as its double dual, and its inclusion extends across the finitely many missing points by Hartogs extension in local bundle frames. The extended map remains injective and has the same first Chern class. This argument does not require the quotient to be locally free.

If the composite $M \to L_2$ is zero, then M maps nontrivially into L_1, so $\deg_P M \le \mu_P(L_1) < \mu_P(V)$. Otherwise its zero divisor D is effective and $M = L_2(-D)$. If $D = 0$, the composite is an isomorphism and its inverse splits q, contrary to the hypothesis. Hence $D \neq 0$, and

$$\deg_P M = \mu_P(V) + 3 - D \cdot P.$$

Every effective class is $aS + bf$ with $a, b \ge 0$, and

$$S \cdot P = 8e + 3, \qquad f \cdot P = 4.$$

For $e \geq 1$, every nonzero effective divisor has P-degree at least four, which proves the strict slope inequality.

For $e = 0$, the only nonzero effective class of P-degree at most three is S. A lift of multiplication by a nonzero section $s \in H^0(X, \mathcal{O}_X(S))$ from $L_2(-S)$ to V would make the pullback of the nonzero extension class vanish. That pullback is the image of the class under the map

$$H^1(X, \mathcal{O}_X(6S - 6f)) \xrightarrow{\cdot s} H^1(X, \mathcal{O}_X(7S - 6f)).$$

On $X = \mathbb{P}^1 \times \mathbb{P}^1$, order the factors so that $\mathcal{O}_X(S) = \mathcal{O}(1, 0)$ and $\mathcal{O}_X(f) = \mathcal{O}(0, 1)$. The Künneth formula identifies this map with

$$\left[H^0(\mathbb{P}^1, \mathcal{O}(6)) \xrightarrow{\cdot s} H^0(\mathbb{P}^1, \mathcal{O}(7))\right] \otimes \mathrm{Id}_{H^1(\mathbb{P}^1, \mathcal{O}(-6))}.$$

Multiplication by a nonzero section is injective on global sections, and tensoring with a vector space preserves injectivity. Thus the nonzero extension class cannot pull back to zero. This excludes the possible equality of slopes and proves stability also for $e = 0$. □

Proposition 4.6.7 *Every extension of L_2 by L_1, including the split extension, is prioritary for the ruling and is not ample. Its restriction to every ruling fiber is $\mathcal{O}_{\mathbb{P}^1}(5) \oplus \mathcal{O}_{\mathbb{P}^1}(-1)$.*

Proof Put $D = K_X + f = -2S - (e + 1)f$. The four line bundles $L_i^* \otimes L_j(D)$ have classes

$$D, \quad D, \quad 4S - (13e + 7)f, \quad -8S + (11e + 5)f.$$

Each has a negative coefficient in the basis S, f, and hence no nonzero section. Applying $\mathrm{Hom}_X(L_i, \cdot)$ to the extension twisted by D gives $\mathrm{Hom}_X(L_i, V(D)) = 0$ for $i = 1, 2$. Applying $\mathrm{Hom}_X(\cdot, V(D))$ to the original extension then gives $\mathrm{Hom}_X(V, V(D)) = 0$. By Serre duality this is the prioritary condition $\mathrm{Ext}^2_X(V, V(-f)) = 0$.

Restriction to a ruling fiber is exact, because the quotient is locally free. The restricted line bundles have degrees five and minus one, and the restricted extension splits, since $\mathrm{Ext}^1_{\mathbb{P}^1}(\mathcal{O}(-1), \mathcal{O}(5)) = H^1(\mathbb{P}^1, \mathcal{O}(6)) = 0$. The quotient of negative degree on this curve excludes ampleness. □

Proposition 4.6.8 *On the smooth bundle underlying E_0 there is a holomorphic one-parameter family of Dolbeault operators $\bar\partial_t = \bar\partial_0 + tA$, $t \in \mathbb{C}$, such that for $t \neq 0$ the holomorphic bundle defined by $\bar\partial_t$ is μ_P-stable and prioritary, but not ample. As $t \to 0$, these operators converge to $\bar\partial_0$ in the C^m norm for every integer $m \geq 0$.*

Proof Choose a nonzero extension class and a smooth Dolbeault representative $\eta \in \Omega^{0,1}(X, L_2^* \otimes L_1)$ of it, so that $\bar\partial\eta = 0$. On the smooth direct sum, set

$$A = \begin{pmatrix} 0 & \eta \\ 0 & 0 \end{pmatrix}.$$

The covariant Dolbeault derivative of A is zero and $A \wedge A = 0$, so $\bar\partial_t^2 = 0$. Adding the Dolbeault operator of the base $\mathbb{C}$ of the parameter t also gives an integrable operator on $X \times \mathbb{C}$, because the family depends holomorphically on t. This defines a holomorphic family of bundles whose extension class is $t[\eta]$. It is nonsplit for $t \neq 0$, so the two preceding propositions apply. For a fixed smooth background connection and fixed metrics,

$$\|\bar\partial_t - \bar\partial_0\|_{C^m} = |t|\,\|A\|_{C^m} \longrightarrow 0,$$

and the norm $\|A\|_{C^m}$ is finite for every m because X is compact. □

Thus stability and ampleness have been realized separately in the prioritary family of E_0: the nonsplit extensions are stable but not ample, while E_{amp} is ample. The deformation argument of Theorem 4.6.3 joins the stable locus to the ample one and provides stable ample bundles arbitrarily close to E_0.

4.6.6 Deforming to stable ample bundles

We keep the Hirzebruch surface $X = \mathbb{F}_e$ and the data H, P, L_1, L_2, E_0 of Sections 4.6.4 and 4.6.5. The ample quotient E_{amp} and a nonsplit extension are two prioritary bundles with the same Chern classes as E_0; the former is ample and the latter is stable. Prioritary bundles with these invariants form an irreducible family in which ampleness and stability are open conditions, so bundles with both properties are dense in the family, and in particular they accumulate at E_0. We first prove the required openness assertions for algebraic families.

Throughout this subsection, T denotes a smooth complex algebraic variety. A *flat family* is a coherent sheaf $\mathcal{E}$ on $X \times T$ that is flat over T, and its fiber $\mathcal{E}_t$ at $t \in T$ is its restriction to $X \times \{t\}$.

Lemma 4.6.11 *If a flat family $\mathcal{E}$ has a locally free fiber at $t_0 \in T$, then $\mathcal{E}$ is a vector bundle on $X \times T'$ for some Zariski-open neighborhood T' of t_0.*

Proof At a point of $X \times \{t_0\}$, lift a local basis of the fiber to $\mathcal{E}$. By Nakayama's lemma, the resulting map from a free module of finite rank is surjective near that point. Tensor its kernel sequence with the residue field of t_0. Flatness over T makes the first Tor term zero, so the kernel restricts to the kernel of the chosen isomorphism on the fiber, namely zero, and Nakayama's lemma shows that the kernel vanishes near that point. Thus $\mathcal{E}$ is locally free near every point of the central fiber. The locus where $\mathcal{E}$ is not locally free is closed. Since the projection $X \times T \to T$ is proper, the image of that locus is closed and misses t_0, and we remove this image. □

Lemma 4.6.12 *For a vector bundle $\mathcal{E}$ on $X \times T$, the parameters t for which $\mathcal{E}_t$ is ample form a Zariski-open subset of T.*

Proof Put $Y = \mathbb{P}_{X\times T}(\mathcal{E}^*)$, with the line convention, and let $p : Y \to T$ be the projection, a projective flat morphism. Write $\mathcal{L} = \mathcal{O}_Y(1)$. If $\mathcal{E}_{t_0}$ is ample, then $\mathcal{L}_{t_0}$ is ample. Choose k so that its kth power is very ample and has vanishing higher cohomology. By Serre vanishing, semicontinuity, and cohomology and base change, after shrinking T around t_0 the sheaf $\mathcal{V} = p_*\mathcal{L}^k$ is locally free and commutes with restriction to fibers. After a further shrinking, the evaluation map $p^*\mathcal{V} \to \mathcal{L}^k$ is surjective: its cokernel vanishes on the central fiber, and the image of its support under the proper map p is closed and misses t_0.

Evaluation gives a proper morphism

$$g : Y \longrightarrow \mathbb{P}_T(\mathcal{V}^*), \qquad g^*\mathcal{O}(1) = \mathcal{L}^k,$$

whose restriction to the central fiber is a closed immersion. The locus where g is quasi-finite is open; its complement has closed image in T by properness and misses t_0, so after a further shrinking g is proper and quasi-finite, hence finite. For a finite morphism, pushforward commutes with base change. The cokernel of

$$\mathcal{O}_{\mathbb{P}_T(\mathcal{V}^*)} \longrightarrow g_*\mathcal{O}_Y$$

therefore vanishes on the central fiber, and its support projects to a closed subset of T missing t_0. After removing that subset, the map is surjective, so g is a closed immersion. Consequently $\mathcal{L}^k$ is very ample on every fiber, and $\mathcal{E}_t$ is ample there. □

Lemma 4.6.13 *For a family $\mathcal{E}$ of rank-two vector bundles on $X \times T$ whose fibers have a fixed first Chern class, the parameters t for which $\mathcal{E}_t$ is μ_P-stable form a Zariski-open subset of T.*

Proof Fix a stable fiber at t_0 and put $\nu = c_1(\mathcal{E}_t) \cdot P/2$, which is independent of t. Choose $k \geq 1$ such that $\mathcal{E}_{t_0}^*(kP)$ is globally generated and has vanishing higher cohomology. The argument with Serre vanishing, base change and evaluation used in the previous proof gives, over a neighborhood of t_0, maps

$$\mathcal{E}_t \longrightarrow \mathcal{O}_X(kP)^{\oplus N}$$

that are injective on every fiber. By the double-dual argument for rank-one subsheaves in the proof of Proposition 4.6.6, a destabilizing subsheaf of $\mathcal{E}_t$ yields a nonzero map from a line bundle $M = \mathcal{O}_X(aS + bf)$ with $\deg_P M \geq \nu$. At least one component of its composite with the injection above is nonzero, and since effective classes have nonnegative coefficients,

$$a \leq 4k, \qquad b \leq (12e + 3)k.$$

Since $\deg_P M = (8e + 3)a + 4b$, the inequality $\deg_P M \geq \nu$ also gives

$$a \geq \frac{\nu - 4(12e+3)k}{8e+3}, \qquad b \geq \frac{\nu - 4k(8e+3)}{4}.$$

Only finitely many integral pairs (a, b) satisfy these four bounds. For each such pair with $\deg_P M \geq \nu$, semicontinuity makes the set

$$\{t : H^0(X, \mathcal{E}_t \otimes M^*) \neq 0\}$$

closed, and it does not contain t_0. Conversely, a nonzero map from such an M is injective as a map of sheaves and violates stability. Thus the set of parameters with unstable fibers is, on this neighborhood, exactly the finite union of these closed subsets, and removing the union proves the claim. □

Lemma 4.6.14 *Let T be smooth and irreducible, let $U \subset T$ be a nonempty Zariski-open subset, and let $\mathcal{E}$ be a vector bundle on $X \times T$. For every $t_0 \in T$, there are points $t_j \in U$ tending to t_0 in the analytic topology, together with smooth complex-linear identifications of the bundles underlying $\mathcal{E}_{t_j}$ and $\mathcal{E}_{t_0}$, under which the Dolbeault operators of the fibers converge in the C^m norm for every integer $m \geq 0$. The dual operators converge in the same sense.*

Proof The proper algebraic closed subset $T \setminus U$ has empty interior in the analytic topology. In an analytic coordinate ball B around t_0, choose $t_j \in U \cap B$ with $t_j \to t_0$. Choose a smooth complex connection on $\mathcal{E}|_{X \times B}$. Parallel transport along radial paths in B, keeping $x \in X$ fixed, gives identifications

$$\Phi_t : \mathcal{E}_{t_0}^{\mathrm{sm}} \longrightarrow \mathcal{E}_t^{\mathrm{sm}}, \qquad \Phi_{t_0} = \mathrm{id},$$

depending smoothly on (x, t), where the superscript sm denotes the underlying smooth complex bundle. These identifications need not be holomorphic. Transport the Dolbeault operators by these maps and write

$$\bar\partial_t = \Phi_t^{-1} \bar\partial_{\mathcal{E}_t} \Phi_t, \qquad A_t = \bar\partial_t - \bar\partial_{\mathcal{E}_{t_0}}.$$

Since both operators satisfy the same Leibniz rule, A_t is an endomorphism-valued $(0,1)$-form. Its coefficients are smooth in (x, t), and $A_{t_0} = 0$. Fix background metrics and a smooth connection on the central bundle. Compactness of X and continuity of every finite collection of derivatives give

$$\|A_{t_j}\|_{C^m(X)} \longrightarrow 0 \qquad \text{for every integer } m \geq 0.$$

The dual identifications are $(\Phi_t^{-1})^*$. In transported dual frames the perturbation is $-A_t^{\mathsf{T}}$, so the same convergence holds for the dual Dolbeault operators. □

We use Walter's theorem on prioritary stacks: on a birationally ruled surface, a nonempty stack of prioritary torsion-free sheaves with fixed rank $r \geq 2$ and fixed numerical Chern classes is smooth and irreducible. Here prioritary means that $\mathrm{Ext}^2(E, E(-f)) = 0$ for every ruling fiber f; on X all ruling fibers are linearly

equivalent. The theorem concerns the full prioritary stack and has no semistability hypothesis.

Theorem 4.6.3 *For every $e \geq 0$, there are integrable Dolbeault operators on the smooth bundle underlying E_0 that converge to its split operator in every C^m norm, $m \geq 0$, and define ample μ_P-stable bundles of rank two with $c_1 = 4H$ and $c_2 = 13H^2$. The induced dual operators converge to the split dual operator in every C^m norm.*

Proof Let $\mathcal{P}$ be the prioritary stack with invariants $(2, 4H, 13H^2)$. It contains E_0 by Proposition 4.6.7, and Walter's theorem makes it smooth and irreducible. Let $\mathcal{A}$ and $\mathcal{S}$ be the loci of ample and of μ_P-stable vector bundles in $\mathcal{P}$. They are open by the three preceding family lemmas, which apply on smooth local charts of $\mathcal{P}$; the first lemma allows restriction to locally free families near a point given by a vector bundle. The ample bundle of Proposition 4.6.4 is prioritary by Lemma 4.6.10, so $\mathcal{A}$ is nonempty. A nonsplit extension is stable and prioritary by Propositions 4.6.6 and 4.6.7, so $\mathcal{S}$ is nonempty. By irreducibility, $\mathcal{U} = \mathcal{A} \cap \mathcal{S}$ is nonempty and dense.

Choose a smooth local chart $q : T \to \mathcal{P}$ of finite type over $\mathbb{C}$, with a point t_0 representing E_0, and let $\mathcal{E}$ be the corresponding flat family on $X \times T$. Fix an identification $\mathcal{E}_{t_0} \simeq E_0$. The variety T is smooth because the stack and the chart are smooth. Shrink T to an irreducible neighborhood of t_0 and use Lemma 4.6.11 to make $\mathcal{E}$ a vector bundle on the whole product. The inverse image $q^{-1}(\mathcal{U})$ is dense: every nonempty open $T' \subset T$ has nonempty open image $q(T')$ under the smooth map q, and this image meets $\mathcal{U}$. Apply Lemma 4.6.14 to this dense open set. Each transported operator defines a bundle isomorphic to the corresponding ample stable fiber. The fixed invariants of the stack give its Chern classes, and the lemma also gives the convergence of the dual operators. □

Corollary 4.6.5 *For every $e \geq 0$, there is an ample μ_P-stable bundle E of rank two on X with $c_1(E) = 4H$ and $c_2(E) = 13H^2$ that admits no smooth strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature.*

Proof By Proposition 4.6.5, the two line summands of E_0^* have positive degrees with respect to suitable test forms. The preceding theorem gives an ample stable bundle E whose dual Dolbeault operator is as close to the split dual operator in C^4 as required. Apply Corollary 4.6.4 to $F = E^*$. □

4.6.7 A fixed Stein hypersurface for all Finsler metrics

Corollary 4.6.5 shows that no Finsler metric on E has semipositive Kobayashi curvature, but it does not locate the failure. For a single metric, a point where the curvature is not semipositive gives a local hypersurface through that point on which the metric has a nondegenerate critical point with many positive Levi directions. Holomorphic approximation on a Stein manifold allows one hypersurface to serve for all metrics at once.

In this subsection, X is a connected smooth projective variety of dimension $n \geq 1$, and $E \to X$ is an algebraic vector bundle of rank $r \geq 2$, viewed as a holomorphic bundle. We use the squared Finsler metrics and the convention for Kobayashi curvature of Section 4.6.3. A compact subset K of a Stein manifold Y is *holomorphically convex* if it coincides with its holomorphic hull $\{y \in Y : |f(y)| \leq \sup_K |f| \text{ for all } f \in \mathcal{O}(Y)\}$. We use the classical Oka–Weil theorem in the following form: a function holomorphic near a holomorphically convex compact subset of a Stein manifold can be approximated uniformly there by global holomorphic functions. We also use polynomial Runge approximation in one variable on a union of two disjoint closed disks.

Lemma 4.6.15 *Let K, L be holomorphically convex compact subsets of a Stein manifold Y. If a global holomorphic function maps them into disjoint closed disks in $\mathbb{C}$, then $K \cup L$ is holomorphically convex.*

Proof Write h for the function and Δ_K, Δ_L for the disks. Their union is polynomially convex, so testing with polynomials in h shows that h maps the holomorphic hull of $K \cup L$ into $\Delta_K \cup \Delta_L$. Suppose that $p \notin K \cup L$ and $h(p) \in \Delta_K$. Holomorphic convexity of K gives $a \in \mathcal{O}(Y)$ with $|a(p)| > \sup_K |a|$. Choose polynomials tending uniformly to one on Δ_K and to zero on Δ_L. Their compositions with h, multiplied by a, converge to a at p and on K, and to zero on L. A sufficiently good approximation therefore separates p from $K \cup L$. The case $h(p) \in \Delta_L$ is identical, with K and L interchanged. Thus no point outside $K \cup L$ belongs to its hull. □

Lemma 4.6.16 *Let U be a connected smooth affine variety and let $q \geq 0$ be an integer. Put $B = U \times \mathbb{C}^* \times \mathbb{C}^q$, with coordinates (x, t, s), and for $\lambda \in \mathbb{C}^*$ let $d_\lambda(x, t, s) = (x, \lambda t, \lambda s)$. For each $j \geq 1$, let $C_j \subset B$ be a holomorphically convex compact set, let g_j be holomorphic near C_j, and let $\delta_j > 0$. Suppose that $t(C_j)$ lies in the disk $|t - t_j| \leq |t_j|/4$ for some $t_j \neq 0$. Then there are $\lambda_j \in \mathbb{C}^*$ and $f \in \mathcal{O}(B)$ such that*

$$\sup_{d_{\lambda_j}(C_j)} |f - \lambda_j g_j \circ d_{\lambda_j}^{-1}| < |\lambda_j| \delta_j \qquad (j \geq 1).$$

Proof Choose an exhaustion $(L_j)_{j \geq 0}$ of the affine, hence Stein, manifold B by holomorphically convex compact sets with $L_j \subset \operatorname{int} L_{j+1}$. We construct $f_j \in \mathcal{O}(B)$ and compact sets K_j inductively, starting with $f_0 = 0$ and $K_0 = L_0$.

At stage $j \geq 1$, choose $M > 0$ with $t(K_{j-1}) \subset \{|t| \leq M\}$, and choose $R > 4M/3$. Dilation by $\lambda_j = R/t_j$ moves the t-projection of C_j into the disk $|t - R| \leq R/4$, which is disjoint from $|t| \leq M$. For the rest of the induction we replace C_j, g_j and δ_j by the dilated compact set $d_{\lambda_j}(C_j)$, the function $\lambda_j g_j \circ d_{\lambda_j}^{-1}$ and the tolerance $|\lambda_j|\delta_j$, keeping the same notation. Lemma 4.6.15, applied with the function t, makes $K_{j-1} \cup C_j$ holomorphically convex.

On disjoint neighborhoods of K_{j-1} and C_j, prescribe f_{j-1} and g_j, respectively. Oka–Weil approximation gives $f_j \in \mathcal{O}(B)$ with

$$\sup_{K_{j-1}} |f_j - f_{j-1}| < \epsilon_j, \qquad \sup_{C_j} |f_j - g_j| < \epsilon_j, \qquad \epsilon_j = 2^{-j-2} \min(1, \delta_1, \ldots, \delta_j).$$

Let K_j be a member of the fixed exhaustion containing $K_{j-1} \cup C_j \cup L_j$ in its interior. The interiors of the sets K_j exhaust B, and the summable errors make f_j converge locally uniformly to some $f \in \mathcal{O}(B)$. For a fixed j, every later approximation controls its error on C_j, since $C_j \subset K_{m-1}$ for $m > j$. Consequently

$$\sup_{C_j} |f - g_j| \leq \sum_{m \geq j} \epsilon_m \leq 2^{-j-1}\delta_j < \delta_j.$$

Returning to the original notation gives the stated tolerances. □

Theorem 4.6.4 *Suppose that E admits no smooth strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature. Then there is a connected smooth Stein hypersurface $\mathcal{S} \subset E^{\times}$, locally closed in the analytic topology, with the following property: for every smooth strongly pseudoconvex squared Finsler metric G on E, the restriction $G|_{\mathcal{S}}$ has a nondegenerate critical point with at least r positive Levi eigenvalues, and hence with at most $n-1$ negative ones.*

Proof *Step 1: coordinates.* An algebraic frame trivializes E over a nonempty affine open subset $U \subset X$. Since X is smooth and connected, it is irreducible, so U is dense and connected. Write the fiber coordinates as $(w, t, s) \in \mathbb{C} \times \mathbb{C} \times \mathbb{C}^{r-2}$, and put $B = U \times \mathbb{C}^* \times \mathbb{C}^{r-2}$. We seek $\mathcal{S}$ as a graph $w = f(x, t, s)$ over B; such a graph avoids the zero section because $t \neq 0$.

Step 2: a local test for one metric. Fix a candidate metric G. Since its Kobayashi curvature is not semipositive, its horizontal Schur complement has a positive direction somewhere. This condition is open, so it holds at a point $v_0 = (x_0, w_0, t_0, s_0)$ with $x_0 \in U$, $t_0 \neq 0$ and $G_w(v_0) \neq 0$. Indeed, the first two conditions define a dense open set, and the zero set of G_w has empty interior, since vanishing of G_w on an open set would give $G_{w\bar{w}} = 0$ there, contradicting the positivity of the vertical Hessian.

Let H be the Levi-orthogonal complement of the vertical tangent space V at v_0. The Euler identities in the proof of Lemma 4.6.7 give

$$K := \ker \partial G(v_0) = H \oplus (V \cap K), \qquad \dim_{\mathbb{C}}(V \cap K) = r - 1.$$

Indeed, ∂G vanishes on H, and its value on the vertical radial vector is $G(v_0) > 0$. The two summands are Levi orthogonal, the vertical summand is positive definite, and the horizontal summand has a positive direction. Thus the Levi form of G restricted to K has at least r positive eigenvalues.

Since $G_w(v_0) \neq 0$, the space K is the graph of a linear map defined on $T^{1,0}_{b_0}B$, where $b_0 = (x_0, t_0, s_0)$. Choose a local holomorphic function g near b_0 with $g(b_0) = w_0$ whose graph has tangent space K at v_0. Then $F = G \circ \mathrm{Graph}(g)$ has a critical point at b_0, and its Levi form there is the restriction of the Levi form of G to K. Keep this first jet of g fixed and vary its quadratic jet. The mixed second derivatives of F do not change, while in local coordinates z on B the pure second derivatives satisfy

$$F_{\alpha\beta}(b_0) = A_{\alpha\beta} + G_w(v_0) g_{\alpha\beta}(b_0),$$

where A is fixed. Since $G_w(v_0) \neq 0$, we can prescribe the pure quadratic part of F to be $\tau \operatorname{Re} \sum_\alpha z_\alpha^2$, whose real Hessian has eigenvalues $\pm 2\tau$. If τ is larger than half the operator norm of the real Hessian of the fixed mixed part, the full real Hessian is invertible by the Neumann-series criterion. The critical point is then nondegenerate, with the same Levi form.

Step 3: stability of the test. Choose compact neighborhoods $C' \subset \operatorname{int} C$ of b_0 on which g is defined, with C holomorphically convex and $t(C) \subset \{|t - t_0| \leq |t_0|/4\}$. A small closed Euclidean ball in a closed affine embedding of B is such a set C, since linear functions separate points outside the ball from the ball. Fix a smooth Hermitian background metric on E and its compact unit sphere bundle Σ. By homogeneity, the C^2 distance between metrics on Σ controls their C^2 distance on each fixed compact subset of $E^\times$. Persistence of nondegenerate critical points and openness of the conditions on the Levi eigenvalues therefore give a neighborhood $\mathcal{V}_G$ of $G|_\Sigma$ for the C^2 topology and a number $\delta_G > 0$ with the following property: for every metric whose restriction to Σ lies in $\mathcal{V}_G$ and every holomorphic function within δ_G of g uniformly on C, the restriction of the metric to the graph of the function still has a nondegenerate critical point over C' with at least r positive Levi eigenvalues. Here the Cauchy estimates on C' turn uniform closeness on C into C^2 closeness on C'.

Step 4: one hypersurface for all metrics. The restrictions of the candidate metrics to Σ form a subspace of the separable metrizable space $C^2(\Sigma)$. This subspace is second countable, hence Lindelöf, so the cover by the neighborhoods $\mathcal{V}_G$ has a countable subcover $(\mathcal{V}_j)_{j \geq 1}$, with associated data C_j, g_j, δ_j. For $D_\lambda(x, w, t, s) = (x, \lambda w, \lambda t, \lambda s)$,

$$G \circ D_\lambda = |\lambda|^2 G.$$

Dilation therefore preserves critical points of restrictions to graphs, their real nondegeneracy and their Levi inertia, for every candidate metric. It maps the graph of a function g over C to the graph of $\lambda g \circ d_\lambda^{-1}$ over $d_\lambda(C)$, with d_λ as in Lemma 4.6.16. A function within $|\lambda|\delta_j$ of $\lambda g_j \circ d_\lambda^{-1}$ on $d_\lambda(C_j)$ pulls back under the dilation to a function within δ_j of g_j on C_j. In particular, the metric neighborhood $\mathcal{V}_j$ needs no change.

Applying Lemma 4.6.16, we obtain one function $f \in \mathcal{O}(B)$ that satisfies all the dilated tests. Its graph $\mathcal{S}$ is biholomorphic to the connected affine Stein manifold B, and it is smooth and closed in the open subset $\{x \in U,\ t \neq 0\}$ of $E^\times$. Every candidate metric belongs to some $\mathcal{V}_j$, so its restriction to $\mathcal{S}$ has the required nondegenerate critical point. Since $\dim_{\mathbb{C}} \mathcal{S} = n + r - 1$, at least r positive Levi eigenvalues leave at most $n - 1$ negative ones. □

Corollary 4.6.6 *For each $e \geq 0$, the bundle E of Corollary 4.6.5 can be chosen so that $E^\times$ contains a connected smooth Stein hypersurface on which the restriction of every smooth strongly pseudoconvex squared Finsler metric on E has a nondegenerate critical point with at least two positive Levi eigenvalues and at most one negative Levi eigenvalue.*

Proof The bundle constructed in the proof of Theorem 4.6.3 is a fiber of an algebraic family on a chart of the prioritary stack, so it is algebraic. Apply Theorem 4.6.4 with $n = r = 2$, using the curvature obstruction of Corollary 4.6.5. □

4.6.8 Concave neighborhoods and dual norms

A relatively compact neighborhood Ω of the zero section of a vector bundle E determines a norm on E^*, the support function $\xi \mapsto \max_{v \in \overline{\Omega} \cap E_x} |\xi(v)|$ of its fibers. If the boundary of Ω is sufficiently concave in the horizontal directions, holomorphic sections touching the boundary from inside show that this support norm has plurisubharmonic square, and supporting balls give it uniform convexity in the fibers. Consequently, when the dual norms are obstructed as in Theorem 4.6.1, such neighborhoods cannot exist. In terms of exhaustion functions, this bounds the convexity of the complement of the zero section in the projective completion of E.

In this subsection, $E \to X$ is a holomorphic vector bundle of rank $r \geq 1$, and $n \geq 1$. Fix a smooth Hermitian metric k on E, with real inner product $k_{\mathbb{R}} = \operatorname{Re} k$ and dual norm $|\cdot|_{k^*}$. For a smooth real function f, write $\mathcal{L}_f$ for its complex Hessian. Let Ω be an open set with smooth boundary, defined near $\partial\Omega$ by $f < 0$ with $\mathrm{d}f \neq 0$ on $\partial\Omega$. We say that $\partial\Omega$ has *at least n negative Levi directions* if, at every boundary point, $\mathcal{L}_f$ has at least n negative eigenvalues on $\ker \partial f$.

Lemma 4.6.17 *Fix $\delta, B > 0$. On a finite-dimensional Hermitian vector space, put*

$$s_c(\xi) = |\xi(c)| + \delta|\xi|$$

for covectors ξ and vectors c with $|c| \leq B$. There is $\gamma > 0$, depending only on δ and B, such that $s_c^2 - \gamma|\xi|^2$ is real convex for every such c.

Proof For $0 < \tau \leq 1$, replace s_c by the norm

$$s_{c,\tau}(\xi) = \sqrt{|\xi(c)|^2 + \tau|\xi|^2} + \delta|\xi|,$$

which is smooth off zero. Its Lipschitz constant is at most $L = \sqrt{B^2 + 1} + \delta$, uniformly in c and τ. All derivatives below are real derivatives on the dual space. At $\xi \neq 0$, set $u = \xi/|\xi|$ and decompose a vector as $w = \alpha u + b$ with b orthogonal to u for the real inner product. Write $s = s_{c,\tau}$ and $A = \mathrm{d}s_\xi(w)$. Since the first summand of s is convex and $s \geq \delta|\xi|$,

$$D^2 s(w,w) \geq \delta \frac{|b|^2}{|\xi|}, \qquad D^2(s^2)(w,w) \geq 2A^2 + 2\delta^2|b|^2.$$

Homogeneity gives $\mathrm{d}s_\xi(u) = s(\xi)/|\xi| \geq \delta$. Since $|\mathrm{d}s_\xi(b)| \leq L|b|$, we have

$$|w|^2 \leq \frac{2A^2}{\delta^2} + \left(1 + \frac{2L^2}{\delta^2}\right)|b|^2.$$

Take $\gamma = \delta^4/(\delta^2 + 2L^2)$. Then $\gamma \leq \delta^2/2$ and $\gamma(1 + 2L^2/\delta^2) = \delta^2$, so $D^2(s^2)(w,w) \geq 2\gamma|w|^2$.

The homogeneous function $s^2 - \gamma|\xi|^2$ of degree two extends as a C^1 function at zero with differential zero. Its restriction to every real line is convex, including at zero, because its second derivative is nonnegative away from zero and its first derivatives match there. Thus it is convex on the whole space. Finally,

$$0 \leq s_{c,\tau}(\xi) - s_c(\xi) \leq \sqrt{\tau}\,|\xi|,$$

and the locally uniform limit as $\tau \downarrow 0$ proves the assertion with the same γ. □

Theorem 4.6.5 *Suppose that a relatively compact neighborhood $\Omega \Subset E$ of the zero section has smooth boundary with at least n negative Levi directions. Then*

$$p(x,\xi) = \max_{v \in \overline{\Omega} \cap E_x} |\xi(v)|$$

is a continuous complex norm on E^* whose square $Q = p^2$ is plurisubharmonic on the total space of E^*. For some $\gamma > 0$, each function $Q(x,\cdot) - \gamma|\cdot|^2_{k^*}$ is real convex. If E is ample, E^* also admits a smooth complex norm with strictly plurisubharmonic square off the zero section.

Proof *Step 1: basic bounds.* Put $A_x = \overline{\Omega} \cap E_x$. By compactness of X there are $0 < a_0 < b_0$ such that, in every fiber, the closed k-ball of radius a_0 is contained in Ω and $\overline{\Omega}$ lies in the open ball of radius b_0. The maximum defining p is attained, and

$$a_0|\xi|_{k^*} \leq p(x,\xi) \leq b_0|\xi|_{k^*}.$$

As a supremum of absolute values of linear functionals, p is complex homogeneous and satisfies the triangle inequality.

Step 2: support points. Fix $\xi_0 \neq 0$ and a maximizing point $v_0 \in A_{x_0}$. It lies on $\partial\Omega$, since at an interior point a small vertical displacement would increase $|\xi_0(v)|$. Multiply ξ_0 by a complex number of modulus one to obtain η with $\eta(v_0) = p(x_0,\xi_0) = a > 0$. Then $\ell = \operatorname{Re}\eta$ satisfies $\ell \leq a$ on A_{x_0}. Choose a smooth defining function f near the boundary, with $\Omega = \{f < 0\}$ and $\mathrm{d}f \neq 0$ there.

Let $V = T^{1,0}_{v_0}E_{x_0}$ be the vertical tangent space and $T = \ker \partial f(v_0)$. Choose an n-dimensional complex subspace $W \subset T$ on which $\mathcal{L}_f$ is negative definite. We first show that the vertical differential $\mathrm{d}_v f(v_0)$ is nonzero. Otherwise $V \subset T$, and counting dimensions gives $W \cap V \neq \{0\}$. A vector in this intersection has negative vertical Levi form, and the two corresponding real directions show that the real vertical Hessian of f has a negative direction. Its negative cone is open, hence contains a direction w

with $\ell(w) > 0$. Since the vertical first derivative vanishes, Taylor expansion gives $f(v_0 + tw) < 0$ for small $t > 0$, contradicting $\ell \le a$ on A_{x_0}.

The boundary of A_{x_0} is therefore smooth at v_0. Since the supporting functional ℓ attains its maximum on A_{x_0} there,

$$\mathrm{d}_v f(v_0) = c\,\mathrm{d}\ell, \qquad c > 0;$$

the sign follows because an inward direction along which ℓ increases would contradict the maximality. On the affine hyperplane $\{\ell = a\}$ of the fiber, the restriction of f has a local minimum zero at v_0: a point there with $f < 0$ would allow an additional displacement increasing ℓ within Ω. The real vertical Hessian of f is thus nonnegative on $\ker \mathrm{d}\ell$. Consequently $\mathcal{L}_f$ is nonnegative on the complex space $V \cap T$, of dimension $r - 1$. Hence $W \cap V = \{0\}$, and the projection $W \to T^{1,0}_{x_0} X$ is an isomorphism.

Step 3: plurisubharmonicity. In local coordinates z centered at x_0, choose a holomorphic section σ_0 through v_0 with tangent space W. The function $f \circ \sigma_0$ has zero first derivative and negative definite mixed Hessian. Its quadratic expansion is

$$f(\sigma_0(z)) = \sum H_{\alpha\bar\beta} z_\alpha \bar z_\beta + 2\,\mathrm{Re}\,P(z) + O(|z|^3),$$

where P is a holomorphic quadratic polynomial. Choose a vertical vector b with $\partial_v f(b) = 1$, and replace σ_0 by $\sigma = \sigma_0 - bP$. This preserves the first jet and cancels the pure quadratic part. Thus, after shrinking the chart,

$$f(\sigma(z)) \le -\epsilon|z|^2, \qquad \sigma(0) = v_0,$$

for some $\epsilon > 0$. In particular $\sigma(z) \in A_z$ throughout the chart.

Compactness of $\overline{\Omega}$ makes p upper semicontinuous: for convergent covectors, the corresponding maximizing vectors have a subsequence whose limit lies in the limiting fiber of $\overline{\Omega}$. The supporting section gives the opposite inequality $p(z, \xi) \ge |\xi(\sigma(z))|$, with equality at (x_0, ξ_0). Therefore p is continuous off the zero section, and its upper bound gives continuity at zero. The holomorphic pairing $\xi(\sigma(z))$ is nonzero near the contact point, and its logarithmic absolute value is a pluriharmonic function lying below $\log p$ and equal to it at (x_0, ξ_0). The mean-value property on small holomorphic disks therefore gives the submean inequality for $\log p$ at every point off the zero section. Thus $\log p$, and then $Q = \exp(2 \log p)$ by Jensen's inequality, are plurisubharmonic there. At the zero section the continuous nonnegative function Q vanishes, so its submean inequality on disks also holds there.

Step 4: uniform convexity in the fibers. Consider all maximizing triples (x, ξ, v) with $|\xi|_{k^*} = 1$. They form a compact set, since p is continuous, and by Step 2 the vertical differential $\mathrm{d}_v f$ does not vanish at these support points. Thus there are uniform constants $m > 0$, $\rho > 0$ and $C \ge 1$ such that, for vertical vectors w,

$$|\mathrm{d}_v f| \ge m, \qquad f(v + w) \le \mathrm{d}_v f(w) + C|w|_k^2 \quad (|w|_k \le \rho).$$

Choose $0 < \delta < \min\{a_0/2, \rho/2, m/(2C)\}$. At a support point, write N for the outward real vertical unit normal and set $c = v - \delta N$. If $|w + \delta N|_k \le \delta$, then

$$k_{\mathbb{R}}(w,N) \le -\frac{|w|_k^2}{2\delta}, \qquad f(v+w) \le -\left(\frac{m}{2\delta} - C\right)|w|_k^2 \le 0.$$

All these points lie in the neighborhood where f is defined, so the closed ball $\overline{B}_k(c,\delta)$ is contained in A_x.

The support function of this ball is $s_c(\xi) = |\xi(c)| + \delta|\xi|_{k^*} \le p(x,\xi)$. For a maximizing covector of unit norm, with its phase normalized as in Step 2, the real part $\operatorname{Re}\eta$ has real dual norm one and its metric dual vector is N. Hence $\operatorname{Re}\eta(N) = 1$, and since $|\eta(N)| \le 1$, also $\eta(N) = 1$. We obtain $\eta(c) = a - \delta > 0$, and therefore $s_c(\xi) = a$. Homogeneity now gives

$$Q(x,\xi) = \sup_c s_c(\xi)^2,$$

where c ranges over the centers of the supporting balls in the fiber. Every such center satisfies $|c|_k \le b_0 + \delta$, so by Lemma 4.6.17 all the functions $s_c^2 - \gamma|\xi|_{k^*}^2$ are convex for the same $\gamma > 0$. Their supremum is finite, and it proves the asserted strong convexity of Q.

Step 5: smoothing. Finally, if E is ample, Proposition 4.6.2 gives the smooth strictly plurisubharmonic homogeneous function on E^* required in Proposition 4.6.1, and applying that proposition to Q gives the smooth norm. □

For a complex manifold of dimension N and an integer $1 \le q \le N$, we say that the manifold is *q-convex* if it has a smooth real exhaustion function with at least $N-q+1$ positive Levi eigenvalues outside a compact set; here an exhaustion function is one whose sublevel sets are compact. A q-convex manifold is also q'-convex for $q \le q' \le N$. We call such integers q the *smooth convexity indices* of the manifold, and the smallest of them, when one exists, its *least smooth convexity index*.

Lemma 4.6.18 *Let Y be a complex manifold of dimension N, and let $Z \subset Y$ be a closed complex submanifold of dimension $D \ge 1$. If the least smooth convexity index of Z is $\kappa \le D$, then every smooth convexity index of Y is at least κ.*

Proof Suppose that Y is p-convex for an integer $1 \le p < \kappa$. Then a smooth exhaustion function ψ has at least $N - p + 1$ positive Levi eigenvalues outside a compact set $K \subset Y$. Its restriction to the closed submanifold Z is an exhaustion function, since its sublevel sets are closed subsets of the compact sublevel sets of ψ, and $K \cap Z$ is compact.

At a point of $Z \setminus K$, choose a complex subspace $P \subset T^{1,0}Y$ of dimension $N - p + 1$ on which the Levi form of ψ is positive definite. Then

$$\dim_{\mathbb{C}}(P \cap T^{1,0}Z) \ge (N - p + 1) + D - N = D - p + 1.$$

The Levi form of $\psi|_Z$ is the restriction of the Levi form of ψ, since the inclusion is holomorphic, so it has at least $D - p + 1$ positive eigenvalues. Since $p < \kappa \le D$, this shows that Z is p-convex, which contradicts the definition of κ. □

In the following results, projectivizations parametrize complex lines.

Corollary 4.6.7 *Suppose that E is ample and that E^* admits no smooth complex norm with plurisubharmonic square off the zero section. Then the complement*

$$Z \setminus Y, \qquad Z = \mathbb{P}(\mathcal{O}_X \oplus E), \quad Y = \mathbb{P}(\mathcal{O}_X),$$

is not r-convex.

Proof The chart of Z where the $\mathcal{O}_X$-coordinate is nonzero is identified with the total space of E, and Y is its zero section. Suppose that $Z \setminus Y$ is r-convex. Since $\dim Z = n + r$, a smooth exhaustion function ψ then has at least $n + 1$ positive Levi eigenvalues outside a compact set K. Choose a relatively compact disk-bundle neighborhood $D \Subset E$ of Y. The set $Z \setminus D$ is compact and disjoint from Y. Choose a regular value c of ψ greater than its maximum on $Z \setminus D$ and on K.

Since $\{\psi \le c\}$ is compact in $Z \setminus Y$, the set $\Omega = \{\psi > c\} \cup Y$ is an open neighborhood of Y. Its closure is a compact subset of D, and its boundary is the regular level set $\{\psi = c\}$. The defining function $f = c - \psi$ has at least $n + 1$ negative Levi eigenvalues there. Restriction to the complex tangent hyperplane removes at most one negative direction, leaving at least n. Since E is ample, Theorem 4.6.5 produces a smooth complex norm on E^* with plurisubharmonic square, a contradiction. □

Corollary 4.6.8 *For every $e \ge 0$, there is an ample rank-two bundle E on the Hirzebruch surface $X = \mathbb{F}_e$ such that $\mathbb{P}(\mathcal{O}_X \oplus E) \setminus \mathbb{P}(\mathcal{O}_X)$ is not 2-convex. The bundle may be chosen with the slope-stability and Chern classes of Theorem 4.6.3.*

Proof Use Theorem 4.6.3 to choose E whose dual Dolbeault operator lies in the C^4 neighborhood of Theorem 4.6.1; the split dual bundle satisfies the hypotheses of that theorem by Proposition 4.6.5. Thus E^* admits no smooth complex norm with plurisubharmonic square, and Corollary 4.6.7 with $r = 2$ gives the assertion. □

4.6.9 Curvature and projective complement exhaustions

Corollary 4.6.7 excludes r-convexity of the complement of the zero section in the projective completion, but it does not decide which larger indices occur. Upper bounds come from curvature. The reciprocal of the squared norm of a Hermitian metric is an exhaustion near the removed zero section, and every positive direction of the curvature, evaluated at a fiber vector, contributes a positive Levi eigenvalue. For a stable bundle of positive Gauduchon degree, the Hermitian–Einstein metric provides such a direction at every fiber vector.

In this subsection, $E \to X$ is a holomorphic vector bundle of rank $r \ge 1$, $n \ge 1$, and h is a smooth Hermitian metric on E. In a holomorphic frame, write the matrix of h as M, using column vectors and an inner product linear in its first argument, so that $h(v, v) = v^* M v$. Put

$$F_h = \bar\partial(M^{-1}\partial M) = \sum_{\alpha,\beta} F_{\alpha\bar\beta}\, \mathrm{d}z_\alpha \wedge \mathrm{d}\bar z_\beta, \qquad R_h(u, \bar u) = \sum_{\alpha,\beta} F_{\alpha\bar\beta} u_\alpha \bar u_\beta.$$

For $v \in E_x$, the real $(1,1)$-form $\alpha_{h,v} = \mathrm{i}\, h(F_h v, v)$ has the Hermitian coefficient form $u \mapsto h(R_h(u,\bar u)v, v)$. For a Hermitian form ω on X, the *mean curvature* of h is the h-Hermitian endomorphism $K_{\omega,h} = \Lambda_\omega(\mathrm{i}F_h)$, where Λ_ω denotes contraction with ω, so that $\Lambda_\omega(\beta)\,\omega^n = n\beta \wedge \omega^{n-1}$ for $(1,1)$-forms β. The curvature F_h is unscaled: for a line bundle, the curvature $-\mathrm{dd}^{\mathrm{c}} \log h$ of Section 4.6 is $\mathrm{i}F_h/(2\pi)$.

Use the line convention for projectivization and put

$$U_E = \mathbb{P}(\mathcal{O}_X \oplus E) \setminus \mathbb{P}(\mathcal{O}_X).$$

The chart $[1 : v]$ identifies the total space of E with an open subset of $\mathbb{P}(\mathcal{O}_X \oplus E)$, in which $\mathbb{P}(\mathcal{O}_X)$ is the zero section; thus U_E contains $E^\times$. Its complex dimension is $n+r$. Convexity is understood in the sense of the smooth exhaustions of Section 4.6.8.

Lemma 4.6.19 *Put $G(v) = h(v,v)$ and $\rho = G^{-1}$ on $E^\times$. In a holomorphic frame that is unitary and* Chern-normal *at x, meaning that $M(x)$ is the identity and the first derivatives of M vanish at x, the complex Hessian of ρ at (x,v) is*

$$\mathcal{L}_\rho(u,w) = \frac{h(R_h(u,\bar u)v, v)}{G^2} - \frac{|w|_h^2}{G^2} + \frac{2|h(w,v)|^2}{G^3}, \qquad u \in T_x^{1,0}X, \quad w \in E_x,$$

where (u,w) are the horizontal and vertical components of a tangent vector. There are no mixed horizontal–vertical terms, and the vertical block has exactly one positive and $r-1$ negative eigenvalues.

Proof Such a frame is obtained by a constant change of frame making it unitary at x, followed by a holomorphic change of frame, linear in the coordinates, that cancels ∂M. Then $F_{\alpha\bar\beta} = -\partial_\alpha \partial_{\bar\beta} M$ at x. The horizontal first derivatives of G and its mixed horizontal–vertical second derivatives vanish. The horizontal complex Hessian of G is $-h(R_h(u,\bar u)v, v)$, its vertical complex Hessian is $|w|_h^2$, and its vertical first derivative in the direction w is $h(w,v)$. Apply

$$\partial\bar\partial(G^{-1}) = 2G^{-3}\partial G \wedge \bar\partial G - G^{-2}\partial\bar\partial G.$$

The vertical block equals $G^{-1} > 0$ at $w = v$ and equals $-|w|_h^2/G^2$ when $w \perp_h v$. These two subspaces are orthogonal for the vertical block, which proves the statement about its eigenvalues. □

Theorem 4.6.6 *Let s be an integer with $0 \le s \le n$. Suppose that for every $x \in X$ and every $0 \ne v \in E_x$, the coefficient form of $\alpha_{h,v}$ has at least s positive eigenvalues. Then U_E is $(n+r-s)$-convex.*

Proof By Lemma 4.6.19, the horizontal block of $\mathcal{L}_\rho$ has at least s positive eigenvalues and the vertical block has one. Their direct sum thus has at least $s+1$ positive eigenvalues at every point of $E^\times$.

Choose $\epsilon > 0$ and a smooth function $\chi : [0,+\infty) \to [0,1]$ equal to one on $[0,\epsilon]$ and to zero on $[2\epsilon, +\infty)$. Define

$$\psi([1:v]) = \frac{\chi(G(v))}{G(v)} \quad (v \neq 0),$$

and extend ψ by zero on the divisor at infinity $\mathbb{P}(E)$. This extension is smooth. Indeed, near a point $[0:v]$ with $v \neq 0$, use a local representative $[u:v]$ in a projective chart. On its intersection with the affine chart, $G(v/u) = h(v,v)/|u|^2$ tends to infinity as $u \to 0$, so $\chi(G)$ vanishes in a neighborhood of the point.

The function ψ tends to infinity near the removed zero section. Since the ambient projective bundle is compact, every sublevel set of ψ is compact in U_E: it is closed there and cannot accumulate on the removed section. Put $D = \{G < \epsilon\} \subset E$, including the zero section, and $K = \mathbb{P}(\mathcal{O}_X \oplus E) \setminus D$. Then K is a compact subset of U_E, and $\psi = \rho$ on $U_E \setminus K$. Thus the exhaustion ψ has at least $s+1$ positive Levi eigenvalues outside a compact set. In dimension $n+r$, this is $(n+r-s)$-convexity.□

Taking $s = 0$ gives $(n+r)$-convexity for every bundle. For $s = 1$, the curvature hypothesis is precisely RC-positivity of the metric, as in Definition 4.11.1. A positive definite mean curvature provides such a direction by taking a trace.

To apply this to stable bundles, we extend the degree of line bundles of Section 4.6 to vector bundles through their determinants.

Definition 4.6.1 For a Gauduchon form ω on X, define

$$\deg_\omega E = \deg_{\omega^{n-1}} \det E = \int_X \frac{\mathrm{i}\operatorname{tr} F_h}{2\pi} \wedge \omega^{n-1}, \qquad \mu_\omega(E) = \frac{\deg_\omega E}{r}.$$

For a nonzero torsion-free coherent sheaf $\mathcal{F}$, use the determinant line bundle $\det \mathcal{F} = (\bigwedge^{\operatorname{rank}\mathcal{F}} \mathcal{F})^{**}$ to define its degree and slope. The bundle E is *ω-slope-stable* if $\mu_\omega(\mathcal{F}) < \mu_\omega(E)$ for every coherent subsheaf $\mathcal{F} \subset E$ with $0 < \operatorname{rank}\mathcal{F} < r$ and torsion-free quotient.

If $\det h' = \mathrm{e}^f \det h$, the two curvature representatives differ by $-\mathrm{dd}^{\mathrm{c}} f$, whose integral against ω^{n-1} vanishes by Lemma 2.1.1. Thus the degree depends only on the Bott–Chern class $c_1^{\mathrm{BC}}(E)$ of the closed form $\mathrm{i}\operatorname{tr} F_h/(2\pi)$, and it is the pairing of this class with ω^{n-1}. The Hopf example in Example 4.6.2 shows that the de Rham first Chern class of E does not determine the degree.

Corollary 4.6.9 *If $K_{\omega,h}$ is positive definite for a Hermitian form ω on X, then U_E is $(n+r-1)$-convex. This holds, in particular, when ω is Gauduchon, E is ω-slope-stable, and $\deg_\omega E > 0$.*

Proof For $v \neq 0$, the trace of $\alpha_{h,v}$ with respect to ω is $h(K_{\omega,h}v, v) > 0$, and a Hermitian form with positive trace has a positive eigenvalue. Apply Theorem 4.6.6 with $s = 1$.

Under the Gauduchon and stability hypotheses, the classical existence theorem for Hermitian–Einstein metrics on stable bundles gives a metric h with $K_{\omega,h} = \lambda \operatorname{Id}_E$, where λ is a constant. Taking the trace and integrating the contraction identity gives

$$r\lambda \int_X \omega^n = n \int_X \operatorname{tr}(\mathrm{i}F_h) \wedge \omega^{n-1} = 2\pi n \deg_\omega E > 0.$$

Here $\operatorname{tr} F_h = \bar\partial\partial \log\det M$, so $\mathrm{i}\operatorname{tr} F_h/(2\pi)$ represents $c_1^{\mathrm{BC}}(E)$. Thus $\lambda > 0$, and the first assertion applies. □

Corollary 4.6.10 *For every $e \geq 0$, there is a stable ample rank-two bundle E on $X = \mathbb{F}_e$ as in Corollary 4.6.8 for which U_E is 3-convex but not 2-convex. Its least smooth convexity index is three.*

Proof Use the ruling section S and fiber f of Lemma 4.6.9, and put $H = S + (3e+1)f$ and $P = 4H - f$. Choose E as in Corollary 4.6.8, μ_P-stable and with $c_1(E) = 4H$. The intersection numbers of Lemma 4.6.9 give

$$c_1(E) \cdot P = 4H \cdot (4H - f) = 80e + 28 > 0.$$

By the same lemma, $P = 4S + (12e + 3)f$ is very ample. Take for ω the pulled-back Fubini–Study Kähler form representing $c_1(\mathcal{O}_X(P))$. Degrees with respect to ω are intersection numbers with P, so E is ω-slope-stable with $\deg_\omega E > 0$, and Corollary 4.6.9 gives 3-convexity, since $n = r = 2$. By the choice of E, the complement is not 2-convex. Finally, 1-convexity would imply 2-convexity, so the least index is three. □

4.6.10 Negative bundle metrics and logarithmic weights

For positive curvature, the reciprocal norm in Lemma 4.6.19 is useful near a removed zero section. With negative curvature, the squared norm itself is plurisubharmonic. Adding its logarithm gives a weight whose Levi form controls both the base and the fiber directions.

In this subsection the base X need not be compact. Suppose that it has a Kähler form ω and a smooth nonnegative plurisubharmonic exhaustion ρ. Here an exhaustion has compact sublevel sets; a constant function qualifies on a compact base. Let $\pi : E \to X$ be a holomorphic vector bundle of rank $r \geq 1$, with a smooth Hermitian metric h, and let Z be its zero section. Use the unscaled curvature and coefficient forms $\alpha_{h,v}$ of Section 4.6.9, and assume

$$\alpha_{h,v} \leq -|v|_h^2 \omega \qquad (x \in X,\ v \in E_x).$$

This is a uniform negative curvature bound with respect to the chosen base form.

Proposition 4.6.9 *Put $U(v) = |v|_h^2$, $q = U\mathrm{e}^U$ and $\Psi = \rho \circ \pi + U$. Then Ψ is a smooth plurisubharmonic exhaustion of E and*

$$\Omega = \pi^*\omega + 2\pi \mathrm{dd}^{\mathrm{c}} U$$

is a Kähler form on E. The function $\log q$, extended by $-\infty$ on Z, is plurisubharmonic and satisfies

$$2\pi \mathrm{dd}^{\mathrm{c}} \log q \geq \Omega \quad \text{on } E \setminus Z.$$

Both U and q are strictly plurisubharmonic off Z. For the real radial vector field $\mathcal{R}$, whose flow is $v \mapsto \mathrm{e}^s v$, one has $\mathcal{R}q = 2(1+U)q$. In particular q has no critical points off Z.

Proof At x, choose a Chern-normal unitary holomorphic frame as in Lemma 4.6.19. Write a tangent vector at (x, v) as (a, b), with a horizontal and b vertical. The first base derivatives and mixed base–fiber derivatives of U vanish there. The same normal-frame calculation gives

$$\mathcal{L}_U(a,b) = -h(R_h(a,\bar{a})v,v) + |b|_h^2 \geq U\omega(a,\bar{a}) + |b|_h^2,$$
$$\mathcal{L}_{\log U}(a,b) = -\frac{h(R_h(a,\bar{a})v,v)}{U} + \frac{|b|_h^2 U - |h(b,v)|^2}{U^2} \geq \omega(a,\bar{a}) \quad (v \neq 0).$$

The last vertical term is nonnegative by Cauchy–Schwarz. Here $\mathcal{L}$ is the unscaled complex Hessian, corresponding to $2\pi\mathrm{dd}^{\mathrm{c}} = \mathrm{i}\partial\bar{\partial}$. These formulas show that U is plurisubharmonic, that Ω is positive definite even on Z, and that $2\pi\mathrm{dd}^{\mathrm{c}}(\log U + U) \geq \Omega$ off Z. The form Ω is closed because ω is closed. The first formula gives strict positivity for U off Z; exponentiating $\log q$ gives it for q. Locally, U is comparable to the squared Euclidean fiber norm, so $\log q$ tends to $-\infty$ at Z and is locally bounded above. By Lemma 1.3.7, the upper-limit extension is plurisubharmonic and has value $-\infty$ on Z.

The function Ψ is plurisubharmonic. Its sublevel set of height M lies over the compact set $\{\rho \leq M\}$ and in the disk bundle $\{U \leq M\}$ over that set, which is compact. The sublevel is closed, so Ψ is an exhaustion. Finally, $\mathcal{R}U = 2U$ gives the radial identity and excludes critical points where $q > 0$. □

Corollary 4.6.11 *For every $m > 0$,*

$$\mathcal{I}(m \log q) = \mathcal{I}_Z^{\max\{\lfloor m \rfloor - r + 1, 0\}}.$$

In particular, if $k \geq 1$ is an integer and $m \geq r + k - 1$, a holomorphic function that is locally square integrable against q^{-m} times a smooth positive volume form vanishes to order at least k along Z. If $m < r + k - 1$, this conclusion fails for some local holomorphic functions.

Proof In a local bundle frame, $\log q = \log|v|^2 + O(1)$ near Z. Apply Lemma 1.16.1 in codimension r. Its radial integrability condition for a homogeneous fiber term of degree a is $a + r > m$. For $m < r + k - 1$, a monomial of degree $k - 1$ satisfies this condition and has insufficient vanishing order. Smooth positive volume forms do not change local integrability. □

Corollary 4.6.12 *The manifold $E \setminus Z$ admits a complete Kähler metric.*

Proof Choose a smooth convex increasing function η on $\mathbb{R}$ equal to $-\log(-t)$ for $t \leq -1$. On $E \setminus Z$ put

$$\widehat{\Omega} = \Omega + 2\pi\mathrm{dd}^{\mathrm{c}}(\Psi^2) + 2\pi\mathrm{dd}^{\mathrm{c}}\eta(\log q).$$

The added forms are nonnegative, so this is Kähler. Since $\Psi \geq 0$ is plurisubharmonic, $2\pi \mathrm{dd}^{\mathrm{c}}(\Psi^2) \geq 2\mathrm{i}\partial\Psi \wedge \bar{\partial}\Psi$. Thus Ψ has bounded gradient for $\widehat{\Omega}$, and a curve of finite length stays in a compact sublevel of Ψ in E. The only possible escape from that compact set within $E \setminus Z$ is approach to Z. Where $\log q \leq -1$, set $\tau = \log(-\log q)$. Convexity and the chain rule give

$$2\pi \mathrm{dd}^{\mathrm{c}} \eta(\log q) \geq \mathrm{i}\partial\tau \wedge \bar{\partial}\tau.$$

Hence τ also has bounded gradient there, while $\tau \to +\infty$ on approach to Z. A finite-length curve cannot escape in this way either. The criterion that every escaping curve has infinite length proves completeness. □

For example, let $B \to X$ have a smooth Hermitian metric with positive unscaled curvature form ω. The direct sum $E = (B^*)^{\oplus r}$ with its induced metric satisfies $\alpha_{h,v} = -|v|_h^2 \omega$. Thus the construction applies whenever this base also has the stated plurisubharmonic exhaustion, including a compact base.

If the base is connected, compact and has positive dimension, one may take $\rho = 0$. Then U is an exhaustion that is strictly plurisubharmonic off Z, but the total space E is not Stein: every holomorphic function on E restricts to a constant on the compact connected zero section and therefore fails to separate its distinct points. Strict positivity away from a compact analytic set does not remove this obstruction.

4.6.11 External tensor products and complement convexity

On a product of k manifolds, the external tensor product of bundles with positive mean curvature has, at every nonzero fiber vector, a positive curvature direction tangent to each factor. Indeed, the curvature of the tensor product metric has no components mixing different factors, so this count applies to every fiber vector, including vectors that are not decomposable tensors. Theorem 4.6.6 then improves the convexity bound by k.

Let $k \geq 2$. For $1 \leq i \leq k$, let X_i be a connected compact complex manifold of dimension $n_i \geq 1$, let $E_i \to X_i$ be a holomorphic vector bundle of rank $r_i \geq 1$, and choose a smooth Hermitian metric h_i on E_i and a Hermitian form ω_i on X_i. With $p_i : X = \prod_i X_i \to X_i$ the projections, put

$$E = \bigotimes_{i=1}^{k} p_i^* E_i, \qquad h = \bigotimes_{i=1}^{k} p_i^* h_i, \qquad n = \sum_i n_i, \quad r = \prod_i r_i.$$

For an endomorphism A_i of E_i, write $\widehat{A}_i$ for its action on the ith tensor factor, with the identity on every other factor. We use the Chern curvature, the forms $\alpha_{h,v}$ and the mean curvatures of Section 4.6.9.

Lemma 4.6.20 *The curvature of h is*

$$F_h = \sum_i \widehat{p_i^* F_{h_i}}.$$

For every $v \in E_x$, the coefficient form of $\alpha_{h,v}$ is block diagonal with respect to the decomposition $T^{1,0}_x X = \bigoplus_i T^{1,0}_{x_i} X_i$, and

$$\operatorname{tr}_{\omega_i}\left(\alpha_{h,v}|_{T_{x_i}X_i}\right) = h\big(\widehat{K}_i v, v\big), \qquad K_i = K_{\omega_i,h_i}.$$

Proof In product holomorphic frames, the matrix of the metric is $M = \bigotimes_i M_i$, and its connection matrix is

$$M^{-1}\partial M = \sum_i \widehat{M_i^{-1}\partial M_i}.$$

Each summand depends only on the coordinates of X_i. Applying $\bar\partial$ gives the curvature formula and shows that all components mixing different factors vanish. Pairing with v gives the block diagonal form. Contracting the ith block with ω_i commutes with the identity actions on the other tensor factors, which gives the trace identity. □

Theorem 4.6.7 *If every K_i is positive definite, then*

$$\mathbb{P}(\mathcal{O}_X \oplus E) \setminus \mathbb{P}(\mathcal{O}_X)$$

is $(n + r - k)$-convex.

Proof At each point, choose an h_i-orthonormal eigenbasis of K_i. The resulting product basis is h-orthonormal, and $\widehat{K}_i$ has the positive eigenvalues of K_i, repeated according to the dimensions of the other tensor factors. Hence $h(\widehat{K}_i v, v) > 0$ for every nonzero v, whether or not v is decomposable.

By Lemma 4.6.20, each diagonal block of $\alpha_{h,v}$ has positive trace and therefore a positive eigenvalue, so the block diagonal form has at least k positive eigenvalues. Since $k \le n$, Theorem 4.6.6 with $s = k$ gives the assertion. □

Corollary 4.6.13 *Suppose that each ω_i is Gauduchon, that E_i is ω_i-slope-stable as in Definition 4.6.1, and that $\deg_{\omega_i} E_i > 0$. Then the complement $\mathbb{P}(\mathcal{O}_X \oplus E) \setminus \mathbb{P}(\mathcal{O}_X)$ is $(n+r-k)$-convex. For k stable ample Hirzebruch examples as in Corollary 4.6.10, with their polarizations, this gives $(2^k + k)$-convexity.*

Proof As in the proof of Corollary 4.6.9, choose a Hermitian–Einstein metric on each E_i. Its mean curvature is $\lambda_i \operatorname{Id}_{E_i}$, with $\lambda_i > 0$ by the positivity of the degree and the integrated trace identity. Apply Theorem 4.6.7. For the Hirzebruch factors, $n_i = r_i = 2$, so $n + r - k = 2k + 2^k - k = 2^k + k$. □

4.6.12 Homogeneous plurisubharmonic functions and Hopf complements

Curvature gives upper bounds for the least convexity index of a projective complement. Lower bounds come from plurisubharmonic functions: a smooth positive plurisubharmonic function on the punctured bundle that is homogeneous of degree two excludes every improvement of the trivial bound, and closed submanifolds transfer such lower bounds by Lemma 4.6.18. On Hopf manifolds these tools determine the least index for line bundles whose de Rham first Chern class vanishes. The answer depends on the sign of their Gauduchon degree, which therefore detects information invisible to de Rham cohomology.

Let $F \to B$ be a holomorphic vector bundle of rank $r \geq 1$ over a connected compact complex manifold B of dimension $n \geq 1$. Write $F^\times$ for the complement of its zero section, and put $N = n + r$ and

$$U_F = \mathbb{P}(\mathcal{O}_B \oplus F) \setminus \mathbb{P}(\mathcal{O}_B).$$

The reciprocal-norm exhaustion in Theorem 4.6.6 with $s = 0$ shows that U_F is N-convex.

Proposition 4.6.10 *Suppose that $F^\times$ admits a smooth positive plurisubharmonic function G satisfying $G(cv) = |c|^2 G(v)$ for every $c \in \mathbb{C}^*$ and $v \in F^\times$. Then the least smooth convexity index of U_F is N.*

Proof Since every smaller convexity index would imply it, it suffices to exclude $(N-1)$-convexity. Suppose that a smooth exhaustion function ψ of U_F has at least two positive Levi eigenvalues outside a compact set $K \subset U_F$.

Fix a reference Hermitian norm on F. On its compact unit sphere bundle, G has a positive minimum and a finite maximum, so by homogeneity G is comparable to the squared reference norm uniformly on $F^\times$. Thus the level sets

$$\Sigma_t = \{G = t^2\}, \qquad t > 0,$$

are compact, and multiplication by t maps Σ_1 onto Σ_t. They are smooth hypersurfaces by the Euler identity: if $R_v = v$ is the real radial vector at v, then $\mathrm{d}G(R_v) = 2G(v) > 0$. Since K stays away from the removed zero section, there is $\epsilon > 0$ such that Σ_t is disjoint from K for $0 < t < \epsilon$.

Put

$$M(t) = \max_{v \in \Sigma_1} \psi([1 : tv]), \qquad 0 < t < \epsilon.$$

On any closed interval in $(0, \epsilon)$, the radial derivatives of the smooth function under the maximum are uniformly bounded over the compact level set, so M is locally Lipschitz. Since ψ is an exhaustion, $M(t) \to +\infty$ as $t \to 0$: otherwise maximizing points along a sequence $t \to 0$ would lie in one compact sublevel set while accumulating on the removed section. Choose $0 < t_0 < t_1 < \epsilon$ with $M(t_0) > M(t_1)$. Since a Lipschitz function is absolutely continuous and is the integral of its derivative, there is a point $t \in (t_0, t_1)$ at which M is differentiable with $M'(t) < 0$.

Choose $v \in \Sigma_1$ attaining $M(t)$, and set $p = tv$. For both signs of h, the inequality

$$M(t+h) \geq \psi([1 : (t+h)v])$$

is an equality at $h = 0$, so differentiability of M gives $\frac{\mathrm{d}}{\mathrm{d}t}\psi([1 : tv]) = M'(t)$. Since ψ restricted to Σ_t attains its maximum at p and $\mathrm{d}G \neq 0$, there is a real number λ with $\mathrm{d}\psi = \lambda\,\mathrm{d}G$ at p. Evaluating on the radial direction gives

$$\lambda = \frac{M'(t)}{2t} < 0.$$

The function $\psi - \lambda G$ has zero differential at p and nonpositive real Hessian on $T_p\Sigma_t$. Indeed, its restriction to Σ_t is ψ minus a constant, which has a maximum at p, and since its differential vanishes at p, its second derivative along a curve in Σ_t is the Hessian evaluated on the tangent vector. On the complex tangent hyperplane $H = T_p\Sigma_t \cap \mathrm{i}T_p\Sigma_t$, this implies

$$\mathcal{L}_\psi|_H \leq \lambda \mathcal{L}_G|_H \leq 0.$$

The first inequality follows by adding the real Hessian inequalities for a tangent vector and its complex rotation; the second uses plurisubharmonicity of G and $\lambda < 0$. A two-dimensional complex subspace on which $\mathcal{L}_\psi$ is positive definite would meet the hyperplane H nontrivially, so ψ has at most one positive Levi eigenvalue at $p \notin K$. This contradiction excludes $(N-1)$-convexity. Together with Theorem 4.6.6 for $s = 0$, it proves the proposition. □

Corollary 4.6.14 *If F admits a smooth Hermitian metric h with*

$$h(R_h(u, \bar{u})v, v) \leq 0 \quad \textit{for every } x \in B,\ u \in T_x^{1,0}B,\ v \in F_x,$$

then the least smooth convexity index of U_F is $n + r$.

Proof Put $G(v) = h(v, v)$. At $x \in B$, take a holomorphic frame that is unitary and Chern-normal at x, and write a tangent vector to F at $v \in F_x$ as (u, w), with $u \in T_x^{1,0}B$ and $w \in F_x$. The calculation in the proof of Lemma 4.6.19 gives

$$\mathcal{L}_G(u, w) = -h(R_h(u, \bar{u})v, v) + |w|_h^2 \geq 0,$$

with zero mixed block. Thus G is smooth, plurisubharmonic and positive off the zero section, and it satisfies $G(cv) = |c|^2 G(v)$. Apply Proposition 4.6.10. □

Corollary 4.6.15 *If F admits a Hermitian metric with flat Chern connection, then the least smooth convexity index of U_F is $n + r$.*

Proof In parallel holomorphic unitary frames, the squared norm is $G(v) = \sum_j |v_j|^2$, which is plurisubharmonic on the total space. Since the transition matrices are constant and unitary, G is globally defined; it is smooth, positive on $F^\times$ and homogeneous of degree two under complex scalars. Apply Proposition 4.6.10. □

Fix $n \geq 2$, a real number $0 < q < 1$ and a complex number $a \neq 0$. On the scalar Hopf manifold

$$X_q = (\mathbb{C}^n \setminus \{0\})/\langle z \mapsto qz \rangle,$$

let E_a be the holomorphic line bundle obtained as the quotient of $(\mathbb{C}^n \setminus \{0\}) \times \mathbb{C}$ by $(z, v) \sim (qz, av)$. Put

$$b = -\frac{\log |a|}{\log q}, \qquad G(z, v) = |z|^{2b}|v|^2.$$

Since $q^{2b}|a|^2 = 1$, the function G descends to the squared norm of a Hermitian metric on E_a.

Example 4.6.2 The least smooth convexity index of U_{E_a} is two when $0 < |a| < 1$, and $n + 1$ when $|a| \geq 1$. For every Gauduchon form γ on X_q, the degree of E_a with respect to γ^{n-1} is positive, zero or negative according as $|a| < 1$, $|a| = 1$ or $|a| > 1$. The de Rham first Chern class of E_a vanishes in all cases.

Proof Let α be the form on X_q induced by $\mathrm{dd}^{\mathrm{c}} \log |z|^2$; it descends because the contraction changes $\log |z|^2$ by a constant. For $u \in T^{1,0}_z(\mathbb{C}^n \setminus \{0\})$, its coefficient form is, up to the positive factor $1/(2\pi)$,

$$\frac{|u|^2}{|z|^2} - \frac{|\langle u, z\rangle|^2}{|z|^4},$$

where $\langle \cdot, \cdot \rangle$ is the Euclidean Hermitian inner product. By the Cauchy–Schwarz inequality, it is positive semidefinite with kernel $\mathbb{C}z$, hence of rank $n - 1$. The curvature $-\mathrm{dd}^{\mathrm{c}} \log |z|^{2b}$ of the metric G is $-b\alpha$. The integral of $\alpha \wedge \gamma^{n-1}$ is strictly positive, so the degree has the sign of $-b$, which gives the three stated cases. The map $z \mapsto (z/|z|, \log |z|)$ identifies the covering space with $S^{2n-1} \times \mathbb{R}$, and the contraction translates the second coordinate by $\log q$. Hence X_q is diffeomorphic to $S^{2n-1} \times S^1$, and $H^2_{\mathrm{dR}}(X_q, \mathbb{R}) = 0$ since $n \geq 2$.

If $|a| < 1$, then $b < 0$, so every nonzero fiber vector gives $n - 1$ positive curvature directions. Applying Theorem 4.6.6 with $r = 1$ and $s = n - 1$, we obtain 2-convexity. For the lower bound, consider the map $X_q \to \mathbb{P}^{n-1}$, $[z] \mapsto [z]$, whose fibers are compact embedded elliptic curves $C \simeq \mathbb{C}^*/q^{\mathbb{Z}}$. On a lifted fiber $z = \zeta z_0$, the logarithm of the metric coefficient is $b \log |\zeta|^2 + b \log |z_0|^2$, which is pluriharmonic in ζ. Thus $E_a|_C$ has flat Chern connection. The complement $U_{E_a|_C}$ is a closed complex submanifold of U_{E_a}. A 1-convex exhaustion function of U_{E_a} would restrict to an exhaustion function of this submanifold that is strictly plurisubharmonic outside a

compact set. This contradicts Corollary 4.6.15, since the restricted bundle has base dimension one and rank one. The phase of a affects the gluing but not these metric and curvature calculations.

If $|a| \geq 1$, then $b \geq 0$. On the covering space of $E_a^\times$, the function

$$\log G = b \log |z|^2 + \log |v|^2$$

is plurisubharmonic: the first summand has semipositive Levi form and the second is pluriharmonic for $v \neq 0$. Consequently

$$\mathcal{L}_G = G\big(\mathcal{L}_{\log G} + \partial \log G \otimes \overline{\partial \log G}\big) \geq 0.$$

The descended function G is smooth, positive and homogeneous of degree two under complex scalars. Apply Proposition 4.6.10 with rank one and total dimension $n+1$.□

On the same scalar Hopf manifold X_q, consider a direct sum of rank $r \geq 1$ with complex parameters $a_1, \ldots, a_r \neq 0$:

$$F = \bigoplus_{j=1}^{r} E_{a_j}, \qquad b_j = -\frac{\log |a_j|}{\log q}, \qquad G(z, v) = \sum_{j=1}^{r} |z|^{2b_j} |v_j|^2.$$

Here E_{a_j} is defined by the rule $(z, v_j) \sim (qz, a_j v_j)$. Since $q^{2b_j}|a_j|^2 = 1$, the function G descends to the squared norm of the direct sum metric on F.

Proposition 4.6.11 *The least smooth convexity index of U_F is $r+1$ if every $|a_j| < 1$, and $n+r$ if every $|a_j| \geq 1$.*

Proof Let α be the form induced by $\mathrm{dd}^{\mathrm{c}} \log |z|^2$. By the calculation in Example 4.6.2, it is semipositive of rank $n-1$, with radial kernel. The direct sum metric has diagonal curvature, and the normalized curvature evaluated at v is

$$\frac{\mathrm{i}}{2\pi} h(F_h v, v) = \left(\sum_{j=1}^{r} (-b_j) |z|^{2b_j} |v_j|^2 \right) \alpha.$$

If every $|a_j| < 1$, then every $b_j < 0$. The coefficient is then strictly positive for $v \neq 0$, so Theorem 4.6.6 with $s = n-1$ shows that U_F is $(r+1)$-convex. On any embedded elliptic fiber C of $X_q \to \mathbb{P}^{n-1}$, each line metric has flat Chern connection by the logarithmic calculation in Example 4.6.2, and so does their direct sum. Hence Corollary 4.6.15 gives least index $r+1$ for $U_{F|_C}$. This is a closed complex submanifold of U_F, being its inverse image over C, and Lemma 4.6.18 gives the lower bound.

If every $|a_j| \geq 1$, then every $b_j \geq 0$. For $v_j \neq 0$, the function $|z|^{2b_j}|v_j|^2$ is plurisubharmonic by the calculation with the logarithm and the exponential in Example 4.6.2. It is also smooth at $v_j = 0$, because $z \neq 0$, and by continuity its complex Hessian is nonnegative there as well. The sum G is therefore plurisubharmonic on the covering space of the total space and descends to F. It is positive on $F^\times$ and homogeneous of degree two under complex scalars, so Proposition 4.6.10 applies.□

For a mixed sum, let $t = \#\{j : |a_j| \geq 1\}$ and assume $0 < t < r$. If $\kappa(F)$ denotes the least smooth convexity index of U_F, then

$$\max\{r+1, n+t\} \leq \kappa(F) \leq n+r.$$

Indeed, the same flat restriction to elliptic fibers gives the lower bound $r+1$. The direct sum of the t summands with $|a_j| \geq 1$ is a holomorphic subbundle $F_0 \subset F$, and U_{F_0} is closed in U_F by the inclusion of projective subbundles. Its least index is $n+t$ by Proposition 4.6.11, and Lemma 4.6.18 applies again. The upper bound is Theorem 4.6.6 with $s = 0$. In the mixed case these bounds leave the least index undetermined.

4.7 Pluriharmonic currents

A current is *pluriharmonic* if its dd^{c} vanishes. The normalized Gauduchon currents of Section 4.4 are positive pluriharmonic currents of bidegree $(n-1, n-1)$. This section proves four basic properties of positive pluriharmonic currents of arbitrary bidegree. Positivity and the second-order equation control their concentration on a smooth hypersurface. On compact Kähler manifolds, a closed test form bounds the mass of their pullbacks, and the heat equation smooths those with continuous coefficients. Finally, a positive pluriharmonic $(1,1)$-current with vanishing vertical trace descends along a fiber bundle whose fibers are entire lines or compact curves; this is used for elliptic fibrations in Chapter 28.

Lemma 4.7.1 *Let Z be a complex manifold of dimension $m \geq 2$, and let $j : D \hookrightarrow Z$ be a smooth closed hypersurface. If a positive (q,q)-current R, $1 \leq q \leq m$, is supported on D and $\mathrm{dd}^{\mathrm{c}} R$ has order zero, then there is a unique positive $(q-1, q-1)$-current S on D such that $R = j_* S$. If $\mathrm{dd}^{\mathrm{c}} R = 0$, then $\mathrm{dd}^{\mathrm{c}} S = 0$. In particular, if $q = 1$, D is compact and connected, and $\mathrm{dd}^{\mathrm{c}} R = 0$, then $R = c[D]$ for some $c \geq 0$.*

Proof Use local coordinates $(z, w_1, \ldots, w_{m-1})$ with $D = \{z = 0\}$. Both R and $\mathrm{dd}^{\mathrm{c}} R$ have measure coefficients supported on D. Suppose first that $q < m$. For every compactly supported smooth form η of bidegree $(m-q-1, m-q-1)$,

$$0 = \langle \mathrm{dd}^{\mathrm{c}} R, |z|^2 \eta \rangle = \langle R, \mathrm{dd}^{\mathrm{c}}(|z|^2 \eta) \rangle = \langle R, \mathrm{dd}^{\mathrm{c}} |z|^2 \wedge \eta \rangle,$$

where the first equality holds because $\mathrm{dd}^{\mathrm{c}} R$ is a measure supported on D, on which $|z|^2$ vanishes, and the last one because the terms containing $|z|^2$ or its first derivatives vanish on D. Thus $R \wedge \mathrm{i}\, \mathrm{d}z \wedge \mathrm{d}\bar{z} = 0$, which removes the coefficients of R containing neither normal differential.

Fix a constant positive Hermitian form τ in the w variables. The current $M_\tau = R \wedge \tau^{m-q-1}$ is positive of bidegree $(m-1, m-1)$, and $M_\tau \wedge \mathrm{i}\, \mathrm{d}z \wedge \mathrm{d}\bar{z} = 0$. Its Hermitian matrix of measure densities therefore has zero diagonal entry in the normal direction, and positivity removes the corresponding row and column, so

$$M_\tau \wedge \mathrm{d}z = 0, \qquad M_\tau \wedge \mathrm{d}\bar{z} = 0.$$

Put $s = m - q - 1$. The powers τ^s, as τ varies over the positive Hermitian forms, span the real horizontal (s, s)-forms. Indeed, a linear functional vanishing on these powers vanishes on a polynomial over an open cone; polarization makes it vanish on products of arbitrary real $(1, 1)$-forms, and these products span the forms of that bidegree. Their products with a horizontal one-form span the complementary test forms for the mixed coefficients of R. The identities above therefore remove every coefficient containing exactly one normal differential. For $q = m$, every top-degree coefficient already contains both normal differentials, and this reduction is unnecessary.

The remaining coefficients are measures on $\{z = 0\}$ multiplying both normal differentials. They therefore define a unique current S on D with $R = j_*S$. Testing against extensions of strongly positive forms on D proves positivity of S, and uniqueness makes these local currents agree on overlaps. Pushforward commutes with $\mathrm{dd^c}$ and is injective for a closed embedding, so $\mathrm{dd^c}R = 0$ implies $\mathrm{dd^c}S = 0$.

When $q = 1$, the current S is a nonnegative distribution on D. The equation $\mathrm{dd^c}S = 0$ and Weyl's lemma make it a smooth nonnegative pluriharmonic function. If D is compact and connected, the maximum principle makes it a constant $c \geq 0$, proving the last assertion. □

For smooth pluriharmonic forms on compact Kähler manifolds, the mass of the pullback under a fixed holomorphic map is controlled by pairing with a fixed closed form. The test object is the pushforward of a power of the Kähler form on the source, which is closed; the form being pulled back need only be $\mathrm{dd^c}$-closed.

Lemma 4.7.2 *Let $F : Y \to X$ be a holomorphic map between compact Kähler manifolds of dimensions $N \geq n$, with Kähler forms Ω and ω. For $1 \leq p \leq n$, there is a constant C such that every smooth positive (p, p)-form S on X with $\mathrm{dd^c}S = 0$ satisfies*

$$\int_Y F^*S \wedge \Omega^{N-p} \leq C \int_X S \wedge \omega^{n-p}.$$

Proof The positive closed current $\Gamma = F_*(\Omega^{N-p})$ has bidegree $(n - p, n - p)$ on X. The classical $\mathrm{dd^c}$-lemma for currents on compact Kähler manifolds gives a smooth real closed form γ of this bidegree and a current U with $\Gamma = \gamma + \mathrm{dd^c}U$. For $p = n$, a closed current of degree zero is already a smooth locally constant function, and one may take $U = 0$. Since S is smooth, pairing it with U is legitimate, and

$$\int_Y F^*S \wedge \Omega^{N-p} = \langle \Gamma, S \rangle = \int_X \gamma \wedge S + \langle U, \mathrm{dd^c}S \rangle = \int_X \gamma \wedge S.$$

The pairing with the fixed smooth form γ is bounded in absolute value by a constant times the trace mass $\int_X S \wedge \omega^{n-p}$ of the positive form S. This proves the estimate.□

For continuous coefficients on a compact Kähler manifold, the Hodge heat flow smooths a positive form while preserving the pluriharmonic equation, and a small multiple of a power of the Kähler form restores positivity.

Lemma 4.7.3 *Let (X, ω) be a compact Kähler manifold of dimension n, and let $1 \le p \le n$. Every continuous positive real (p,p)-form R satisfying $\mathrm{dd^c} R = 0$ in the sense of currents is a uniform limit of smooth positive real (p,p)-forms R_j with $\mathrm{dd^c} R_j = 0$. If R is closed, the approximants can also be chosen closed.*

Proof Let Δ be the real Hodge Laplacian of the Kähler metric. Its heat operators $H_t = \mathrm{e}^{-t\Delta}$ are smoothing for $t > 0$. The Kähler identities give $\Delta = 2\Delta_\partial = 2\Delta_{\bar\partial}$, so H_t preserves bidegree, reality and the equation $\mathrm{dd^c} R = 0$.

We recall why $H_t R \to R$ uniformly for a continuous form R. The Weitzenböck formula writes $\Delta = \nabla^*\nabla + A$, with a bounded curvature term A of order zero. For smooth initial data β, the heat equation and the maximum principle give

$$\|H_t\beta\|_{C^0} \le \mathrm{e}^{Ct}\|\beta\|_{C^0} \qquad (0 < t \le 1),$$

where C depends only on the fixed metric and the degree. Indeed, the scalar equation for $|H_t\beta|^2$ has a nonpositive gradient term and a curvature term bounded above by $2C|H_t\beta|^2$. The classical smooth heat solution converges uniformly to its smooth initial data. Approximating a continuous form by smooth forms and using this bound proves uniform convergence for continuous initial data. The resulting heat solution is smooth for $t > 0$, and since the commutation with $\mathrm{dd^c}$ extends to currents, $\mathrm{dd^c} H_t R = 0$.

Set $\epsilon_t = \|H_t R - R\|_{C^0}$, which tends to zero. A fixed constant $c > 0$ satisfies

$$E + c\|E\|_{C^0}\omega^p \ge 0$$

for every continuous real (p,p)-form E; to see this, evaluate on decomposable unit p-vectors, on which ω^p has a uniformly positive value. Consequently

$$R_t = H_t R + c\epsilon_t \omega^p$$

is smooth and positive. Since ω is Kähler, $\mathrm{dd^c}\omega^p = 0$, and hence $\mathrm{dd^c} R_t = 0$. Moreover, $R_t \to R$ uniformly. The Hodge heat flow also commutes with d, and ω^p is closed, so $\mathrm{d}R = 0$ implies $\mathrm{d}R_t = 0$. Choosing any sequence $t_j \downarrow 0$ proves the assertion. □

We next consider a positive $(1,1)$-current with vanishing vertical trace on the total space of a fiber bundle. Positivity removes its vertical and mixed coefficients. For a closed current the remaining coefficients are constant along the fibers. For a pluriharmonic current they are only harmonic along the fibers, but positivity gives the same conclusion when the fiber is the whole complex line or a compact connected curve.

Lemma 4.7.4 *Let Y be a complex manifold of dimension $\ell \ge 1$, let η be a Hermitian form on Y, and let $\pi : Z \to Y$ be a holomorphic fiber bundle whose fiber is either $\mathbb{C}$ or a compact connected Riemann surface. If S is a positive real $(1,1)$-current on Z with $\mathrm{dd^c} S = 0$ and $S \wedge \pi^*\eta^\ell = 0$, then there is a unique positive $\mathrm{dd^c}$-closed $(1,1)$-current R on Y such that $S = \pi^* R$. If S is closed, then R is closed.*

Proof Fix a local trivialization $\pi^{-1}(U) = U \times F$ of the bundle, with base coordinates $w = (w_1, \dots, w_\ell)$ and a local fiber coordinate z. The coefficient measures of S

have a positive Hermitian matrix of densities relative to their trace measure. The identity $S \wedge \pi^*\eta^\ell = 0$ makes the vertical diagonal entry zero, and the inequality $|s_{\alpha\bar{z}}|^2 \le s_{\alpha\bar{\alpha}} s_{z\bar{z}}$ then removes all mixed entries. Thus

$$S = \frac{\mathrm{i}}{2\pi} \sum_{\alpha,\beta=1}^{\ell} s_{\alpha\bar{\beta}}(w,z)\, \mathrm{d}w_\alpha \wedge \mathrm{d}\bar{w}_\beta,$$

with distribution coefficients. In the equation $\partial\bar{\partial} S = 0$, the coefficient containing both vertical differentials and the horizontal pair (α,β) gives $\partial_z \partial_{\bar{z}} s_{\alpha\bar{\beta}} = 0$.

Fix $v \in \mathbb{C}^\ell$ and a nonnegative smooth function ξ with compact support in U. Pairing the positive coefficient distribution $\sum_{\alpha,\beta} s_{\alpha\bar{\beta}} v_\alpha \bar{v}_\beta$, in the base variables, with ξ times the Euclidean volume form defines a nonnegative harmonic distribution on the whole fiber F. Its definition does not depend on the fiber coordinate, since the remaining differentials are horizontal. Weyl's lemma makes it a nonnegative harmonic function. Such a function is constant on $\mathbb{C}$ by the Liouville theorem for harmonic functions, and on a compact connected curve by the maximum principle.

Polarization in v and linearity in the base test function show that every coefficient $s_{\alpha\bar{\beta}}$ is the pullback of a distribution $r_{\alpha\bar{\beta}}$ on U. To identify this distribution, pair against any nonnegative smooth fiber density of total integral one; this also proves positivity of the resulting current R_U on U and injectivity of the pullback. Consequently $\mathrm{dd^c} S = \pi^*(\mathrm{dd^c} R_U) = 0$ implies $\mathrm{dd^c} R_U = 0$. On overlaps, injectivity makes the currents R_U agree, so they glue to a current R, and injectivity also proves uniqueness. If $\mathrm{d}S = 0$, the same argument gives $\mathrm{d}R = 0$. □

The assumption that the fibers are entire lines or compact curves is essential. On the bidisk $\Delta_z \times \Delta_w$, the current

$$S = (2 + \operatorname{Re} z)\frac{\mathrm{i}}{2\pi}\, \mathrm{d}w \wedge \mathrm{d}\bar{w}$$

is positive and $\mathrm{dd^c}$-closed, and its vertical trace vanishes. Its horizontal coefficient depends on z, so it does not descend under the projection to Δ_w.

4.8 The adjoint measure of the linearization

The derivative of the logarithmic Monge–Ampère operator $u \mapsto \log(\omega_u^n/\mathrm{d}V)$ annihilates the constants, so its linearized equation can be solved only under a compatibility condition. The Gauduchon multiplier of Theorem 4.1.1 identifies this condition. Fix $u \in \mathcal{H}_\omega$ and write $\eta = \omega_u$. For a smooth real direction v, logarithmic differentiation gives the linearized operator

$$L_u v = n\, \frac{\mathrm{dd^c} v \wedge \eta^{n-1}}{\eta^n}. \tag{4.8}$$

Choose the Gauduchon multiplier ρ_u of η given by Theorem 4.1.1, normalized by

$$\int_X \rho_u \eta^n = 1, \qquad \text{and put} \qquad \mathrm{d}\mu_u := \rho_u \eta^n.$$

The *adjoint measure* μ_u is a smooth positive probability measure.

Proposition 4.8.1 *For every smooth real v,*

$$\int_X L_u v \, \mathrm{d}\mu_u = 0. \tag{4.9}$$

Moreover, for smooth real h, the equation $L_u v = h$ has a smooth solution if and only if $\int_X h \, \mathrm{d}\mu_u = 0$. When it exists, the solution is unique modulo constants.

Proof The integral in (4.9) is

$$n \int_X \mathrm{dd^c} v \wedge \rho_u \eta^{n-1} = n \int_X v \, \mathrm{dd^c}(\rho_u \eta^{n-1}) = 0.$$

This proves that the compatibility condition is necessary.

By the Fredholm argument in the proof of Theorem 4.1.1, the range of $L_u : C^{k+2,\alpha}(X) \to C^{k,\alpha}(X)$ has codimension one for every integer $k \geq 0$ and $0 < \alpha < 1$. The nonzero functional $h \mapsto \int_X h \, \mathrm{d}\mu_u$ annihilates that range, so its kernel is the range. Elliptic regularity gives a smooth solution, and since the kernel of L_u consists of the constants, the solution is unique modulo constants. □

By its defining equation and the uniqueness in Theorem 4.1.1, the multiplier ρ_u is constant precisely when η is Gauduchon. Thus

$$\mu_u = \frac{\eta^n}{\int_X \eta^n} \quad \text{if } \mathrm{dd^c}(\eta^{n-1}) = 0.$$

On a surface, $\mathrm{dd^c}\omega_u = \mathrm{dd^c}\omega$, so every positive potential perturbation of a Gauduchon form is still Gauduchon. In higher dimension this persistence requires more than the Gauduchon condition at $u = 0$. Write $M = \int_X \omega^n$.

Proposition 4.8.2 *Every form ω_u with $u \in \mathcal{H}_\omega$ is Gauduchon if and only if*

$$\int_X \omega_u^n = M \quad \text{for every } u \in \mathcal{H}_\omega.$$

In that case the normalized multiplier is $\rho_u = M^{-1}$ and $\mu_u = M^{-1}\omega_u^n$ for every $u \in \mathcal{H}_\omega$.

Proof If all the forms ω_u are Gauduchon, the mass derivative (2.2) vanishes at every point of $\mathcal{H}_\omega$ and in every direction. Since $\mathcal{H}_\omega$ is convex, integration along the segment from 0 to u gives the mass identity. Conversely, Proposition 2.2.1 shows that constant mass forces $\mathrm{dd^c}(\omega_u^{n-1}) = 0$ for every $u \in \mathcal{H}_\omega$. In that case the normalized multiplier is the constant M^{-1}, by Theorem 4.1.1. □

By Theorem 2.2.2, this persistence is equivalent to $\mathrm{dd^c}(\omega^j) = 0$ for all integers $1 \le j \le n-1$. The following example distinguishes it from the single Gauduchon identity in dimension three.

Example 4.8.1 Let $E = \mathbb{C}/(\mathbb{Z} + \mathrm{i}\mathbb{Z})$ and $X = E^3$. For $1 \le j \le 3$, write $z_j = x_j + \mathrm{i}y_j$ for the coordinates on the covering space, and let η_j be the form on X induced by $(\mathrm{i}/2)\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j$. The periodic functions

$$b = \exp(\cos(2\pi x_1)), \qquad c = b^{-1}$$

define a Hermitian form

$$\omega = \eta_1 + b\eta_2 + c\eta_3.$$

Since $bc = 1$,

$$\omega^2 = 2b\eta_1 \wedge \eta_2 + 2c\eta_1 \wedge \eta_3 + 2\eta_2 \wedge \eta_3.$$

The functions b and c depend only on x_1, so $\mathrm{dd^c}b$ and $\mathrm{dd^c}c$ are multiples of η_1, and $\mathrm{dd^c}(\omega^2) = 0$. Thus ω is Gauduchon.

Put $v = \cos(2\pi x_2)$ and $h = -\pi\cos(2\pi x_2)$, so that $\mathrm{dd^c}v = h\eta_2$. For a real s with $0 < |s| < 1/(\pi\mathrm{e})$, the form

$$\omega_{sv} = \eta_1 + (b + sh)\eta_2 + c\eta_3$$

is positive, since $b \ge \mathrm{e}^{-1}$ and $|h| \le \pi$. However,

$$\mathrm{dd^c}(\omega_{sv}^2) = 2s\mathrm{dd^c}\omega \wedge \mathrm{dd^c}v = 2sh\mathrm{dd^c}c \wedge \eta_2 \wedge \eta_3 \neq 0.$$

Indeed, $\mathrm{dd^c}c = (c''/(4\pi))\eta_1$, where the prime denotes differentiation in x_1, and $c''(0) = 4\pi^2\mathrm{e}^{-1}$, while $h = -\pi$ at $x_2 = 0$. Thus a Gauduchon form can have arbitrarily small positive potential perturbations that are not Gauduchon.

When persistence holds, the one-form $v \mapsto \int_X v\,\mathrm{d}\mu_u$ on $\mathcal{H}_\omega$ is the Monge–Ampère one-form of Chapter 3 divided by M. By Theorem 3.1.1, it therefore has a primitive exactly when ω is closed.

4.8.1 Convex entropies along a Monge–Ampère flow

The logarithmic Monge–Ampère operator generates a parabolic flow whose linearization is the operator L_u of (4.8). Along this flow, the ratio of the Monge–Ampère measure to a fixed target measure satisfies a heat-type equation. Integrating a convex function of this ratio by parts produces, besides the usual nonpositive gradient term, a term involving $\mathrm{dd^c}(\omega_{u_t}^{n-1})$. If the forms along the flow are Gauduchon, this additional term vanishes and all convex entropies decrease. Requiring decrease for every smooth positive target at the initial time characterizes the Gauduchon condition.

Recall that $M = \int_X \omega^n$, and fix a smooth strictly positive probability volume form ν on X. Consider a smooth solution on an interval $[0, T)$ of the *logarithmic Monge–Ampère flow*

$$\dot{u}_t = \log \rho_t, \qquad \rho_t = \frac{\omega_{u_t}^n}{M\nu}, \qquad u_0 = 0, \qquad \omega_{u_t} > 0. \tag{4.10}$$

We keep the initial normalizing constant M fixed; the evolving mass $\int_X \omega_{u_t}^n$ need not equal M. Define the linearized operator Δ_t by

$$\Delta_t v \, \omega_{u_t}^n = n \mathrm{dd^c} v \wedge \omega_{u_t}^{n-1};$$

it is the operator L_{u_t} of (4.8). Logarithmic differentiation gives $\partial_t \log \rho_t = \Delta_t \dot{u}_t = \Delta_t \log \rho_t$. Integration by parts against $\omega_{u_t}^{n-1}$ then produces the same derivative of the background power that appears in the mass variation of Proposition 2.2.1.

Proposition 4.8.3 *Let $\Phi \in C^2((0, +\infty), \mathbb{R})$, and choose a function G with $G'(r) = \Phi'(r)/r$. Along (4.10),*

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} \int_X \Phi(\rho_t)\nu = \frac{n}{M} \int_X G(\rho_t) \mathrm{dd^c}(\omega_{u_t}^{n-1}) \\ - \frac{n}{M} \int_X \frac{\Phi''(\rho_t)}{\rho_t} \mathrm{d}\rho_t \wedge \mathrm{d^c}\rho_t \wedge \omega_{u_t}^{n-1}. \end{aligned} \tag{4.11}$$

In particular, for $p > 1$,

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} \int_X \rho_t^p \nu = \frac{np}{(p-1)M} \int_X \rho_t^{p-1} \mathrm{dd^c}(\omega_{u_t}^{n-1}) \\ - \frac{np(p-1)}{M} \int_X \rho_t^{p-3} \mathrm{d}\rho_t \wedge \mathrm{d^c}\rho_t \wedge \omega_{u_t}^{n-1}. \end{aligned} \tag{4.12}$$

Proof Using $\partial_t \rho_t = \rho_t \Delta_t \log \rho_t$ and $\rho_t \nu = M^{-1} \omega_{u_t}^n$, we find that the derivative of the entropy is

$$\frac{n}{M} \int_X \Phi'(\rho_t) \mathrm{dd^c} \log \rho_t \wedge \omega_{u_t}^{n-1}.$$

The chain rule and the definition of G give

$$\Phi'(r)\mathrm{dd^c}\log r = \mathrm{dd^c}G(r) - \frac{\Phi''(r)}{r}\mathrm{d}r\wedge\mathrm{d^c}r,$$

and Lemma 2.1.1 applies to the first term. Adding a constant to G does not change the result, since $\int_X \mathrm{dd^c}(\omega_{u_t}^{n-1}) = 0$. Taking $\Phi(r) = r^p$ and $G(r) = pr^{p-1}/(p-1)$ proves the second formula. □

Corollary 4.8.1 *Suppose that every form ω_{u_t} in (4.10) is Gauduchon. Then $\int_X \rho_t \nu = 1$, and $t \mapsto \int_X \Phi(\rho_t)\nu$ is nonincreasing for every convex function $\Phi \in C^2((0,+\infty),\mathbb{R})$. In particular,*

$$\|\rho_t\|_{L^p(\nu)} \le \|\rho_s\|_{L^p(\nu)} \quad (0 \le s \le t < T,\ p > 1).$$

If $\Phi'' > 0$, the derivative of the entropy vanishes at a time t precisely when $\rho_t = 1$, in which case $\dot{u}_t = 0$.

The hypothesis holds on a Gauduchon surface, and in any dimension it holds if $\mathrm{dd^c}(\omega^j) = 0$ for $1 \le j \le n-1$.

Proof The derivative of the mass is

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_X \rho_t\nu = \frac{n}{M}\int_X \dot{u}_t\,\mathrm{dd^c}(\omega_{u_t}^{n-1}) = 0,$$

and its initial value is one. In (4.11) the first term vanishes, while the second is nonpositive, because $\mathrm{d}\rho_t\wedge\mathrm{d^c}\rho_t$ is a semipositive $(1,1)$-form and $\Phi'' \ge 0$. If $\Phi'' > 0$, the vanishing of this term forces $\mathrm{d}\rho_t = 0$, and connectedness together with the mass normalization gives $\rho_t = 1$. The converse and the assertion about $\dot{u}_t$ follow from the equation.

On a surface, $\mathrm{dd^c}\omega_{u_t} = \mathrm{dd^c}\omega = 0$. Under the power identities, expand $\omega_{u_t}^{n-1}$ by the binomial theorem; since the factors $\mathrm{dd^c}u_t$ are annihilated by d and $\mathrm{d^c}$, each term has vanishing complex Hessian. These are also the persistence conditions of Proposition 4.8.2 and Theorem 2.2.2. □

For $\Phi(r) = r\log r$, the same formula gives the dissipation of the relative entropy. In higher dimension, the Gauduchon condition on the initial form alone need not persist along potential perturbations, as Example 4.8.1 shows. The next criterion determines the role of this condition at the initial time, without assuming that the flow exists.

Proposition 4.8.4 *Fix $p > 1$. For each smooth strictly positive probability volume form ν, put $\rho_\nu = \omega^n/(M\nu)$ and define*

$$\mathcal{D}_p(\omega,\nu) := \frac{\mathrm{d}}{\mathrm{d}t}\bigg|_{t=0}\int_X \left(\frac{(\omega + t\mathrm{dd^c}\log\rho_\nu)^n}{M\nu}\right)^p \nu.$$

Then $\mathcal{D}_p(\omega,\nu) \le 0$ for every such ν if and only if ω is Gauduchon. If ω is not Gauduchon, there is such a ν with $\mathcal{D}_p(\omega,\nu) > 0$.

Proof The form in the definition is positive for sufficiently small $|t|$. The path $u_t = t \log \rho_\nu$ starts at $u_0 = 0$ with the velocity $\log \rho_\nu$ prescribed by (4.10) at time zero. The proof of Proposition 4.8.3 at a given time uses only the potential and its velocity at that time, so (4.12) holds for the derivative at $t = 0$. If ω is Gauduchon, its first term vanishes and the derivative is nonpositive.

Conversely, suppose that $\lambda := \mathrm{dd}^{\mathrm{c}}(\omega^{n-1}) \neq 0$. Write $\lambda = f\omega^n/M$, where f is smooth and real. Stokes' theorem gives $\int_X f\omega^n = 0$, whereas

$$\int_X f\lambda = \frac{1}{M}\int_X f^2\omega^n > 0.$$

For small $\varepsilon > 0$, set

$$c_\varepsilon = \frac{1}{M}\int_X \mathrm{e}^{-\varepsilon f}\omega^n, \qquad r_\varepsilon = c_\varepsilon \mathrm{e}^{\varepsilon f}, \qquad \nu_\varepsilon = \frac{\omega^n}{M r_\varepsilon}.$$

Then ν_ε is a smooth strictly positive probability volume form, and $\rho_{\nu_\varepsilon} = r_\varepsilon$. Since $c_\varepsilon = 1 + O(\varepsilon^2)$, $\int_X \lambda = 0$ and $\mathrm{d}r_\varepsilon = \varepsilon r_\varepsilon \mathrm{d}f$, the two terms in (4.12) give

$$\mathcal{D}_p(\omega, \nu_\varepsilon) = \frac{np}{M}\varepsilon \int_X f\lambda + O(\varepsilon^2) > 0$$

for sufficiently small $\varepsilon > 0$. This proves necessity and the last assertion. □

The criterion involves only the initial velocity: every smooth solution of (4.10) with target ν has the same initial entropy derivative, independently of its existence for later times or its convergence. Quantification over all targets is essential. For the target $\nu = \omega^n/M$, the flow $u_t = 0$ is stationary for every Hermitian ω, and all entropy derivatives vanish.

4.8.2 Total variation between two evolving probabilities

The entropies of Section 4.8.1 compare one evolving probability with the fixed target. Two solutions of the flow with different initial potentials can nevertheless move apart. On a flat torus, even with a closed background, their total-variation distance can increase at the initial time, while no convex entropy relative to the target increases. We show this by computing the initial derivatives explicitly. By a *logarithmic Monge–Ampère flow with target* ν we mean a smooth solution of the equation in (4.10), with an arbitrary smooth initial potential.

For this example, let $E = \mathbb{C}/(\mathbb{Z} + \mathrm{i}\mathbb{Z})$ and $X = E^2$, with covering coordinates $z_j = x_j + \mathrm{i}y_j$. Write

$$\eta_j = \frac{\mathrm{i}}{2}\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j, \qquad \kappa = \eta_1 + \eta_2, \qquad \mu = \eta_1 \wedge \eta_2 = \frac{\kappa^2}{2}.$$

Thus μ is a probability volume form and $\int_X \kappa^2 = 2$. Put

$$c_j = \cos(2\pi x_j), \qquad S = c_1 + c_2, \qquad P = c_1 c_2.$$

Lemma 4.8.1 *The averages of $|S|$ and $P|S|$ are*

$$\int_X |S|\mu = \frac{8}{\pi^2}, \qquad \int_X P|S|\mu = \frac{8}{3\pi^2}.$$

Proof The integrands do not depend on y_1, y_2. The degree-two map of real tori $(a, b) \mapsto (a+b, a-b)$ preserves normalized Haar averages. With the angles $A = 2\pi a$ and $B = 2\pi b$, it gives

$$S = 2\cos A \cos B, \qquad P = \frac{\cos(2A) + \cos(2B)}{2}.$$

The one-variable averages of $|\cos A|$ and $|\cos A|^3$ are $2/\pi$ and $4/(3\pi)$, respectively, so the average of $\cos(2A)|\cos A|$ is $2/(3\pi)$. Multiplying the averages over the two independent angles gives both formulas. □

For a fixed real number $K > 3$, define the smooth target probability ν_K by

$$Z_K = \int_X \mathrm{e}^{KP}\mu, \qquad f_K = Z_K^{-1}\mathrm{e}^{KP}, \qquad \nu_K = f_K\mu.$$

For $0 < \varepsilon < 1/\pi$, the initial potentials εS and zero give positive forms. Set

$$A_\varepsilon = 1 - \pi\varepsilon c_1, \qquad B_\varepsilon = 1 - \pi\varepsilon c_2, \qquad r_\varepsilon = A_\varepsilon B_\varepsilon,$$

so that $\kappa + \mathrm{dd}^{\mathrm{c}}(\varepsilon S) = A_\varepsilon\eta_1 + B_\varepsilon\eta_2$ and its normalized Monge–Ampère probability is $r_\varepsilon\mu$.

Consider the short smooth paths

$$U_\varepsilon(t) = \varepsilon S + t\log\frac{r_\varepsilon}{f_K}, \qquad V(t) = -t\log f_K. \tag{4.13}$$

They remain positive for sufficiently small $|t|$, and at $t = 0$ their velocities are exactly those prescribed by the logarithmic Monge–Ampère flow with target ν_K. Their normalized probabilities are

$$\mu_\varepsilon(t) = \frac{(\kappa + \mathrm{dd}^{\mathrm{c}}U_\varepsilon(t))^2}{2}, \qquad \mu_0(t) = \frac{(\kappa + \mathrm{dd}^{\mathrm{c}}V(t))^2}{2},$$

which have mass one because the background κ is closed. Define their total-variation distance, with the convention for probabilities, by

$$D_\varepsilon(t) = \frac{1}{2}\int_X |\mu_\varepsilon(t) - \mu_0(t)|.$$

Proposition 4.8.5 *For the paths* (4.13),

$$D'_\varepsilon(0) = 4\varepsilon\left(\frac{K}{3} - 1\right) + o(\varepsilon) \quad \text{as } \varepsilon \downarrow 0.$$

In particular, this derivative is positive for sufficiently small $\varepsilon > 0$. Any two logarithmic Monge–Ampère flows with target ν_K and these initial potentials have the same positive initial derivative of their total-variation distance.

Proof For a real function h depending only on x_1, x_2, the coefficient matrix of $\mathrm{dd^c}h$ with respect to the forms $(\mathrm{i}/2)\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_k$ is $(4\pi)^{-1}(h_{x_j x_k})$. Put $R_\varepsilon(t) = \mathrm{d}\mu_\varepsilon(t)/\mathrm{d}\mu$ and $R_0(t) = \mathrm{d}\mu_0(t)/\mathrm{d}\mu$. Differentiating the determinant at the diagonal initial matrices gives

$$\partial_t(R_\varepsilon - R_0)|_{t=0} = \frac{1}{4\pi}\big(B_\varepsilon \partial^2_{x_1} \log A_\varepsilon + A_\varepsilon \partial^2_{x_2} \log B_\varepsilon \\ - K(B_\varepsilon - 1)\partial^2_{x_1} P - K(A_\varepsilon - 1)\partial^2_{x_2} P\big).$$

Since $\partial^2_{x_j} P = -4\pi^2 P$, Taylor expansion in ε yields the uniform estimate

$$\partial_t(R_\varepsilon - R_0)|_{t=0} = \pi^2 \varepsilon S(1 - KP) + O(\varepsilon^2).$$

At $t = 0$, the difference of the densities is

$$q_\varepsilon = r_\varepsilon - 1 = -\pi\varepsilon S + \pi^2 \varepsilon^2 P.$$

For each fixed x_2, its coefficient of c_1 is $-\pi\varepsilon(1 - \pi\varepsilon c_2) \neq 0$, so as a function of x_1 it has at most two zeros in a period, and its zero set has measure zero. Differentiation under the integral sign, justified by the uniform bound on the derivatives of the smooth densities, gives

$$D'_\varepsilon(0) = \frac{1}{2}\int_X \operatorname{sgn}(q_\varepsilon)\, \partial_t(R_\varepsilon - R_0)|_{t=0}\, \mu.$$

The set $\{S = 0\}$ also has measure zero, and $\operatorname{sgn}(q_\varepsilon) \to -\operatorname{sgn}(S)$ off this set. Dominated convergence and Lemma 4.8.1 give

$$\lim_{\varepsilon \downarrow 0} \frac{D'_\varepsilon(0)}{\varepsilon} = \frac{\pi^2}{2}\int_X |S|(KP - 1)\mu = 4\left(\frac{K}{3} - 1\right).$$

Every flow with the stated initial data has the velocities (4.13) at $t = 0$, so its initial density derivatives, and hence the derivative of the distance, coincide with this computation. □

Corollary 4.8.2 *For these paths, the initial derivative of every C^2 convex entropy of each probability relative to ν_K is nonpositive, while the total-variation distance between the two probabilities has positive initial derivative for sufficiently small $\varepsilon > 0$.*

Proof The initial velocities are those of the logarithmic flow, and both initial forms are closed. The chain-rule calculation in the proof of Proposition 4.8.3 therefore applies at $t = 0$: its background term vanishes and its gradient term is nonpositive. The preceding proposition gives the assertion about the pair. □

Since only initial velocities enter, the example shows, without any existence or convergence theorem for the flow, that the logarithmic Monge–Ampère flow need not contract the total-variation distance infinitesimally, even though no convex entropy relative to the target increases at the initial time.

4.9 Fredholm theory for a continuous Hermitian form

A continuous positive Hermitian form still defines a uniformly elliptic trace operator. Its range is most conveniently described in Sobolev spaces: continuity of the coefficients suffices for the local $W^{2,p}$ estimate, while the maximum principle identifies the kernel.

Lemma 4.9.1 *Let σ be a continuous positive real $(1,1)$-form on a connected compact complex n-fold, and let $\mathrm{d}V$ be a smooth positive volume. For $p > 2n$, the real operator*

$$L_\sigma v = \operatorname{tr}_\sigma \mathrm{dd}^{\mathrm{c}} v, \qquad L_\sigma : W^{2,p}(X) \longrightarrow L^p(\mathrm{d}V),$$

is Fredholm of index zero. Its kernel consists of the constants, and its range has a one-dimensional annihilator in $L^{p'}(\mathrm{d}V)$, where $p' = p/(p-1)$.

Proof Fix a smooth positive Hermitian form η and put $L_s = (1-s)L_\eta + sL_\sigma$, $0 \le s \le 1$. On a finite holomorphic cover these operators have uniformly positive real principal matrices and a common modulus of continuity. They have no lower-order terms in these coordinates. Write $d = 2n$ for the real dimension.

Local estimates. For a constant positive real matrix a_0, the symbols $\xi_i\xi_j/(1 + a_0^{kl}\xi_k\xi_l)$ satisfy the order-zero multiplier estimates. Consequently

$$\|D^2 z\|_p \le C\big(\|a_0^{ij} D_{ij} z\|_p + \|z\|_p\big) \qquad (z \in C_c^\infty).$$

Freeze the principal matrix of L_s at a point and shrink the ball until the coefficient oscillation times this constant is less than $1/2$. The oscillation term can then be absorbed on the left. Differentiating a cutoff adds first derivatives; the interpolation inequality $\|Dz\|_p \le \varepsilon\|D^2 z\|_p + C_\varepsilon\|z\|_p$ absorbs them. This inequality follows by comparing Dz with its mollification at scale ε and estimating the derivative of the mollified function by $C\varepsilon^{-1}\|z\|_p$. A partition of unity and smooth density give, uniformly in s,

$$\|v\|_{W^{2,p}} \le C\big(\|L_s v\|_p + \|v\|_p\big). \tag{4.14}$$

Maximum principles. We give the local estimate needed to pass comparison to $W^{2,p}$. Let $L = a^{ij} D_{ij}$ on a bounded smooth coordinate domain D, with $a \ge \vartheta I$,

and let z be smooth with nonnegative boundary values and minimum $-M < 0$. Set $R = \operatorname{diam} D$. Every vector ξ with $|\xi| < M/(2R)$ is the gradient at an interior lower supporting point of z: minimize $z(x) - \xi \cdot (x - x_0)$, where $z(x_0) = -M$. Its boundary values exceed $-M/2$, whereas its value at x_0 is $-M$. At a supporting point $D^2 z \geq 0$, and the arithmetic–geometric mean inequality gives

$$\det D^2 z \leq \left(\frac{\operatorname{tr}(a D^2 z)}{d\vartheta} \right)^d .$$

The area formula for the gradient, restricted to these supporting points, therefore bounds the volume of the slope ball by $(d\vartheta)^{-d} \int_D ((Lz)^+)^d$. Thus

$$-\min_D z \leq C_d \vartheta^{-1} R \| (Lz)^+ \|_{L^d(D)}. \tag{4.15}$$

This calculation uses no derivative of a. Approximate a $W^{2,p}$ function smoothly on the closure of a smaller smooth domain. The approximation converges in C^1, and its L errors converge in L^d because $p > d$. Correct the vanishing boundary error in (4.15). Passage to the limit shows that $Lv \leq 0$ and $v|_{\partial D} \geq 0$ imply $v \geq 0$.

The same comparison proves the strong maximum principle. If $v \in W^{2,p}$, $Lv \geq 0$, and v has an interior maximum M, put $w = M - v \geq 0$. If w is positive somewhere and zero somewhere, a small ball contained in $\{w > 0\}$ and tangent to its zero set can be chosen inside a coordinate chart. On the outer half-annulus of this ball,

$$\zeta(x) = \exp(-k|x - c|^2) - \exp(-kr^2)$$

is positive and has $L\zeta > 0$ for sufficiently large k, by uniform ellipticity. A small positive multiple of ζ is bounded above by w on both boundary spheres, hence throughout the annulus by comparison. At the tangent point this forces a positive inward derivative of w, contradicting $Dw = 0$. Connectedness proves that v is constant. Applied to L_s on X, it gives $\ker L_s = \mathbb{R}$. If $(L_s - 1)v = 0$ and v has a positive maximum, apply the strong maximum principle on its positive component, where $L_s v = v > 0$. Constancy contradicts that equation. Applying the argument to $-v$ rules out a negative minimum. Hence $\ker(L_s - 1) = 0$.

Index and range. Compactness of $W^{2,p} \hookrightarrow L^p$ and (4.14) now give

$$\|v\|_{W^{2,p}} \leq C \|(L_s - 1)v\|_p \tag{4.16}$$

uniformly in s. Otherwise normalize a contradicting sequence in $W^{2,p}$, pass to $s_j \to s$ and a strongly L^p convergent subsequence, and apply (4.14) to differences. Operator norm continuity in s gives strong $W^{2,p}$ convergence to a nonzero member of $\ker(L_s - 1)$, which is impossible. The smooth operator $L_\eta - 1$ has index zero and trivial kernel, hence is an isomorphism, by smooth elliptic theory. The method of continuity and (4.16) show that every $L_s - 1$ is an isomorphism. Finally, L_σ differs from $L_\sigma - 1$ by the compact inclusion $W^{2,p} \hookrightarrow L^p$, so it is Fredholm of index zero. Its one-dimensional kernel makes its range have codimension one. L^p duality gives the annihilator assertion. □

4.10 Limits of adjoint measures

When every positive potential perturbation of ω is Gauduchon, the adjoint probability is the normalized Monge–Ampère measure. Mass invariance and the continuity of bounded products then extend this description to bounded potentials.

Proposition 4.10.1 *Assume that ω_v is Gauduchon for every $v \in \mathcal{H}_\omega$. For every $u \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$, the measure*

$$\mu_u := M^{-1}(\omega + \mathrm{dd^c} u)^n$$

is a probability measure, which agrees with the preceding definition when $u \in \mathcal{H}_\omega$. If $u_j, u \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$ are uniformly bounded and $u_j \to u$ in capacity, then $\mu_{u_j} \rightharpoonup \mu_u$.

Proof By Proposition 4.8.2 and Theorem 2.2.2, the positive bounded product $(\omega + \mathrm{dd^c} u)^n$ has mass M, and for $u \in \mathcal{H}_\omega$ its normalization is the smooth adjoint measure by Proposition 4.8.2. The continuity of bounded products under convergence in capacity, in the sense of Section 1.8, gives weak convergence of the products, and division by M preserves it. □

The proposition applies in particular to Gauduchon surfaces. For a general Hermitian background, passing from smooth $u_j \in \mathcal{H}_\omega$ to a limit $u \in \mathrm{PSH}(X,\omega)$ requires control of the multipliers ρ_{u_j} as well as of the potentials. The supporting probabilities of Chapter 15 recover μ_u in the smooth case. If a bounded solution has a continuous positive complex Hessian, Theorem 15.2.4 gives a stationary supporting probability and approximation independence under uniform convergence of the logarithmic densities. We do not know whether, in general, the limit is independent of the approximating sequence, or whether a weak linearization satisfies an adjoint identity.

4.11 Conformal changes and directional curvature positivity

The compatibility condition of Proposition 4.8.1 decides which right-hand sides a scalar trace equation can have, and it can be used to improve the curvature of a Hermitian metric on a vector bundle. A conformal change $h \mapsto \mathrm{e}^{-tf} h$ adds the same form $t\, i\partial\bar\partial f$ to the curvature in every fiber direction. Solving a Poisson equation for a Gauduchon form, we can make the trace of this form positive outside any prescribed ball. If the original curvature already has a positive direction for every fiber vector over that ball, a small conformal change produces such a direction everywhere.

Throughout this section, $E \to X$ is a holomorphic vector bundle of positive rank, and $n \geq 2$. For a smooth Hermitian metric h on E, we use the Chern curvature F_h, the Hermitian endomorphisms $R_h(u,\bar u)$, the directional forms $\alpha_{h,v}$ and the mean curvature $K_{\omega,h}$ of Section 4.6.9; recall that h is linear in its first argument.

Definition 4.11.1 The metric h is *RC-positive* at x if, for every $0 \neq v \in E_x$, there is a tangent vector $u \in T_x^{1,0}X$ such that

$$h(R_h(u,\bar{u})v, v) > 0.$$

It is *uniformly RC-positive* at x if one tangent vector u works for every nonzero $v \in E_x$. A metric has either property on a set if it has that property at every point of the set.

Lemma 4.11.1 *Suppose that $K_{\omega,h}(x) \geq 0$. Then h is RC-positive at x if and only if $\alpha_{h,v} \neq 0$ for every $0 \neq v \in E_x$.*

Proof The trace of $\alpha_{h,v}$ with respect to ω is $h(K_{\omega,h}v, v) \geq 0$. A nonzero Hermitian form with nonnegative trace has a positive eigenvalue, since if all its eigenvalues were nonpositive, their nonnegative sum would force all of them to vanish. This gives the required tangent direction. Conversely, a tangent vector with positive evaluation shows that $\alpha_{h,v} \neq 0$. □

Theorem 4.11.1 *Suppose that $K_{\omega,h} \geq 0$ on X and that h is RC-positive on a nonempty open set U. Then there is a smooth real function f such that $h_t = \mathrm{e}^{-tf}h$ is RC-positive on all of X for every sufficiently small $t > 0$.*

Proof By Theorem 4.1.1, choose a conformal Gauduchon form $\gamma = \mathrm{e}^a\omega$. Then $K_{\gamma,h} = \mathrm{e}^{-a}K_{\omega,h} \geq 0$. Choose a closed coordinate ball $Q \subset U$ and a smooth function $\chi \geq 0$ supported in its interior, with $\int_X \chi\gamma^n > 0$, and set

$$\rho = 1 - \frac{\int_X \gamma^n}{\int_X \chi\gamma^n}\chi.$$

Thus $\rho = 1$ on $X \setminus Q$ and $\int_X \rho\gamma^n = 0$. Since γ is Gauduchon, Proposition 4.8.1, applied with γ in place of ω and $u = 0$, gives a smooth real solution f of

$$P_\gamma f := \mathrm{tr}_\gamma(\mathrm{i}\partial\bar{\partial}f) = \rho. \tag{4.17}$$

Indeed, with $L_\gamma f = n\mathrm{dd}^{\mathrm{c}}f \wedge \gamma^{n-1}/\gamma^n$ as in (4.8), we have $P_\gamma = 2\pi L_\gamma$, and the adjoint probability of L_γ is $\gamma^n/\int_X \gamma^n$.

The curvature transforms by

$$F_{h_t} = F_h + t\partial\bar{\partial}f\ \mathrm{Id}_E, \qquad \alpha_{h_t,v} = \mathrm{e}^{-tf}\left(\alpha_{h,v} + t|v|_h^2\mathrm{i}\partial\bar{\partial}f\right). \tag{4.18}$$

On $X \setminus Q$, the γ-trace of the expression in parentheses is at least $t|v|_h^2\rho = t|v|_h^2 > 0$ for $v \neq 0$, so it has a positive eigenvalue there.

Over Q, the unit sphere bundle $\{|v|_h = 1\}$ is compact. The largest γ-eigenvalue of $\alpha_{h,v}$ is continuous and strictly positive on it, so it has a positive minimum δ. Let C be the maximum on X of the operator norm of $\mathrm{i}\partial\bar{\partial}f$ relative to γ. For every unit vector over Q, the largest eigenvalue of the expression in parentheses in (4.18) is at least $\delta - tC$, which is positive for small $t > 0$. Homogeneity in v and the positive factor e^{-tf} prove the assertion on Q as well. □

In this conclusion, the positive direction may depend on the fiber vector v. The distinction from uniform RC-positivity already occurs for a local metric with zero mean curvature.

Example 4.11.1 On a sufficiently small ball in $\mathbb{C}^2$, equip the trivial bundle of rank two with the metric

$$H(z) = \mathrm{Id} - zz^* + \tfrac{1}{2}|z|^2\,\mathrm{Id}\,.$$

At the origin this metric has zero mean curvature for the Euclidean Hermitian form and is RC-positive, but it is not uniformly RC-positive.

Proof The two eigenvalues of $H(z)$ are $1 - \frac{1}{2}|z|^2$ and $1 + \frac{1}{2}|z|^2$, so the metric is positive on a small ball. Its first derivatives vanish at the origin, where

$$F_{i\bar{j}} = e_i e_j^* - \tfrac{1}{2}\delta_{ij}\,\mathrm{Id}, \qquad h(R_h(u,\bar{u})v, v) = |v^* u|^2 - \tfrac{1}{2}|u|^2|v|^2.$$

The sum $F_{1\bar{1}} + F_{2\bar{2}}$ is zero. For each nonzero v, taking $u = v$ gives a positive evaluation. For each nonzero u, taking $v \perp u$ gives a negative evaluation, so no single u works for every v. □

Proposition 4.11.1 *If* $\det E$ *admits a flat Hermitian metric, then no smooth Hermitian metric on* E *is uniformly RC-positive on* X *or has positive definite mean curvature relative to a Hermitian form. This applies in particular when* $\det E$ *is holomorphically trivial.*

Proof If h were uniformly RC-positive, then at each point some u would make the h-Hermitian endomorphism $R_h(u,\bar{u})$ positive definite, and its trace would be strictly positive. Since the curvature of the induced metric on $\det E$ is $\operatorname{tr} F_h$, the determinant metric would be RC-positive as a metric on a line bundle. If instead $K_{\omega,h} > 0$, the ω-trace of the determinant curvature would be $\operatorname{tr} K_{\omega,h} > 0$, which again gives a positive tangent evaluation.

Fix a flat Hermitian metric h_0 on $\det E$ and write $\det h = \mathrm{e}^b h_0$ for a smooth real function b. The determinant curvature is then $-\partial\bar{\partial} b$. At a global minimum of b, this curvature has no positive tangent evaluation, contradicting the RC-positivity of the determinant metric. Finally, a holomorphic trivialization of $\det E$ gives a flat metric, by assigning constant norm to the trivializing frame. □

Consequently, if $\det E$ admits a flat Hermitian metric and the hypotheses of Theorem 4.11.1 hold, the conformally changed metric is RC-positive, whereas E admits neither a uniformly RC-positive metric nor a metric with positive definite mean curvature. The next section shows that the tangent bundle of a nonflat Ricci-flat Kähler surface has these properties, and the local example above shows the pointwise distinction.

4.12 Ricci-flat Kähler surfaces

The tangent bundle of a Ricci-flat Kähler surface gives an example for the conformal construction of Section 4.11. Ricci-flatness makes the mean curvature of the tangent metric zero and its determinant metric flat, but it does not make every directional curvature zero. In real dimension four, the remaining curvature acts on the three-dimensional space of anti-self-dual two-forms, and its invertibility gives exactly the positive directions needed for the conformal construction.

In this section, X is a compact complex surface, so $n = 2$, and ω is a Ricci-flat Kähler form on X. Write h for the Hermitian metric on $T^{1,0}X$ defined by ω, and g for the associated Riemannian metric, so that $\omega(S, T) = g(JS, T)$.

Use g to identify bivectors and two-forms. For the complex orientation, the Hodge star gives

$$\Lambda^2 = \Lambda^+ \oplus \Lambda^-, \qquad \Lambda^\pm = \{\zeta : *\zeta = \pm\zeta\}.$$

Each summand has real rank three. The first is spanned by ω and the real parts of $(2, 0)$-forms, and the second consists of the real primitive $(1, 1)$-forms; both descriptions follow by writing the star in a unitary real frame.

Let R^∇ be the curvature of the Levi–Civita connection, with $R^\nabla(S, T) = \nabla_S\nabla_T - \nabla_T\nabla_S - \nabla_{[S,T]}$, and define the self-adjoint curvature operator $\mathscr{R}$ on Λ^2 by

$$\langle \mathscr{R}(S \wedge T), U \wedge V\rangle = g(R^\nabla(S, T)V, U).$$

Since the curvature of a Kähler metric has type $(1, 1)$, the operator $\mathscr{R}$ annihilates the real parts of $(2, 0)$-forms. Its value on ω is the Ricci form, which vanishes. Thus

$$\mathscr{R} = 0 \oplus A, \qquad A : \Lambda^- \longrightarrow \Lambda^-.$$

The endomorphism A is symmetric and trace free, since the trace of $\mathscr{R}$ is half the scalar curvature; in this Ricci-flat setting it is the anti-self-dual Weyl operator. Norms of curvature tensors below are Hilbert–Schmidt norms of these endomorphisms.

Lemma 4.12.1 *At a point x, the metric h is RC-positive if and only if A_x is invertible.*

Proof For a real tangent vector V, set $v = \frac{1}{2}(V - \mathrm{i}JV)$. The Chern and Levi–Civita connections agree on a Kähler manifold. Their curvature pairings give

$$\alpha_{h,v} = \tfrac{1}{2}\big(\mathscr{R}(V \wedge JV)\big)^\flat.$$

Indeed, $h(v, w) = \frac{1}{2}(g(V, W) - \mathrm{i}g(JV, W))$ for $w = \frac{1}{2}(W - \mathrm{i}JW)$, and R^∇ commutes with J. Since R^∇ is skew-adjoint, the real part of $h(F_h v, v)$ vanishes, which gives the formula.

The anti-self-dual projection of $V \wedge JV$ is

$$\Pi(V) = V \wedge JV - \tfrac{1}{2}|V|^2\omega.$$

It is nonzero for $V \neq 0$, and every nonzero element of Λ^- is of this form. To see this, diagonalize a nonzero real primitive $(1,1)$-form in a unitary real frame. It has the form $c(e_1 \wedge Je_1 - e_2 \wedge Je_2)$, with $c > 0$ after interchanging the two complex lines. Taking $V = \sqrt{2c}\, e_1$ gives exactly this form as $\Pi(V)$. Also $|\Pi(V)|^2 = |V|^4/2$.

Consequently, since $\mathscr{R}$ vanishes on Λ^+, we have $\alpha_{h,v} \neq 0$ for every nonzero v if and only if $\ker A_x = 0$. Since $K_{\omega,h} = 0$, Lemma 4.11.1 gives the assertion. □

Lemma 4.12.2 *If g is not flat, the open set $\{x : \det A_x \neq 0\}$ is nonempty.*

Proof Suppose that $\det A = 0$ everywhere. On the open set where $A \neq 0$, its three eigenvalues are $\lambda_0, -\lambda_0, 0$ with $\lambda_0 > 0$; they are distinct, so A has smooth local eigenframes there.

Step 1: a Bochner identity. On an open set where A has distinct eigenvalues, we compute $\Delta|A|^2$, keeping track of the normalizations.

Choose an oriented local eigenframe ξ_1, ξ_2, ξ_3 of Λ^- with $|\xi_i|^2 = 2$, and denote the corresponding eigenvalues by λ, μ, ν. As skew-adjoint endomorphisms, these forms satisfy the multiplication rules of the quaternions. Write

$$\nabla\xi_1 = c \otimes \xi_2 - b \otimes \xi_3, \quad \nabla\xi_2 = -c \otimes \xi_1 + a \otimes \xi_3, \quad \nabla\xi_3 = b \otimes \xi_1 - a \otimes \xi_2.$$

Here a, b, c are real one-forms. The Ricci identity and the contracted Bianchi identity, using $\mathrm{Ric}(g) = 0$, give

$$\mathrm{d}a + b \wedge c = \lambda\xi_1, \qquad \mathrm{d}\lambda = (\lambda - \mu)\xi_3 c + (\lambda - \nu)\xi_2 b,$$

and their simultaneous cyclic permutations. In the second formula the two-forms act as skew-adjoint endomorphisms on one-forms. Put $D = \mathrm{d}^*\mathrm{d} = -\operatorname{div}_g \nabla$ on functions. Applying d^* to the second formula yields

$$D\lambda = 2\lambda^2 + 4\mu\nu + 2(\nu - \lambda)|b|^2 + 2(\mu - \lambda)|c|^2.$$

For example, the calculation uses

$$\mathrm{d}^*(\xi_3 c) = -\langle b, \xi_1 c\rangle + \langle a, \xi_2 c\rangle + \langle a, \xi_3 b\rangle - 2\nu,$$
$$\mathrm{d}^*(\xi_2 b) = -\langle b, \xi_1 c\rangle - \langle a, \xi_2 c\rangle - \langle a, \xi_3 b\rangle - 2\mu,$$

which follow from the connection and curvature formulas above; substitution and the cyclic formulas for $\mathrm{d}\mu, \mathrm{d}\nu$ cancel the mixed pairings.

Now $\lambda + \mu + \nu = 0$ and $|A|^2 = \lambda^2 + \mu^2 + \nu^2$. Multiplying the three scalar equations by their eigenvalues and adding gives

$$\lambda D\lambda + \mu D\mu + \nu D\nu = 18\lambda\mu\nu - 2\big((\mu - \nu)^2|a|^2 + (\nu - \lambda)^2|b|^2 + (\lambda - \mu)^2|c|^2\big).$$

The connection expression also gives

$$|\nabla A|^2 = |\mathrm{d}\lambda|^2 + |\mathrm{d}\mu|^2 + |\mathrm{d}\nu|^2 + 2\big((\mu - \nu)^2|a|^2 + (\nu - \lambda)^2|b|^2 + (\lambda - \mu)^2|c|^2\big).$$

The product rule therefore gives, with $\Delta = \operatorname{div}_g \nabla = -D$,

$$\Delta|A|^2 = 2|\nabla A|^2 - 36 \det A = 2|\nabla A|^2. \tag{4.19}$$

This identity also holds on the interior of $\{A = 0\}$. Both sides are smooth functions, and the two open sets have dense union in X, so the identity holds everywhere. Integration over X gives $\nabla A = 0$.

Step 2: a parallel operator A forces flatness. If g is not flat, then $A \neq 0$ somewhere, and since A is parallel and $\det A = 0$, it is nonzero everywhere and has three distinct constant eigenvalues. Its eigenlines are parallel; local unit sections of them are parallel as well. The induced connection on Λ^- therefore has zero curvature. Under $\mathfrak{so}(4) = \Lambda^+ \oplus \Lambda^-$, the two summands commute, while the action of Λ^- on itself is faithful. These facts follow directly from the bases $e_1 \wedge e_2 \pm e_3 \wedge e_4$, $e_1 \wedge e_3 \mp e_2 \wedge e_4$, $e_1 \wedge e_4 \pm e_2 \wedge e_3$. Thus zero induced curvature forces $\mathscr{R}(S \wedge T)$ to lie in Λ^+ for every S, T. It already lies in Λ^-, so $\mathscr{R} = 0$, a contradiction. □

Theorem 4.12.1 *If X has a nonflat Ricci-flat Kähler metric, then $T^{1,0}X$ admits an RC-positive Hermitian metric whose associated $(1,1)$-form is nonclosed. It admits neither a uniformly RC-positive Hermitian metric nor a metric with positive definite mean curvature relative to any Hermitian form.*

Proof By Lemmas 4.12.1 and 4.12.2, the original tangent metric h is RC-positive on a nonempty open set. Its mean curvature is zero, so Theorem 4.11.1 gives a metric $h_t = \mathrm{e}^{-tf} h$ that is RC-positive everywhere.

In that construction we may take the Gauduchon form to be ω itself, and the closed coordinate ball to be a proper subset of X. Since $P_\omega f = 1$ off that ball, f is not constant. The associated form is $\omega_t = \mathrm{e}^{-tf}\omega$, with

$$\mathrm{d}\omega_t = -t\mathrm{e}^{-tf}\mathrm{d}f \wedge \omega.$$

On a real four-dimensional symplectic vector space, $\zeta \mapsto \zeta \wedge \omega$ is injective on one-forms, as a unitary real frame shows. Thus $\mathrm{d}\omega_t \neq 0$ somewhere.

Finally, the induced determinant metric of h is flat because its Chern curvature is the Ricci form of ω, which vanishes. The two obstructions follow from Proposition 4.11.1. □

The construction does not change the complex surface: it starts from a Ricci-flat Kähler form and produces a nonclosed Hermitian form whose tangent metric is RC-positive. Nonflat Ricci-flat Kähler metrics exist, for example, on K3 surfaces, by Yau's solution of the Calabi conjecture.

Combined with Theorem 4.6.6, the RC-positive tangent metric of Theorem 4.12.1 bounds the convexity of the complement of the zero section in the projective completion of the tangent bundle. This bundle admits no metric with positive definite mean curvature, so Corollary 4.6.9 does not apply to it.

Corollary 4.12.1 *For a connected compact complex surface X admitting a nonflat Ricci-flat Kähler metric, the complement*

$$\mathbb{P}(\mathcal{O}_X \oplus T^{1,0}X) \setminus \mathbb{P}(\mathcal{O}_X)$$

is 3-convex. The tangent bundle admits no Hermitian metric with positive definite mean curvature relative to any Hermitian form.

Proof By Theorem 4.12.1, the tangent bundle has an RC-positive Hermitian metric. Its directional curvature form has a positive eigenvalue for every nonzero fiber vector. Apply Theorem 4.6.6 with $n = r = 2$ and $s = 1$. The mean-curvature obstruction is the second assertion of Theorem 4.12.1. □

4.13 Holomorphic sectional curvature

The curvature conditions above test a tangent direction and a fiber vector separately. For a metric on the tangent bundle, holomorphic sectional curvature tests the same vector in both places. Averaging these diagonal evaluations controls a symmetrized curvature trace. A second trace occurs when one differentiates the trace of the metric itself; their difference contains torsion and an exact form. With a Kähler metric for the contraction, integration removes the exact form and the torsion terms cancel. This gives an obstruction even when the metric whose curvature is tested is not closed.

In this section, g is a Kähler metric on X, with form ω_g, and h is any smooth Hermitian metric on $T^{1,0}X$, with form ω_h. We retain $n \geq 2$. The unscaled Chern curvature convention of Section 4.6.9 gives the coefficients

$$R^h_{i\bar{j}k\bar{l}} = -\partial_i\partial_{\bar{j}}h_{k\bar{l}} + h^{p\bar{q}}(\partial_i h_{k\bar{q}})(\partial_{\bar{j}}h_{p\bar{l}}).$$

The *Chern holomorphic sectional curvature* is

$$H_h(x,[v]) = \frac{R^h(v,\bar{v},v,\bar{v})}{|v|_h^4}, \qquad 0 \neq v \in T^{1,0}_x X. \tag{4.20}$$

It is *quasi-negative* if it is nonpositive everywhere and strictly negative in every direction at some point. Put

$$u = \operatorname{tr}_g h, \qquad q = \operatorname{tr}\big((g^{-1}h)^2\big).$$

In a g-unitary frame, define the real contractions

$$Q_g(h) = \sum_{i,k} R^h_{i\bar{i}k\bar{k}}, \qquad B_g(h) = \sum_{i,k} R^h_{i\bar{k}k\bar{i}}, \qquad \mathcal{R}_g(h) = \tfrac{1}{2}\big(Q_g(h) + B_g(h)\big).$$

These expressions are invariant under a change of unitary frame. For a general h, the two traces $Q_g(h)$ and $B_g(h)$ can differ.

Lemma 4.13.1 *At a point where $H_h \le -\kappa$ for some $\kappa \ge 0$, one has*

$$\mathcal{R}_g(h) \le -\frac{\kappa}{2}(u^2 + q).$$

In particular, nonpositive holomorphic sectional curvature gives $\mathcal{R}_g(h) \le 0$.

Proof In a g-unitary frame, let $Z_1, \dots, Z_n$ be independent standard complex Gaussian variables, with density $\pi^{-1}\mathrm{e}^{-|z|^2}$ on $\mathbb{C}$. Their second and fourth moments are $\mathbb{E}|Z_i|^2 = 1$ and $\mathbb{E}|Z_i|^4 = 2$. Independence and invariance under coordinate phases give

$$\mathbb{E}[Z_i\overline{Z_j}Z_k\overline{Z_l}] = \delta_{ij}\delta_{kl} + \delta_{il}\delta_{kj}.$$

Thus $\mathbb{E}R^h(Z, \bar{Z}, Z, \bar{Z}) = Q_g(h) + B_g(h)$ and $\mathbb{E}|Z|_h^4 = u^2 + q$. Taking expectations in the homogeneous inequality $R^h(Z, \bar{Z}, Z, \bar{Z}) \le -\kappa|Z|_h^4$ proves the result. □

Let $A = \nabla^h - \nabla^g$ be the difference of the Chern connections, viewed as a tensor with two holomorphic covariant indices and a tangent-bundle value. Write

$$S(v, w) = \tfrac{1}{2}\big(A(v, w) + A(w, v)\big), \qquad T(v, w) = A(v, w) - A(w, v).$$

Since g is Kähler, T is the Chern torsion of h. Norms such as $|S|_{g,h}^2 = \sum_{i,k} |S(e_i, e_k)|_h^2$ use g in the covariant indices and h in the value. Let $r_{i\bar{j}}$ be the coefficients of the Ricci form $\mathrm{Ric}(g) = -\mathrm{i}\partial\bar{\partial}\log\det(g_{i\bar{j}})$, and in a g-unitary frame set

$$I_g(h) = \sum_{i,k} r_{i\bar{k}}h_{k\bar{i}}, \qquad \mathrm{d}V_g = \frac{\omega_g^n}{n!}, \qquad P_g f = \mathrm{tr}_{\omega_g}(\mathrm{i}\partial\bar{\partial}f).$$

Proposition 4.13.1 *The two metrics satisfy*

$$\int_X \big(|S|_{g,h}^2 + I_g(h) - \mathcal{R}_g(h)\big)\,\mathrm{d}V_g = 0. \tag{4.21}$$

Proof We first compute the exact term that distinguishes the two curvature traces. Define

$$\begin{aligned} D_{i\bar{j}k\bar{l}} = {} & \partial_i\partial_{\bar{j}}h_{k\bar{l}} + \partial_k\partial_{\bar{l}}h_{i\bar{j}} \\ & - \partial_i\partial_{\bar{l}}h_{k\bar{j}} - \partial_k\partial_{\bar{j}}h_{i\bar{l}}. \end{aligned}$$

This is a tensor: putting holomorphic differentials first gives

$$\mathrm{i}\partial\bar{\partial}\omega_h = \sum_{i<k,\, j<l} D_{i\bar{j}k\bar{l}}\,\mathrm{d}z^i \wedge \mathrm{d}z^k \wedge \mathrm{d}\bar{z}^j \wedge \mathrm{d}\bar{z}^l.$$

For $D_g = \sum_{i,k} D_{i\bar{i}k\bar{k}}$ in a g-unitary frame, expansion of the wedge product gives

$$D_g\,\mathrm{d}V_g = 2\mathrm{i}\partial\bar{\partial}\omega_h \wedge \frac{\omega_g^{n-2}}{(n-2)!}.$$

Indeed, each pair $i < k$ contributes $D_{i\bar{i}k\bar{k}}\mathrm{d}V_g$ to the wedge product and occurs twice in the contraction. Closedness of ω_g and Stokes' theorem therefore give $\int_X D_g \, \mathrm{d}V_g = 0$.

The four-term antisymmetrization of the curvature formula is

$$\begin{aligned} R^h_{i\bar{j}k\bar{l}} + R^h_{k\bar{l}i\bar{j}} - R^h_{i\bar{l}k\bar{j}} - R^h_{k\bar{j}i\bar{l}} \\ = h_{p\bar{q}} T^p_{ik} \overline{T^q_{jl}} - D_{i\bar{j}k\bar{l}}. \end{aligned}$$

The second derivatives give $-D$, and the quadratic terms give the squared connection difference in the two skew indices. Contracting gives $2(Q_g(h) - B_g(h)) = |T|^2_{g,h} - D_g$, hence

$$Q_g(h) = \mathcal{R}_g(h) + \tfrac{1}{4}|T|^2_{g,h} - \tfrac{1}{4}D_g.$$

In g-normal holomorphic coordinates, the first derivatives of g vanish. Differentiating $u = g^{k\bar{l}}h_{k\bar{l}}$ twice, the inverse-metric term is $I_g(h)$ by the Kähler curvature symmetries of g, while the second derivatives of h give $-Q_g(h) + |A|^2_{g,h}$. Thus

$$\begin{aligned} P_g u &= |A|^2_{g,h} + I_g(h) - Q_g(h) \\ &= |S|^2_{g,h} + I_g(h) - \mathcal{R}_g(h) + \tfrac{1}{4}D_g, \end{aligned}$$

where symmetric and skew tensors are orthogonal and $|A|^2_{g,h} = |S|^2_{g,h} + |T|^2_{g,h}/4$. Integrating removes both $P_g u$ and D_g, proving (4.21). □

Corollary 4.13.1 *Suppose that* $\mathrm{Ric}(g) \geq 0$*. Every Hermitian tangent metric* h *with* $H_h \leq 0$ *satisfies* $\mathrm{Ric}(g) = 0$ *and* $H_h = 0$ *in every direction. In particular,* X *admits no Hermitian tangent metric with quasi-negative Chern holomorphic sectional curvature.*

Proof The Ricci assumption gives $I_g(h) \geq 0$, and Lemma 4.13.1 gives $-\mathcal{R}_g(h) \geq 0$. All three continuous terms in (4.21) are nonnegative, so each vanishes everywhere. A positive definite h pairs strictly positively with every nonzero semipositive Ricci matrix; hence $I_g(h) = 0$ forces $\mathrm{Ric}(g) = 0$.

At each point, the Gaussian expectation in the averaging proof is now zero. Its integrand $R^h(Z, \bar{Z}, Z, \bar{Z})$ is nonpositive. If it were negative in one direction, continuity and the strictly positive Gaussian density would make its expectation negative. It is therefore zero in every direction, which gives $H_h = 0$ and excludes quasi-negativity.□

For the Ricci-flat surfaces of Section 4.12, this obstruction concerns all Hermitian tangent metrics, including nonclosed ones. It coexists with the RC-positive metric of Theorem 4.12.1: that condition allows the positive tangent direction to depend on the fiber vector, while holomorphic sectional curvature evaluates the same direction twice.

4.13.1 Rigidity on complex tori

For a flat reference metric, the vanishing symmetric connection term has a stronger consequence. Periodic integration by parts forces the second metric to be translation invariant, and hence to have zero full Chern curvature.

Proposition 4.13.2 *Let $Y = \mathbb{C}^m/\Lambda$ be a complex torus, with $m \geq 1$. A smooth Hermitian tangent metric h on Y has nonpositive Chern holomorphic sectional curvature if and only if it is translation invariant. Such a metric is Kähler and has zero Chern curvature.*

Proof Suppose first that $m \geq 2$, and take the flat Kähler metric g induced by a constant Hermitian inner product on $\mathbb{C}^m$. Choose linear coordinates in which this inner product is the identity. The coordinate vector fields descend to Y, even though the coordinates themselves need not. By Corollary 4.13.1, $H_h = 0$; (4.21) also gives $S = 0$. Since g has zero connection coefficients, multiplying $S = 0$ by h gives

$$\partial_i h_{k\bar{l}} + \partial_k h_{i\bar{l}} = 0 \qquad \text{for all } i, k, l.$$

Fix l and put $a_k = h_{k\bar{l}}$. With respect to the flat volume, integration by parts and commutation of constant coordinate derivatives give

$$\sum_{i,k} \int_Y \partial_i a_k \, \overline{\partial_k a_i} \, \mathrm{d}V_g = \int_Y \left| \sum_k \partial_{\bar{k}} a_k \right|^2 \mathrm{d}V_g .$$

Consequently,

$$\begin{aligned} 0 &= \sum_{i,k} \int_Y |\partial_i a_k + \partial_k a_i|^2 \, \mathrm{d}V_g \\ &= 2 \sum_{i,k} \int_Y |\partial_i a_k|^2 \, \mathrm{d}V_g + 2 \int_Y \left| \sum_k \partial_{\bar{k}} a_k \right|^2 \mathrm{d}V_g . \end{aligned}$$

Thus every $\partial_i h_{k\bar{l}}$ vanishes. Hermitian symmetry gives the vanishing of the conjugate derivatives as well, so all coefficients of h are constant.

For $m = 1$, write the lifted metric as $h(z)|\mathrm{d}z|^2$, with h positive and Λ-periodic. Its curvature coefficient is $-h\,\partial_z \partial_{\bar{z}} \log h$. Nonpositive sectional curvature therefore gives $\partial_z \partial_{\bar{z}} \log h \geq 0$. The complex Laplacian has zero integral over Y, so it vanishes. Integration by parts then shows that $\log h$ has zero gradient, and h is constant.

Conversely, a constant positive Hermitian matrix defines a closed form and has zero connection and curvature coefficients. This proves all the assertions. □

Corollary 4.13.2 *Let Y be a connected compact complex manifold admitting a finite unramified holomorphic covering $\pi : Z \to Y$ by a complex torus. Every smooth Hermitian tangent metric on Y with nonpositive Chern holomorphic sectional curvature is Kähler and Chern flat.*

Proof The covering is locally biholomorphic, so the pullback metric has the same sectional-curvature sign. By Proposition 4.13.2, its associated form is closed and its Chern curvature is zero. Both conclusions descend through the covering. □

4.14 Projective first jets and positive bundle metrics

RC-positivity asks for one positive tangent direction for each fiber vector, whereas Griffiths positivity asks for positivity on every pair of nonzero tangent and fiber vectors. The Lamari criterion of Theorem 4.3.1 characterizes positivity of a $(1,1)$-form by a duality with Gauduchon tests, and Griffiths positivity on a projective manifold admits an analogous duality. A Griffiths-positive metric on E is the same as a strictly plurisubharmonic squared norm on the dual bundle, which is a linear condition on the dual Hermitian form. Twisting by powers of a very ample line bundle gives finite-dimensional spaces of candidate forms. At each level, either some candidate is strictly plurisubharmonic or a finite atomic positive measure annihilates the Levi forms of all candidates, and if every level fails, a weak limit of these measures annihilates the Levi forms of all smooth Hermitian forms. This measure lives over the dual bundle, whereas the Gauduchon currents in Theorem 4.3.1 live on the base.

Throughout this section, X is a projective manifold of dimension $n \geq 2$, $E \to X$ is a holomorphic vector bundle of positive rank, and $F = E^*$. Fix a very ample line bundle A, a basis $t_1, \dots, t_d$ of $H^0(X, A)$, and the Fubini–Study metric a on A determined by this basis. Fix also an integer $m_0 \geq 0$ for which $E \otimes A^{m_0}$ is globally generated; this integer is part of the data. In a local frame of A, put

$$\rho = \sum_{\alpha=1}^{d} |t_\alpha|^2, \qquad a = \mathrm{e}^{-\phi}, \qquad \phi = \log \rho.$$

We use the curvature conventions of Section 4.6.9. A Hermitian metric g on a holomorphic vector bundle over X is *strictly Griffiths-positive* if $g(R_g(u, \bar{u})v, v) > 0$ for every $x \in X$, every nonzero $u \in T^{1,0}_x X$ and every nonzero vector v in the fiber over x; it is *strictly Griffiths-negative* if the reverse strict inequality holds.

For a smooth Hermitian form h on F, not initially assumed positive, let $G_h(v) = h(v, v)$ on its total space. Write $\mathcal{L}G_h(\xi)$ for the complex Hessian evaluated on $\xi \in T^{1,0}F$; in local coordinates it is $\sum (G_h)_{j\bar{k}} \xi_j \bar{\xi}_k$, the coefficient form of $\mathrm{i}\partial\bar{\partial}G_h$, without the factor $1/(2\pi)$.

Lemma 4.14.1 *The function G_h is strictly plurisubharmonic off the zero section if and only if h is a smooth positive Hermitian metric with strictly Griffiths-negative curvature. Equivalently, its dual metric on E is strictly Griffiths-positive.*

Proof On vertical tangent vectors the Levi form is h itself, so strict positivity forces $h > 0$. At a fixed base point, choose a holomorphic frame in which the matrix H of h is the identity and has vanishing first derivatives. Then $R_h(u, \bar{u}) = -H_{u\bar{u}}$ at this point. A tangent vector to F has horizontal and vertical components (u, w), and

$$\mathcal{L}G_h(u, w) = |w|^2 + v^* H_{u\bar{u}} v = |w|^2 - h(R_h(u, \bar{u})v, v).$$

For $v \neq 0$, this is positive for every nonzero (u, w) precisely when the curvature evaluation is negative for every nonzero u. The curvature of the dual metric is the negative transpose of the original curvature, with respect to the dual Hermitian pairing, which gives the last assertion. □

The Levi forms will be tested on a compact set. Choose any smooth Hermitian metric k on F, let $S = \{v : k(v, v) = 1\}$ be its unit sphere bundle, and choose a smooth positive Hermitian form b on the complex vector bundle $W = T^{1,0}F|_S$ over S. The set

$$K = \{(v, \xi) : v \in S,\ \xi \in W_v,\ b(\xi, \xi) = 1\}$$

is compact. Define the real-linear operator D by $Dh = \mathcal{L}G_h|_S$, viewed as a Hermitian form on W. It is continuous from the C^2 norm of Hermitian forms on F to the uniform norm on W, since its coefficients involve at most two base derivatives of h and the fiber vectors range over a compact set. Fiber dilation $v \mapsto cv$ gives

$$G_h(cv) = |c|^2 G_h(v), \qquad \mathcal{L}G_h|_{cv}(\mathrm{d}(v \mapsto cv)\xi) = |c|^2 \mathcal{L}G_h|_v(\xi).$$

Thus strict positivity of $\mathcal{L}G_h$ on K is equivalent to strict positivity off the zero section.

4.14.1 The finite-dimensional alternative

For $m \geq m_0$, choose a basis of $V_m = H^0(X, E \otimes A^m)$ and write $N_m = \dim V_m$. Pairing these sections with $v \in F_x$ and using a local frame of A^m, we obtain a column $p_m(v)$ of local holomorphic functions on the total space of F. For any Hermitian $N_m \times N_m$ matrix B, set

$$G_{m,B}(v) = \mathrm{e}^{-m\phi(x)} p_m(v)^* B p_m(v).$$

This function is globally defined and quadratic on each fiber, so $G_{m,B} = G_{h_{m,B}}$ for a smooth Hermitian form $h_{m,B}$ on F. The matrix B is allowed to have negative eigenvalues.

For $(v, \xi) \in K$, let u be the projection of ξ to $T^{1,0}_x X$, write $\phi_u = \partial\phi(u)$, and put

$$r_m = \mathrm{d}p_m(\xi) - m\phi_u p_m(v), \qquad \kappa = \phi_{u\bar{u}},$$
$$\Psi_m(v, \xi) = \mathrm{e}^{-m\phi}\big(r_m r_m^* - m\kappa p_m p_m^*\big).$$

Differentiating the weighted quadratic function gives

$$(Dh_{m,B})_v(\xi,\xi) = \operatorname{tr}(B\Psi_m(v,\xi)). \tag{4.22}$$

All entries involve only the first jets of the sections: if $t = (t_\alpha)$ is the column of the sections of A, then

$$\phi_u = \frac{t^*\mathrm{d}t(u)}{\rho}, \qquad \kappa = \frac{\rho|\mathrm{d}t(u)|^2 - |t^*\mathrm{d}t(u)|^2}{\rho^2}.$$

Changing the frame of A by a nowhere-zero holomorphic factor λ changes p_m to $\lambda^{-m}p_m$ and ϕ to $\phi - \log|\lambda|^2$. It changes r_m by the same factor and leaves κ unchanged, so Ψ_m is frame independent. A change of the basis of V_m replaces Ψ_m by a congruent matrix, so whether the convex hull of the values of Ψ_m contains zero does not depend on that choice.

Proposition 4.14.1 *At each fixed m, exactly one of the following holds:*

(1) *Some Hermitian matrix B satisfies $\operatorname{tr}(B\Psi_m) > 0$ everywhere on K.*
(2) *There is a probability measure μ on K, supported on at most $N_m^2 + 1$ points, such that $\int_K \Psi_m \,\mathrm{d}\mu = 0$.*

The first alternative holds precisely when $0 \notin \operatorname{conv}(\Psi_m(K))$.

Proof The real vector space of Hermitian $N_m \times N_m$ matrices has dimension N_m^2. Carathéodory's theorem expresses every point of the convex hull as a convex combination of at most $N_m^2 + 1$ points of the compact image $\Psi_m(K)$, so the hull is compact. If it contains zero, the coefficients of such an expression define the required atomic probability measure μ, and then $\int_K \operatorname{tr}(B\Psi_m)\,\mathrm{d}\mu = 0$ excludes the first alternative.

If the hull misses zero, let Z_0 be its point of least Hilbert–Schmidt norm. Differentiating the squared norm along the segment from Z_0 to any Z in the hull gives

$$\operatorname{tr}(Z_0 Z) \geq \operatorname{tr}(Z_0^2) > 0.$$

Taking $B = Z_0$ proves the first alternative. □

4.14.2 Approximation with two derivatives

Let $\mathcal{H}_m = \{h_{m,B} : B = B^*\}$. To pass from these finite-dimensional tests to all smooth metrics, we need approximation in C^2, since D involves two derivatives.

Lemma 4.14.2 *The matrix-valued map $Y = tt^*/\rho$ embeds X as a compact smooth submanifold of the real vector space of Hermitian $d \times d$ matrices. Restrictions of real polynomials in its real coordinates are dense in $C^2(X,\mathbb{R})$ for the C^2 norm.*

Proof The normalized rank-one projector Y determines the point $[t]$ of projective space, and its differential vanishes only in directions in which $\mathrm{d}t$ is proportional to t. Since A is very ample, Y is therefore injective with injective differential, and

compactness makes it an embedding. A C^2 function on this image extends to a C^2 function on an ambient cube: use local coordinates in which the image is a graph, extend constantly in the normal coordinates, and combine these extensions with a finite smooth partition of unity and a cutoff. Rescale the cube to $[0,1]^q$.

For such an extension f, its multivariate Bernstein polynomial is

$$B_N f(y) = \sum_{0 \le j_1, \dots, j_q \le N} f(j/N) \prod_{\ell=1}^{q} \binom{N}{j_\ell} y_\ell^{j_\ell} (1-y_\ell)^{N-j_\ell},$$

where $j = (j_1, \dots, j_q)$. For a multi-index α with $|\alpha| \le 2$, differentiation expresses $\partial^\alpha B_N f$ as an average of $\Delta^\alpha_{1/N} f(j/N)$, with prefactor $\prod_\ell (N)_{\alpha_\ell}$ and Bernstein degrees $N - \alpha_\ell$. Here $(N)_r = N(N-1)\cdots(N-r+1)$, and $\Delta^\alpha_{1/N}$ is the corresponding iterated forward difference with step $1/N$. Repeated use of the fundamental theorem of calculus expresses $N^{|\alpha|}\Delta^\alpha_{1/N} f(j/N)$ as an average of $\partial^\alpha f$ at points within $2/N$ in each affected coordinate.

The remaining Bernstein weights are the law of independent binomial variables of degrees $N - \alpha_\ell$, divided by N. Their means differ from y_ℓ by at most $2/N$ and their variances are at most $1/(4N)$. Uniform continuity of $\partial^\alpha f$, splitting the average into a fixed small neighborhood of y and its complement, and Chebyshev's inequality give uniform convergence to $\partial^\alpha f$. The prefactor divided by $N^{|\alpha|}$ tends to one. This proves convergence for every derivative of order at most two, including the function itself. Restrict to the embedded image and use the chain rule in a finite collection of charts to obtain the asserted C^2 approximation. □

Lemma 4.14.3 *The spaces $\mathcal{H}_m$ are nested, and their union is C^2 dense in the space of C^2 Hermitian forms on F.*

Proof For nesting, multiply the sections in V_m by each t_α and express the products in the basis of V_{m+1}. The identity $\sum_\alpha \mathrm{e}^{-\phi}|t_\alpha|^2 = 1$ writes $G_{m,B}$ as the sum of the corresponding weighted quadratic functions at level $m+1$, which combine into one Hermitian coefficient matrix at that level. Surjectivity of the multiplication map is not needed.

For density, write $p_{m_0}(v) = P_0 v$ in a local frame of F, and put $L = \mathrm{e}^{-m_0\phi/2} P_0$. Global generation of $E \otimes A^{m_0}$ means that L is injective, so $M = L^* L$ is positive definite. If a C^2 Hermitian form has matrix H, define

$$C(x) = L M^{-1} H M^{-1} L^*.$$

Then $L^* C L = H$. A change of frame of F cancels in this expression; a change of frame of A multiplies L by a scalar of modulus one, which also cancels. Thus C is a globally defined C^2 Hermitian matrix function on X.

Applying Lemma 4.14.2 to its real coordinates in the vector space of Hermitian matrices, we obtain Hermitian matrix polynomials in the entries of Y that converge to C in C^2; their degrees may increase along the sequence. Let $C_q(Y)$ be such a polynomial, of degree at most q. Every monomial of degree k in Y has the form

$t^I \bar{t}^J/\rho^k$, with $|I| = |J| = k$. For a polynomial of degree at most q, multiply each numerator by ρ^{q-k} to use the common denominator ρ^q. Consequently

$$e^{-m_0\phi} p^*_{m_0} C_q(Y) p_{m_0}$$

is a quadratic expression in the product sections $\sigma_i t^I$ of $E \otimes A^{m_0+q}$, with weight $e^{-(m_0+q)\phi}$. Express these products in the basis of V_{m_0+q} and replace the coefficient matrix by its Hermitian part, which does not change the real function. The result is an element of $\mathcal{H}_{m_0+q}$. Since $L^*CL = H$ and multiplication by the fixed smooth matrix L is continuous in C^2, these elements converge to H. □

4.14.3 The metric and measure alternatives

A *positive matrix-valued measure* on $W \to S$ is a linear functional T on the space of continuous Hermitian forms Φ on W such that $\langle T, \Phi\rangle \geq 0$ whenever $\Phi \geq 0$. Its trace mass relative to b is $\langle T, b\rangle$. We write $D^*T = 0$ if $\langle T, Dh\rangle = 0$ for every smooth Hermitian form h on F.

Theorem 4.14.1 *With the fixed projective data above, the following are equivalent:*

(1) *E admits a smooth strictly Griffiths-positive Hermitian metric.*
(2) *For some $m \geq m_0$, a Hermitian matrix B makes $G_{m,B}$ strictly plurisubharmonic off the zero section.*
(3) *For some $m \geq m_0$, $0 \notin \operatorname{conv}(\Psi_m(K))$.*
(4) *There is no nonzero positive matrix-valued measure T on $W \to S$ satisfying $D^*T = 0$.*

Proof Given a metric as in the first assertion, its dual metric h on F satisfies $Dh \geq \delta b$ on S for some $\delta > 0$, by Lemma 4.14.1 and compactness. The C^2 density in Lemma 4.14.3 and the continuity of D give a form $h_{m,B}$ with $Dh_{m,B} \geq \delta b/2$, which proves the second assertion. Conversely, if $G_{m,B}$ is strictly plurisubharmonic, its vertical Levi form shows that $h_{m,B}$ is positive, and Lemma 4.14.1 shows that its dual metric is strictly Griffiths-positive. The second and third assertions are equivalent by Proposition 4.14.1.

If the first assertion holds, every nonzero positive matrix-valued measure T has positive trace mass, and

$$\langle T, Dh\rangle \geq \delta\langle T, b\rangle > 0,$$

so such a measure cannot satisfy $D^*T = 0$. Conversely, suppose that the third assertion fails at every level. By Proposition 4.14.1, choose at each level m an atomic probability measure μ_m on K with $\int_K \Psi_m \, d\mu_m = 0$, so that μ_m annihilates Dh for every $h \in \mathcal{H}_m$. A subsequence converges weakly to a probability measure μ on the compact set K. Since the spaces $\mathcal{H}_m$ are nested, the limit annihilates Dh for every h in each fixed $\mathcal{H}_j$, and the C^2 density and the continuity of D extend this to every smooth Hermitian form.

Define

$$\langle T, \Phi \rangle = \int_K \Phi_v(\xi, \xi)\, \mathrm{d}\mu(v, \xi).$$

This is a positive matrix-valued measure on $W \to S$ with $\langle T, b \rangle = 1$ and $D^*T = 0$. Its entries in local frames are represented by scalar measures: positivity bounds the functional on Hermitian forms of uniform norm at most one by the trace mass, so the Riesz representation theorem applies to the coordinate functionals, and a finite partition of unity combines these local representations. This contradicts the fourth assertion and completes the proof. □

The equation $D^*T = 0$ concerns a bundle over the sphere bundle $S \subset F = E^*$; it should not be confused with the equation $\mathrm{dd^c}T = 0$ for currents on X. The theorem gives no bound for the first successful level, and no finite procedure for deciding that all levels fail.

Corollary 4.14.1 *If E is globally generated and $m_0 = 0$, the level-zero test succeeds exactly when the complete evaluation map $\Phi : F \to H^0(X, E)^*$ is an immersion off the zero section.*

Proof At $m = 0$, one has $\Psi_0 = \mathrm{d}\Phi(\xi)\mathrm{d}\Phi(\xi)^*$, where Φ is written in the coordinates given by the chosen basis. If $\mathrm{d}\Phi$ is injective off the zero section, $B = \mathrm{Id}$ gives a strictly positive Levi form. If $\mathrm{d}\Phi$ has a nonzero kernel vector there, fiber dilation and normalization of the tangent vector place such a vector in K, where $\Psi_0 = 0$, and no Hermitian matrix can separate the image from zero. □

When this untwisted test fails, the higher twists remain available. The finite alternatives use all Hermitian coefficient matrices and the complete spaces of sections; testing only positive coefficient matrices or a smaller collection of sections gives a different criterion.

4.15 Ramified section tests and a positive root metric

The untwisted test of Corollary 4.14.1 can fail even for a line bundle with a positively curved metric, because the evaluation map of a globally generated bundle may fail to be an immersion where a holomorphic map ramifies. We give an explicit example on the product of a hyperelliptic curve with a projective space, where the complete spaces of sections can be computed. The same example gives a family of weighted tests, built from a root of the Fubini–Study weight of a very ample power instead of the twists of the preceding section, whose first successful level is explicit and can be made arbitrarily large.

Fix integers $n \geq 2$ and $q \geq 2$. Choose a section $\beta \in H^0(\mathbb{P}^1, O(2q))$ with $2q$ distinct zeros. Let $\pi : C \to \mathbb{P}^1$ be the double cover defined in the total space of $O(q)$ by the equation $w^2 = \beta$, where w is the tautological coordinate, and put

$$X = C \times \mathbb{P}^{n-1}, \qquad L_C = \pi^* O(1),$$
$$L = L_C \boxtimes O(1), \qquad A = L^q, \qquad F = L^{-1}.$$

Lemma 4.15.1 *The manifold X is smooth compact projective. The line bundle L is globally generated, A is very ample, and for every integer $k \geq 0$,*

$$H^0(X, L^k) = \big(H^0(\mathbb{P}^1, O(k)) \oplus H^0(\mathbb{P}^1, O(k-q))\big) \otimes H^0(\mathbb{P}^{n-1}, O(k)).$$

In the second summand, the sections are multiplied by the coordinate w of the cover. In particular,

$$h^0(X, L^k) = \big(k + 1 + \max(k - q + 1, 0)\big)\binom{n-1+k}{k}.$$

For a basis $\sigma_1, \dots, \sigma_N$ of $H^0(X, A)$, the Fubini–Study weight and the corresponding root weight, in a local frame of L and the induced frame of $A = L^q$, are

$$\phi_A = \log \sum_{i=1}^{N} |\sigma_i|^2, \qquad \phi = \phi_A / q.$$

The metric $\mathrm{e}^{-\phi}$ on L has strictly positive curvature. Thus it is strictly Griffiths-positive, and $G(v) = \mathrm{e}^{\phi}|v|^2$ is strictly plurisubharmonic on F off its zero section.

Proof The direct image of the structure sheaf of C is $O \oplus O(-q)$ w, with multiplication of the second summand given by $w^2 = \beta$. Tensoring by $O(k)$, the local basis $1, w$ gives the stated decomposition of sections on C. Simple zeros of β make the cover smooth: near a branch point the equation gives a coordinate w with the base coordinate a nonzero multiple of w^2 to leading order. The cover is connected because the rational function representing β has a simple zero and therefore is not a square. Finiteness over compact $\mathbb{P}^1$ makes C compact.

On C, the complete sections of L_C^q are the degree-q base monomials together with w. The map to projective space defined by these sections separates the base points by the Veronese coordinates, separates the two sheets by w, and has injective differential. At the ramification points the coordinate w gives the missing derivative, and elsewhere the base coordinates do. Compactness makes this map an embedding. This shows that C is projective and that L_C^q is very ample.

For the decomposition of sections on the product, expand a section on each $\mathbb{P}^{n-1}$ fiber in its complete degree-k monomial basis. The coefficients depend holomorphically on C and transform as sections of L_C^k. This proves the displayed tensor identity without a cohomological vanishing assumption. The dimensions follow from the monomial counts, since line bundles of negative degree on $\mathbb{P}^1$ have no nonzero sections. The degree-one base sections generate L_C, hence L. The product of the curve embedding and the degree-q Veronese embedding, followed by the Segre embedding, shows that A is very ample.

Its complete linear system therefore defines an immersion, so the Fubini–Study metric on A has strictly positive curvature. Dividing its weight by q defines a metric on L, since the transition functions of $A = L^q$ are the qth powers of those of L, and its curvature is $1/q$ times that positive form. The final assertion follows from Lemma 4.14.1. □

4.15.1 The weighted family and its first successful level

Keep the root metric $\mathrm{e}^{-\phi}$ on L, and choose the sphere bundle S and the compact set K for F as in Section 4.14. For each integer $j \geq 0$, use the complete space

$$\widetilde{V}_j = H^0(X, L^{j+1})$$

and pair its basis with $v \in F_x$ to get a local column $p_j(v)$, written in a local frame of L^j. For every Hermitian coefficient matrix B, define

$$\widetilde{G}_{j,B}(v) = \mathrm{e}^{-j\phi(x)} p_j(v)^* B p_j(v).$$

These are globally defined functions, quadratic on each fiber. Their Levi matrices are

$$\widetilde{\Psi}_j(v,\xi) = \mathrm{e}^{-j\phi}(r_j r_j^* - j\kappa p_j p_j^*),$$
$$r_j = \mathrm{d}p_j(\xi) - j\phi_u p_j, \qquad \kappa = \phi_{u\bar{u}},$$

where u is the projection of ξ to the base. As in (4.22), direct differentiation gives $\mathcal{L}\widetilde{G}_{j,B}(\xi) = \mathrm{tr}(B\widetilde{\Psi}_j)$, and $\widetilde{\Psi}_j$ transforms in the same way under changes of frames.

Proposition 4.15.1 *The first integer $j \geq 0$ for which some $\widetilde{G}_{j,B}$, with B an arbitrary Hermitian matrix, is strictly plurisubharmonic off the zero section is $j = q - 1$. At every lower level, zero belongs to* $\mathrm{conv}(\widetilde{\Psi}_j(K))$*; one atom witnesses this at $j = 0$, and two atoms suffice at each $1 \leq j < q - 1$.*

Proof At $j = q - 1$, choose the basis σ_i that defines ϕ_A and take $B = \mathrm{Id}$. Since $p_j(v) = v(\sigma_i(x))_i$ in the chosen frames,

$$\widetilde{G}_{q-1,\mathrm{Id}}(v) = \mathrm{e}^{-(q-1)\phi}|v|^2 \mathrm{e}^{q\phi} = \mathrm{e}^{\phi}|v|^2.$$

This function is strictly plurisubharmonic by Lemma 4.15.1.

Now suppose that $0 \leq j < q - 1$. Then $j + 1 < q$, so by Lemma 4.15.1 every section in $\widetilde{V}_j$ comes from the first summand of the decomposition, which does not involve w. At a ramification point of C, choose a local coordinate t on C, and use frames of the bundles pulled back from $\mathbb{P}^1 \times \mathbb{P}^{n-1}$. Writing ζ for the coordinates of the factor $\mathbb{P}^{n-1}$, the column has the form $p_j(v) = vU_j(\pi(t), \zeta)$. It is nonzero for $v \neq 0$, since L^{j+1} is globally generated, and since π ramifies at the point, its derivative in the t direction vanishes there when v is held fixed.

Choose such a fiber vector v on the sphere bundle S. Write tangent vectors to the total space of F by their components in the t direction, in the ζ directions and in the fiber direction. Let $\xi_v = (0, 0, v)$ be the vertical radial vector, let $u = \partial/\partial t$, and let $\xi_h = (u, 0, j\phi_u v)$. At this point $\mathrm{d}p_j(\xi_v) = p_j$ and $r_j(\xi_h) = 0$. Thus

$$\widetilde{\Psi}_j(v, \xi_v) = \mathrm{e}^{-j\phi} p_j p_j^*,$$
$$\widetilde{\Psi}_j(v, \xi_h) = -j\kappa \mathrm{e}^{-j\phi} p_j p_j^*, \qquad \kappa > 0.$$

Let a_v and a_h be the squared norms of ξ_v and ξ_h for the form b, and divide each tangent vector by its norm to obtain points of K. At $j = 0$ the second matrix is zero, which gives the witness with one atom. For $j > 0$, the matrix at the second normalized point is $-c$ times the matrix at the first, with $c = j\kappa a_v/a_h > 0$. The probability measure giving these two points the weights $c/(1 + c)$ and $1/(1 + c)$ has zero matrix integral, which excludes strict positivity for every Hermitian B. This proves failure at all lower levels, so the first successful level is $j = q - 1$. □

4.15.2 Relation to the fixed very ample criterion

Corollary 4.15.1 *For the data $E = L$ and $A = L^q$, with the Fubini–Study metric of a basis of $H^0(X, A)$, the criterion of Theorem 4.14.1 applies with $m_0 = 0$. Its untwisted level fails, although E carries a strictly Griffiths-positive metric, and a higher level succeeds. The atom witnessing the failure at level zero annihilates only the Levi forms of the level-zero test space, and does not give a measure with $D^*T = 0$.*

Proof By Lemma 4.15.1, L is globally generated and A is very ample, as the criterion requires. At a ramification point, the complete untwisted evaluation map has a nonzero tangent vector in its kernel, in the direction of the cover, as in the preceding proof; hence Corollary 4.14.1 gives failure at level zero. The positive root metric and Theorem 4.14.1 give success at some higher level. Moreover, the Levi form of the dual of this positive metric pairs strictly positively with every nonzero positive matrix-valued measure on $W \to S$, so the atom at level zero cannot annihilate the Levi forms of all smooth Hermitian forms. □

The level m of the criterion in Theorem 4.14.1 corresponds to $j = qm$ in the root-weight family, since $E \otimes A^m = L^{qm+1}$ and $m\phi_A = qm\phi$. The first success at $j = q - 1$ therefore gives no bound on the first successful level m of that criterion. The root-weight family is nested in steps of q, because multiplication by the sections of A uses $\sum_i |\sigma_i|^2 = \mathrm{e}^{q\phi}$; we do not claim that it is nested in steps of one. As q grows, the root-weight family has arbitrarily many failed initial levels, although the bundle carries a strictly positive metric.

Chapter 5
Gauduchon traces and the topology of potentials

Throughout this chapter, θ is a smooth real $(1,1)$-form on X, $\mathrm{d}V$ is a smooth positive probability volume form used for L^1 norms, and γ is a Gauduchon metric, that is, a Hermitian form with $\mathrm{dd}^{\mathrm{c}}(\gamma^{n-1}) = 0$ (Definition 4.1.1). In dimension one every Hermitian form is Gauduchon, since $\gamma^{n-1} = 1$.

The current $\theta + \mathrm{dd}^{\mathrm{c}}u$ has a conserved linear trace even when its non-pluripolar Monge–Ampère measure has infinite mass, as we shall see in Chapter 6. By Proposition 4.2.1, the positive measure $(\theta + \mathrm{dd}^{\mathrm{c}}u) \wedge \gamma^{n-1}$ has the same total mass for every $u \in \mathrm{PSH}(X,\theta)$. The ellipticity of $f \mapsto \mathrm{dd}^{\mathrm{c}}f \wedge \gamma^{n-1}$ makes the trace more informative than this mass alone: its kernel consists of the constants, so the trace measure determines the potential up to an additive constant.

On mean-normalized potentials, this correspondence also identifies the topologies: weak convergence of trace measures is equivalent to L^1 convergence of potentials. Lipschitz tests give a complete metric for this topology, and the inverse elliptic operator compares it with the L^1 norm by sharp power bounds. Extending the conserved pairing to a positive pluriharmonic current requires more than this elliptic inversion. For continuous potentials, a gradient-energy estimate defines the derivative terms in the product and gives continuity under uniform approximation.

5.1 The trace map

Adding a constant to a potential does not change its current, so we normalize potentials by their mean and consider

$$\mathcal{K}^0_{\theta,\mathrm{d}V} = \left\{ u \in \mathrm{PSH}(X,\theta) : \int_X u \,\mathrm{d}V = 0 \right\}.$$

For $u \in \mathcal{K}^0_{\theta,\mathrm{d}V}$ we call the measure

$$\mathcal{T}_\gamma(u) = (\theta + \mathrm{dd}^{\mathrm{c}}u) \wedge \gamma^{n-1}$$

the *Gauduchon trace* of u, and $\mathcal{T}_\gamma$ the *trace map*. By Proposition 4.2.1 (by Stokes' theorem when $n = 1$), $\mathcal{T}_\gamma(u)$ is a positive measure of total mass

$$M_{\theta,\gamma} = \int_X \theta \wedge \gamma^{n-1}.$$

The trace map is governed by the linear operator

$$Af = \frac{\mathrm{dd^c} f \wedge \gamma^{n-1}}{\mathrm{d}V}, \qquad f \in C^\infty(X, \mathbb{R}).$$

It is a real second-order elliptic operator without zeroth-order term, and $\mathcal{T}_\gamma(u) - \mathcal{T}_\gamma(v) = A(u - v)\,\mathrm{d}V$ in the sense of distributions.

Theorem 5.1.1 *The trace map $\mathcal{T}_\gamma$ is an affine homeomorphism from the compact convex set $\mathcal{K}^0_{\theta,\mathrm{d}V}$, with its L^1 topology, onto a compact convex set of positive measures of mass $M_{\theta,\gamma}$, with the weak topology. In other words, for $u_j, u \in \mathcal{K}^0_{\theta,\mathrm{d}V}$,*

$$u_j \longrightarrow u \text{ in } L^1 \quad \Longleftrightarrow \quad \mathcal{T}_\gamma(u_j) \rightharpoonup \mathcal{T}_\gamma(u).$$

If $M_{\theta,\gamma} = 0$ and $\mathrm{PSH}(X, \theta) \neq \varnothing$, both sets consist of a single point.

Proof The set $\mathcal{K}^0_{\theta,\mathrm{d}V}$ is convex. It is the image of the compact set $\mathcal{K}_\theta$ of Theorem 1.4.1 under the continuous map $v \mapsto v - \int_X v\,\mathrm{d}V$, and is therefore compact.

If $u_j \to u$ in L^1, then $\mathrm{dd^c} u_j \to \mathrm{dd^c} u$ as currents, so the trace measures converge in the sense of distributions. Since they are positive measures of the same finite mass, and every continuous function is a uniform limit of smooth functions, they also converge weakly as measures. Thus $\mathcal{T}_\gamma$ is continuous.

To prove injectivity, suppose that $\mathcal{T}_\gamma(u) = \mathcal{T}_\gamma(v)$. Then $A(u - v) = 0$ in the sense of distributions. Elliptic regularity for A shows that $u - v$ agrees almost everywhere with a smooth function, and the maximum principle shows that this function is constant. Its mean is zero, so $u = v$ almost everywhere, and hence everywhere by Lemma 1.3.3.

A continuous injection from a compact space into a Hausdorff space is a homeomorphism onto its image; here the target is the space of positive measures of mass $M_{\theta,\gamma}$ with the weak topology. Since $\mathcal{T}_\gamma$ is affine, its image is convex. If $M_{\theta,\gamma} = 0$, every trace measure is zero, so injectivity shows that $\mathcal{K}^0_{\theta,\mathrm{d}V}$ has at most one point; it has exactly one when $\mathrm{PSH}(X, \theta)$ is nonempty, since the mean of any θ-plurisubharmonic function can be subtracted. In this case Lemma 4.3.1 also gives $\theta + \mathrm{dd^c} u = 0$ for the unique normalized potential u, which is therefore smooth. □

The inverse of the trace map can be described by a Green operator for A. By the maximum principle, $\ker A = \mathbb{R}$, and A has Fredholm index zero, because the linear path joining it to a Laplace operator consists of elliptic operators. Let A^* be the formal adjoint of A with respect to $\mathrm{d}V$. Stokes' theorem gives $\int_X Af\,\mathrm{d}V = 0$ for all smooth f, that is, $A^*1 = 0$; hence $\ker A^* = \mathbb{R}$ as well. By the Fredholm alternative, A maps smooth functions onto the smooth functions g with $\int_X g\,\mathrm{d}V = 0$, and the same holds

for A^*. In particular, A^* has a continuous inverse on smooth functions of mean zero, normalized to take values of mean zero. By duality with this inverse, every top-degree distribution σ of total mass zero, and in particular every finite signed measure with $\sigma(X) = 0$, determines a unique distribution $G_\gamma\sigma$ with mean zero against $\mathrm{d}V$ such that

$$\mathrm{dd^c}(G_\gamma\sigma) \wedge \gamma^{n-1} = \sigma. \tag{5.1}$$

Inverting the trace map at a positive measure therefore amounts to solving (5.1) and then checking positivity of the full current.

Proposition 5.1.1 *A positive measure ν of mass $M_{\theta,\gamma}$ belongs to the image of $\mathcal{T}_\gamma$ if and only if the distribution*

$$w = G_\gamma\big(\nu - \theta \wedge \gamma^{n-1}\big)$$

satisfies $\theta + \mathrm{dd^c}w \geq 0$. In that case the θ-plurisubharmonic representative of w is the unique $u \in \mathcal{K}^0_{\theta,\mathrm{d}V}$ with $\mathcal{T}_\gamma(u) = \nu$.

Proof If $\nu = \mathcal{T}_\gamma(u)$ with $u \in \mathcal{K}^0_{\theta,\mathrm{d}V}$, then u is a mean-zero solution of (5.1) with $\sigma = \nu - \theta \wedge \gamma^{n-1}$, so uniqueness gives $w = u$ as distributions. Conversely, if $\theta + \mathrm{dd^c}w \geq 0$, then Proposition 1.1.1 gives a θ-plurisubharmonic representative u of w. It has mean zero by construction, and (5.1) gives $\mathcal{T}_\gamma(u) = \nu$. □

In dimension one the positivity condition is automatic, because $\theta + \mathrm{dd^c}w = \nu$; thus every positive measure of mass $M_{\theta,\gamma}$ is the trace of a normalized potential. In higher dimensions, positivity of the trace measure ν does not imply positivity of the $(1,1)$-current $\theta + \mathrm{dd^c}w$, and the condition in Proposition 5.1.1 must be checked separately.

5.2 A metric on normalized potentials

By Theorem 5.1.1, every metric for the weak topology on positive measures of mass $M_{\theta,\gamma}$ pulls back to a metric for the L^1 topology on $\mathcal{K}^0_{\theta,\mathrm{d}V}$. We use the bounded Lipschitz metric on measures, which can be compared quantitatively with the L^1 norm through the inverse of A. Fix a distance d on X induced by a smooth Riemannian metric. For a real Lipschitz function f on X, write $\mathrm{Lip}_d(f) = \sup_{x\neq y} |f(x) - f(y)|/d(x,y)$, and for $u, v \in \mathcal{K}^0_{\theta,\mathrm{d}V}$ put

$$d_{\gamma,d}(u,v) = \sup_{\substack{\|f\|_\infty \leq 1 \\ \mathrm{Lip}_d(f)\leq 1}} \left| \int_X f \,\mathrm{d}\big(\mathcal{T}_\gamma(u) - \mathcal{T}_\gamma(v)\big) \right|.$$

We call $d_{\gamma,d}$ the *Gauduchon trace metric*.

Corollary 5.2.1 *The function $d_{\gamma,d}$ is a bounded complete metric on $\mathcal{K}^0_{\theta,\mathrm{d}V}$ inducing its L^1 topology. Changing γ or d gives the same topology and a uniformly equivalent metric on this compact space.*

Proof Symmetry and the triangle inequality follow directly from the definition, and $d_{\gamma,d} \leq 2M_{\theta,\gamma}$ because both trace measures have mass $M_{\theta,\gamma}$. Let $\mathcal{F}$ denote the family of test functions in the supremum. After rescaling, $\mathcal{F}$ contains a positive multiple of every Lipschitz function, and Lipschitz functions are uniformly dense in $C(X)$. Hence $\mathcal{F}$ separates finite measures, and together with the injectivity of $\mathcal{T}_\gamma$ this shows that $d_{\gamma,d}$ is a metric. The same density, together with the common mass bound, shows that convergence in $d_{\gamma,d}$ implies weak convergence of the trace measures. Conversely, $\mathcal{F}$ is uniformly bounded and equicontinuous, so the Arzelà–Ascoli theorem gives a finite uniform ϵ-net in $\mathcal{F}$ for every $\epsilon > 0$. Weak convergence on the finitely many functions of the net, and the bound $2M_{\theta,\gamma}\epsilon$ for the remaining error, give convergence in $d_{\gamma,d}$.

Thus $d_{\gamma,d}$ is the pullback by the homeomorphism of Theorem 5.1.1 of a metric for the weak topology. The resulting metric space is compact, hence complete. For two choices of the auxiliary data, both metrics induce the same compact L^1 topology, so the identity map is uniformly continuous in both directions. □

Proposition 5.2.1 *There is a constant $C \geq 1$, depending only on $X, \theta, \gamma, \mathrm{d}V$ and d, such that*

$$C^{-1}\|u - v\|_{L^1} \leq d_{\gamma,d}(u, v) \leq C\|u - v\|_{L^1}^{1/2} \qquad (u, v \in \mathcal{K}^0_{\theta,\mathrm{d}V}).$$

Proof The lower bound follows by duality from the inverse of A^*, and the upper bound by smoothing the test functions. Put $w = u - v$, $\sigma = \mathcal{T}_\gamma(u) - \mathcal{T}_\gamma(v)$ and $M = M_{\theta,\gamma}$, and write $\|\sigma\|_{\mathrm{TV}}$ for the total variation of σ. Then $\int_X w\,\mathrm{d}V = 0$, $\sigma = \mathrm{dd}^{\mathrm{c}} w \wedge \gamma^{n-1}$ and $\|\sigma\|_{\mathrm{TV}} \leq 2M$. If $M = 0$, Theorem 5.1.1 gives $u = v$, and both estimates hold trivially.

For the lower bound, let g be a smooth real function. Since $\ker A = \ker A^* = \mathbb{R}$, the equation

$$A^*\phi = g - \int_X g\,\mathrm{d}V, \qquad \int_X \phi\,\mathrm{d}V = 0,$$

has a unique smooth solution. For $p > 2n$, elliptic $W^{2,p}$ estimates on functions of mean zero and the Sobolev embedding theorem give $\|\phi\|_\infty + \mathrm{Lip}_d(\phi) \leq C\|g\|_\infty$.

Pairing the distributional equation $Aw\,\mathrm{d}V = \sigma$ with ϕ, and using $\int_X w\,\mathrm{d}V = 0$, we obtain

$$\left|\int_X wg\,\mathrm{d}V\right| = \left|\int_X \phi\,\mathrm{d}\sigma\right| \leq C\|g\|_\infty d_{\gamma,d}(u, v).$$

Taking the supremum over smooth real g with $\|g\|_\infty \leq 1$ gives $\|w\|_{L^1} \leq C d_{\gamma,d}(u, v)$.

For the upper bound, let f be any test function in the definition of $d_{\gamma,d}$. Using a fixed finite coordinate cover, a smooth partition of unity and convolution at scale $0 < \epsilon < \epsilon_0$, we obtain smooth functions f_ϵ satisfying

$$\|f - f_\epsilon\|_\infty \leq C\epsilon, \qquad \|A^* f_\epsilon\|_\infty \leq C\epsilon^{-1},$$

with constants uniform over this family of test functions. To see the second bound, localize f by the fixed partition of unity. The localized functions have uniformly bounded values and first weak derivatives. In each second derivative of their convolutions, move one derivative onto the mollifier, whose derivative has L^1 norm $O(\epsilon^{-1})$. The lower-order terms of A^* have fixed smooth coefficients and satisfy the same bound. Since $\int_X f_\epsilon \, \mathrm{d}\sigma = \int_X w A^* f_\epsilon \, \mathrm{d}V$, it follows that

$$\left| \int_X f \, \mathrm{d}\sigma \right| \leq C\bigl(M\epsilon + \epsilon^{-1} \|w\|_{L^1}\bigr).$$

If $0 < \|w\|_{L^1} < \epsilon_0^2$, choose $\epsilon = \|w\|_{L^1}^{1/2}$. For larger norms use $d_{\gamma,d}(u, v) \leq 2M$, and for $w = 0$ use injectivity. Taking the supremum over f proves the upper bound. □

Both exponents in Proposition 5.2.1 are optimal, already on an elliptic curve.

Example 5.2.1 Let $X = \mathbb{C}/(\mathbb{Z} + \mathrm{i}\mathbb{Z})$, with coordinate $z = x + \mathrm{i}y$. Take $\theta = \gamma = \eta$, where $\eta = (\mathrm{i}/2)\mathrm{d}z \wedge \mathrm{d}\bar{z}$, together with $\mathrm{d}V = \eta$ and the flat distance d. For integers $k \geq 1$, set

$$u_k = \frac{\cos(2\pi k x)}{2\pi k^2}.$$

These smooth potentials have mean zero and satisfy

$$\theta + \mathrm{dd}^{\mathrm{c}} u_k = \left(1 - \frac{1}{2}\cos(2\pi k x)\right)\eta > 0, \qquad \|u_k\|_{L^1} = \frac{1}{\pi^2 k^2}.$$

The function $f_k = \cos(2\pi k x)/(2\pi k)$ has supremum norm at most one and Lipschitz constant at most one. It follows that

$$d_{\gamma,d}(u_k, 0) \geq \left| \int_X f_k \, \mathrm{dd}^{\mathrm{c}} u_k \right| = \frac{1}{8\pi k}.$$

Consequently, the exponent $1/2$ in Proposition 5.2.1 cannot be replaced by any larger exponent, even for smooth strictly positive potentials on a fixed curve. Nor can the power one in the lower bound be replaced by a smaller positive power: for $0 < t \leq 1$, both $\|tu_1\|_{L^1}$ and $d_{\gamma,d}(tu_1, 0)$ equal t times their positive values at $t = 1$.

5.3 Continuous potentials and pluriharmonic traces

The Gauduchon trace pairs $\theta + \mathrm{dd}^{\mathrm{c}} u$ with the smooth form γ^{n-1}, which is positive and pluriharmonic. In this section $n \geq 2$, ω is a Hermitian form on X, and G is a positive pluriharmonic $(n-1, n-1)$-current, that is, a positive current with $\mathrm{dd}^{\mathrm{c}} G = 0$ (see Section 4.7). Such currents include γ^{n-1}, but in general their coefficients are only measures, and the product $(\theta + \mathrm{dd}^{\mathrm{c}} u) \wedge G$ is not defined a priori. Its integration-by-parts formula contains gradient terms, since G need not be d-closed. The equation $\mathrm{dd}^{\mathrm{c}} G = 0$ converts uniform control of a potential difference into a bound for its

gradient energy against G. This estimate defines the gradient currents for a continuous potential and makes the product stable under uniform approximation.

Lemma 5.3.1 *Let (X,ω) be a compact Hermitian manifold of dimension $n \geq 2$, and let G be a positive $(n-1,n-1)$-current with $\mathrm{dd^c}G = 0$. Put $\mu = \omega \wedge G$ and $M = \mu(X)$. If a, b are smooth real functions and $C \geq 0$ is a constant with $\mathrm{dd^c}a, \mathrm{dd^c}b \geq -C\omega$, then*

$$0 \leq \int_X \mathrm{d}(a-b) \wedge \mathrm{d^c}(a-b) \wedge G \leq 2CM\|a-b\|_\infty.$$

For every smooth real function v, the total variation norms of the order-zero currents $\mathrm{d}v \wedge G$ and $\mathrm{d^c}v \wedge G$ satisfy

$$\|\mathrm{d}v \wedge G\|_{\mathrm{TV}} + \|\mathrm{d^c}v \wedge G\|_{\mathrm{TV}} \leq C_\omega M^{1/2} \left(\int_X \mathrm{d}v \wedge \mathrm{d^c}v \wedge G \right)^{1/2}.$$

Here the total variation norms are computed with respect to ω, and C_ω depends only on (X,ω).

Proof Set $v = a - b$. The identity $\mathrm{dd^c}(v^2) = 2\mathrm{d}v \wedge \mathrm{d^c}v + 2v\mathrm{dd^c}v$, integrated against G, and the equation $\mathrm{dd^c}G = 0$ give

$$\int_X \mathrm{d}v \wedge \mathrm{d^c}v \wedge G = -\int_X v\mathrm{dd^c}v \wedge G.$$

The measures $(\mathrm{dd^c}a + C\omega) \wedge G$ and $(\mathrm{dd^c}b + C\omega) \wedge G$ are positive, and each has mass CM, because the terms $\mathrm{dd^c}a \wedge G$ and $\mathrm{dd^c}b \wedge G$ integrate to zero. Their difference $\mathrm{dd^c}v \wedge G$ therefore has total variation at most $2CM$, which proves the upper bound. The lower bound holds because $\mathrm{d}v \wedge \mathrm{d^c}v = (\mathrm{i}/2\pi)\partial v \wedge \bar{\partial} v$ is a positive $(1,1)$-form.

For the second estimate, work in a local unitary frame for ω. Positivity of G means that its coefficients form a positive semidefinite matrix of measures. These entries are absolutely continuous with respect to the trace measure μ: the diagonal entries are dominated by the trace, and the off-diagonal entries by the Cauchy–Schwarz inequality for positive semidefinite matrices. The resulting matrix of densities has trace bounded by a constant depending only on the normalization. Pairing $\mathrm{d}v \wedge G$ or $\mathrm{d^c}v \wedge G$ with a test one-form η, and applying the matrix Cauchy–Schwarz inequality and then the integral Cauchy–Schwarz inequality, we obtain

$$|\langle \mathrm{d}v \wedge G, \eta\rangle| + |\langle \mathrm{d^c}v \wedge G, \eta\rangle| \leq C_\omega \|\eta\|_\infty M^{1/2} \left(\int_X \mathrm{d}v \wedge \mathrm{d^c}v \wedge G \right)^{1/2}.$$

A finite cover by such frames and a partition of unity give the global estimate. Taking the supremum over smooth test forms of norm at most one yields the total variation bound. When $M = 0$, positivity gives $G = 0$, and both estimates hold trivially. □

Theorem 5.3.1 *Let (X, ω) be a compact Hermitian manifold of dimension $n \geq 2$, let α be a smooth real $(1,1)$-form, and let $u \in \mathrm{PSH}(X,\alpha) \cap C^0(X)$. For every positive $(n-1,n-1)$-current G with $\mathrm{dd^c} G = 0$, the product*

$$(\alpha + \mathrm{dd^c} u) \wedge G$$

has a canonical definition as a positive measure of mass $\int_X \alpha \wedge G$, which agrees with the usual product if u or G is smooth. If $u_j, u \in \mathrm{PSH}(X,\alpha) \cap C^0(X)$ and $u_j \to u$ uniformly, and if positive pluriharmonic currents G_j converge weakly to G, then

$$(\alpha + \mathrm{dd^c} u_j) \wedge G_j \rightharpoonup (\alpha + \mathrm{dd^c} u) \wedge G.$$

Proof We first define the gradient currents $\mathrm{d}u \wedge G$ and $\mathrm{d^c} u \wedge G$ as limits, then define the product by an integration-by-parts formula, and finally prove joint continuity.

Step 1: gradient currents. Choose smooth approximants $a_k \to u$ as in Lemma 1.21.4. There is a common constant $C > 0$ such that $\mathrm{dd^c} a_k \geq -C\omega$. Write $M = \int_X \omega \wedge G$. Since a_k converges uniformly, Lemma 5.3.1 shows that $\mathrm{d}a_k \wedge G$ and $\mathrm{d^c} a_k \wedge G$ are Cauchy sequences in total variation. Denote their limits, which are currents of order zero, by $\mathrm{d}u \wedge G$ and $\mathrm{d^c} u \wedge G$. Applying the same lemma to two uniformly convergent smooth sequences with a common lower Hessian bound shows that the limits do not depend on the sequence. Uniform convergence also gives $a_k G \to uG$ in total variation.

Step 2: the product. Define

$$(\alpha + \mathrm{dd^c} u) \wedge G = \alpha \wedge G + \mathrm{d}(\mathrm{d^c} u \wedge G) - \mathrm{d^c}(\mathrm{d}u \wedge G) - \mathrm{dd^c}(uG) \tag{5.2}$$

in the sense of distributions. For smooth u, the Leibniz rule and $\mathrm{dd^c} G = 0$ show that this agrees with the usual product. Consequently $(\alpha + \mathrm{dd^c} a_k) \wedge G$ converges in distributions to the right-hand side of (5.2). With $\varepsilon_k \to 0$ as in Lemma 1.21.4, the measures $(\alpha + \mathrm{dd^c} a_k + \varepsilon_k \omega) \wedge G$ are positive, with masses $\int_X \alpha \wedge G + \varepsilon_k M$. Their distributional limit is therefore a positive measure, and testing against the constant function one gives its mass. The uniform mass bound upgrades distributional convergence to weak convergence of measures. If G is smooth, the uniform convergence of a_k also identifies the limit with the product of the current $\alpha + \mathrm{dd^c} u$ and the smooth form G.

Step 3: independence of the decomposition. Adding a smooth function h to u adds $\mathrm{d}h \wedge G$ and $\mathrm{d^c} h \wedge G$ to the gradient currents, so replacing (α, u) by $(\alpha - \mathrm{dd^c} h, u + h)$ leaves the product unchanged. If two continuous decompositions define the same $(1,1)$-current, the difference of their potentials has smooth $\mathrm{dd^c}$; taking its trace in a coordinate chart and applying elliptic regularity shows that this difference is smooth. Thus the product depends only on the current $\alpha + \mathrm{dd^c} u$ and on G.

Step 4: joint continuity. For u and for each u_j, keep only those smooth approximants from Lemma 1.21.4 whose curvature errors are at most one. Choosing C with $\alpha \leq (C-1)\omega$, all these approximants satisfy the same lower Hessian bound $-C\omega$. The numbers $M_j = \int_X \omega \wedge G_j$ are bounded, by weak convergence. Fix a smooth

approximant a_k of u, and put $\delta_{j,k} = \|u_j - a_k\|_\infty$. Applying Lemma 5.3.1 to a_k and to smooth approximants of u_j, and passing to the gradient limits, we find that the total variations of the differences $(\mathrm{d}u_j - \mathrm{d}a_k) \wedge G_j$ and $(\mathrm{d}^c u_j - \mathrm{d}^c a_k) \wedge G_j$ are at most $C' M_j \sqrt{\delta_{j,k}}$, where C' is independent of j and k.

For a smooth real test function ϕ, formula (5.2) now gives

$$\left|\left\langle (\alpha + \mathrm{dd}^c u_j) \wedge G_j - (\alpha + \mathrm{dd}^c a_k) \wedge G_j, \phi \right\rangle\right| \leq C_\phi M_j (\sqrt{\delta_{j,k}} + \delta_{j,k}),$$

where C_ϕ depends on the first two derivatives of ϕ, on ω and on C. The same estimate holds with u_j, G_j replaced by u, G. For fixed k, the products $(\alpha + \mathrm{dd}^c a_k) \wedge G_j$ of a fixed smooth form with G_j converge weakly to $(\alpha + \mathrm{dd}^c a_k) \wedge G$. Let first $j \to \infty$ and then $k \to \infty$; since $u_j \to u$ uniformly, the error tends to zero. This proves convergence in distributions, and positivity together with the bounded masses $\int_X \alpha \wedge G_j$ upgrades it to weak convergence of measures. □

For $G = \gamma^{n-1}$ and $\alpha = \theta$, the product in Theorem 5.3.1 is the Gauduchon trace of a continuous potential. Its conserved mass controls a linear pairing of $\theta + \mathrm{dd}^c u$; the nonlinear powers of this current, constructed for unbounded potentials in Chapter 6, require a separate mass analysis.

Chapter 6
Non-pluripolar Monge–Ampère measures

Throughout this chapter, ω is a Hermitian form on X and $\mathrm{d}V$ is a smooth positive probability volume form used for L^1 norms and integrals. As in Section 1.7, we write $\theta_v = \theta + \mathrm{dd^c} v$, and $\mathrm{MA}_\theta(v) = (\theta + \mathrm{dd^c} v)^n$ when v is bounded; convergence in capacity refers to the capacity Cap_ω of Section 1.8.

For an unbounded θ-plurisubharmonic function u, the Bedford–Taylor products of Proposition 1.7.1 are not defined. On the set $\{u > -t\}$, however, u coincides with its bounded truncation $\max(u, -t)$, and since bounded products are plurifinely local, the restricted measures are compatible as t increases. Their limit is a measure on the complement of the pole set, the non-pluripolar Monge–Ampère measure of u. For a general smooth background θ, the truncation need not be θ-plurisubharmonic, so positivity of the restricted products requires a local argument. The total mass of the limit may also be infinite. For a Hermitian background, finiteness of this mass for every potential is equivalent to a uniform bound on the Monge–Ampère masses of bounded potentials, the bounded mass property. When the property fails, we construct a potential of infinite mass whose multiplier ideals are all trivial; its complex Hessian even has integrable coefficients, although its determinant is not integrable.

6.1 Truncation and non-pluripolar measures

Let θ be a smooth real $(1,1)$-form and $u \in \mathrm{PSH}(X, \theta)$. For $t > 0$, put

$$u_t = \max(u, -t), \qquad D_t = \{u > -t\}.$$

Choose a Hermitian form $\Omega \geq \theta$. Then u_t is bounded and Ω-plurisubharmonic, so Proposition 1.7.1 defines the product $(\theta + \mathrm{dd^c} u_t)^n$ as a signed measure. It need not be positive on X, but its restriction to the plurifinely open set D_t is positive. The proof replaces u_t near each point by a local truncation that preserves positivity up to an arbitrarily small smooth error.

Lemma 6.1.1 *With the notation above,*

$$0 \le \mathbf{1}_{D_t}(\theta + \mathrm{dd^c} u_t)^n \le \mathbf{1}_{D_t}(\Omega + \mathrm{dd^c} u_t)^n.$$

More generally, let $\theta_1, \dots, \theta_n$ be smooth real $(1,1)$-forms, let $u^i \in \mathrm{PSH}(X, \theta_i)$, and let D be the set where $u^i > -t$ for every i. Then the mixed product of the currents $\theta_i + \mathrm{dd^c} \max(u^i, -t)$ is positive on D.

Proof Work in a coordinate ball with a fixed positive constant form κ, and fix $\epsilon > 0$. Every point has a smaller neighborhood carrying a constant real form θ' such that

$$-\epsilon\kappa \le \theta - \theta' \le \epsilon\kappa.$$

Take a smooth local potential r for $\theta' + \epsilon\kappa$. Then $u + r$ is plurisubharmonic. On a relatively compact smaller neighborhood choose $k > t + \sup|r|$ and set

$$h_k = \max(u + r, -k) - r.$$

This function is locally bounded and equals $u_t = u$ on D_t. Moreover,

$$\theta + \mathrm{dd^c} h_k + 2\epsilon\kappa = \mathrm{dd^c} \max(u + r, -k) + (\theta - \theta' + \epsilon\kappa)$$

is the sum of a positive closed current with bounded potential and a smooth positive form, so its bounded products are positive. By plurifine locality, the restriction of $(\theta + \mathrm{dd^c} u_t + 2\epsilon\kappa)^n$ to D_t is positive on this neighborhood.

These neighborhoods cover the coordinate ball. Now let $\epsilon \downarrow 0$. The product with the fixed bounded potential u_t is a polynomial in ϵ whose coefficients have locally finite variation, so it converges in local total variation, also after restriction to D_t. This proves the first inequality. The same construction, applied to each factor, gives the positivity of mixed products.

For the second inequality, expand the difference of the two powers by the telescoping identity, using the smooth positive form $\Omega - \theta$. Every summand is a mixed product of factors that are positive on D_t, as just proved. The difference is therefore nonnegative there. □

Theorem 6.1.1 (Extended non-pluripolar measure) *Let θ be a smooth real $(1,1)$-form and $u \in \mathrm{PSH}(X,\theta)$. The measures $\mathbf{1}_{D_t}(\theta + \mathrm{dd^c} u_t)^n$ increase with t. Their limit*

$$\mathrm{MA}^{\mathrm{ext}}_\theta(u) := \lim_{t\to+\infty} \mathbf{1}_{\{u>-t\}}(\theta + \mathrm{dd^c}\max(u,-t))^n \tag{6.1}$$

is a positive Borel measure that puts no mass on pluripolar sets; it is finite on each D_t and σ-finite on X. It depends only on the current $\theta + \mathrm{dd^c} u$; in particular, it is unchanged when a constant is added to u. If Ω is a Hermitian form with $\theta \le \Omega$, then

$$\mathrm{MA}^{\mathrm{ext}}_\theta(u) \le \mathrm{MA}^{\mathrm{ext}}_\Omega(u).$$

The total mass of $\mathrm{MA}^{\mathrm{ext}}_\theta(u)$ may be infinite.

Proof For $s > t$, plurifine locality on $D_t \subset D_s$ gives

$$\mathbf{1}_{D_t}(\theta + \mathrm{dd^c} u_s)^n = \mathbf{1}_{D_t}(\theta + \mathrm{dd^c} u_t)^n.$$

Together with Lemma 6.1.1, this proves that the measures increase. Their increasing limit is countably additive by monotone convergence, and it vanishes on pluripolar sets because each bounded product does. The comparison with Ω passes to the limit. By the compatibility just proved,

$$\mathbf{1}_{D_t}\mathrm{MA}^{\mathrm{ext}}_\theta(u) = \mathbf{1}_{D_t}(\theta + \mathrm{dd^c} u_t)^n,$$

and the mass of this measure is bounded by that of the bounded product $(\Omega + \mathrm{dd^c} u_t)^n$. The sets D_t exhaust the complement of $\{u = -\infty\}$, which has zero mass, so the limit is σ-finite.

For a smooth real function f, consider $\theta' = \theta + \mathrm{dd^c} f$ and $u' = u - f$. On a common superlevel set of u and u', sufficiently deep truncations of u and u' define the same current with bounded potentials, so their restricted products agree. These sets exhaust the complement of the common pole set, which proves invariance under this change of decomposition. By the elliptic-regularity argument in the proof of Proposition 1.7.1, any two smooth decompositions of the same current differ in this way, and adding a constant is a special case. □

We call $\mathrm{MA}^{\mathrm{ext}}_\theta(u)$ the *extended non-pluripolar Monge–Ampère measure* of u; the word *extended* indicates that its total mass may be infinite. On compact X it defines a current of order zero exactly when its total mass is finite. In that case it is the non-pluripolar Monge–Ampère measure in the usual sense, namely the extension by zero across $\{u = -\infty\}$ of the plurifinely local bounded products. If u is bounded, then $D_t = X$ for large t, and $\mathrm{MA}^{\mathrm{ext}}_\theta(u) = \mathrm{MA}_\theta(u)$. In accordance with the usual notation for non-pluripolar products, we also write $\langle(\theta + \mathrm{dd^c} u)^n\rangle$ for $\mathrm{MA}^{\mathrm{ext}}_\theta(u)$; lower powers $\langle(\theta + \mathrm{dd^c} u)^k\rangle$ are defined by the same truncation where they are used.

6.2 Contact sets

The bounded contact inequality of Lemma 1.7.1 extends to unbounded potentials on common finite levels. As in the previous section, local positive corrections are needed, because the global truncations need not remain θ-plurisubharmonic.

Proposition 6.2.1 *Let θ be a smooth real $(1,1)$-form and let $u, v \in \mathrm{PSH}(X,\theta)$ satisfy $u \le v$. Then*

$$\mathbf{1}_{\{u=v\}}\mathrm{MA}_\theta^{\mathrm{ext}}(u) \le \mathbf{1}_{\{u=v\}}\mathrm{MA}_\theta^{\mathrm{ext}}(v).$$

Proof Fix a coordinate ball with a constant positive form κ, a level $t > 0$, and $\epsilon > 0$. On smaller neighborhoods, freeze θ to a constant form θ' with $-\epsilon\kappa \le \theta - \theta' \le \epsilon\kappa$, and choose a quadratic function r with $\mathrm{dd^c} r = \theta' + \epsilon\kappa$. Then $u + r$ and $v + r$ are plurisubharmonic. For a large integer k put

$$a_k = \max(u + r, -k) - r, \qquad b_k = \max(v + r, -k) - r.$$

These functions are bounded on relatively compact neighborhoods, satisfy $a_k \le b_k$, and

$$\theta + 2\epsilon\kappa + \mathrm{dd^c} a_k = \mathrm{dd^c}\max(u + r, -k) + (\theta - \theta' + \epsilon\kappa) \ge 0,$$

with the same inequality for b_k. We may therefore apply the top-degree case of Lemma 1.7.1 with background $\theta + 2\epsilon\kappa$.

On $D_t = \{u > -t\}$, both u and v are larger than $-t$. Taking $k > t + \sup|r|$ makes $a_k = u$ and $b_k = v$ on D_t. Restricting the bounded inequality to $\{u = v\} \cap D_t$ and using locality, we obtain the contact inequality for the background $\theta + 2\epsilon\kappa$ on that set. The smaller neighborhoods cover the original ball, so the restricted inequality holds throughout it.

Choose a Hermitian form $\Omega \ge \theta$. The truncations $u_t = \max(u, -t)$ and $v_t = \max(v, -t)$ are bounded and Ω-plurisubharmonic, so their signed products with background θ are defined. On D_t, the products used above are the restrictions of $(\theta + \mathrm{dd^c} u_t + 2\epsilon\kappa)^n$ and $(\theta + \mathrm{dd^c} v_t + 2\epsilon\kappa)^n$. These are polynomials in ϵ whose coefficients have locally finite variation, so they converge in local total variation as $\epsilon \downarrow 0$, also after restriction to $\{u = v\} \cap D_t$. This proves the inequality for the background θ on each finite level. Finally let $t \to +\infty$: the common pole set has zero extended mass, and the sets $\{u = v\} \cap D_t$ exhaust its complement in the contact set.□

6.3 Weighted lower semicontinuity

Products of uniformly bounded potentials are continuous under convergence in capacity. Multiplying the extended measure by a cutoff in the potential that vanishes below a fixed level reduces it to such bounded products, and letting the level tend to $-\infty$ gives lower semicontinuity of the extended measures, even when their masses are infinite. The weights are allowed to vary with the potentials.

Lemma 6.3.1 *Let θ be a smooth real $(1,1)$-form. Suppose $u_j, u \in \mathrm{PSH}(X,\theta)$ have a common upper bound and $u_j \to u$ in capacity. If b_j, b are nonnegative uniformly bounded quasi-continuous functions and $b_j \to b$ in capacity, then*

$$\int_X b\,\mathrm{MA}_\theta^{\mathrm{ext}}(u) \le \liminf_j \int_X b_j\,\mathrm{MA}_\theta^{\mathrm{ext}}(u_j).$$

Both sides may be infinite.

Proof Subtracting a common constant, we may assume that all the potentials are nonpositive. Choose a Hermitian form $\Omega \ge \theta$. For $T > 0$, let $g_T : [-\infty, 0] \to [0,1]$ be a continuous nondecreasing cutoff, equal to zero on $[-\infty, -2T]$ and to one on $[-T, 0]$, chosen so that g_T increases pointwise to one on $(-\infty, 0]$ as $T \to \infty$. Put $v_j = \max(u_j, -2T)$ and $v = \max(u, -2T)$. These are uniformly bounded Ω-plurisubharmonic functions, and they converge in capacity.

Fix T. Expanding $(\theta + \mathrm{dd^c} v_j)^n$ by means of $\theta + \mathrm{dd^c} v_j = (\Omega + \mathrm{dd^c} v_j) + (\theta - \Omega)$, and bounding each smooth factor by a constant multiple of Ω, we see that the total variations of the signed terms are controlled by positive bounded mixed measures. By Lemma 1.8.6, these have a common capacity bound. Bounded Bedford–Taylor continuity gives weak convergence term by term. It also allows the weights $b_j g_T(v_j)$: their differences from the limiting weight tend to zero in capacity, so the common capacity bound makes the corresponding integrals tend to zero. For the fixed limiting weight, remove an open set of arbitrarily small capacity, extend the weight continuously from its complement, and control the discarded part by the same bound. Since the cutoff vanishes at the truncation level $-2T$, locality gives

$$\begin{aligned}\int_X b_j g_T(u_j)\,\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) &= \int_X b_j g_T(v_j)(\theta + \mathrm{dd^c} v_j)^n \\ &\longrightarrow \int_X b g_T(u)\,\mathrm{MA}_\theta^{\mathrm{ext}}(u).\end{aligned}$$

The first integral is nonnegative and at most the corresponding integral without the cutoff, although the bounded product $(\theta + \mathrm{dd^c} v_j)^n$ may be signed. Hence the limit is bounded by the lower limit in the assertion. Letting $T \to \infty$ and using monotone convergence completes the proof. □

6.4 Density and trace inequalities

The mixed density inequality of Lemma 1.7.3 passes to unbounded potentials on common finite levels. It gives a lower bound for the extended measure of a convex combination of potentials and, by comparison with a smooth metric, a lower bound for the full trace measure.

Lemma 6.4.1 *Let θ be a smooth semipositive $(1,1)$-form and let $f, g \geq 0$ be measurable functions on X. Suppose $u, v \in \mathrm{PSH}(X,\theta)$ satisfy*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) \geq f\,\mathrm{d}V, \qquad \mathrm{MA}_\theta^{\mathrm{ext}}(v) \geq g\,\mathrm{d}V.$$

Then, for $0 \leq t \leq 1$,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(tu + (1-t)v) \geq \left(tf^{1/n} + (1-t)g^{1/n}\right)^n \mathrm{d}V. \tag{6.2}$$

Proof The cases $t = 0$ and $t = 1$ are the hypotheses. Let $0 < t < 1$, translate u, v to be nonpositive, and put $u_k = \max(u, -k)$ and $v_k = \max(v, -k)$. Since θ is semipositive, these are bounded θ-plurisubharmonic functions, and by locality

$$\mathrm{MA}_\theta(u_k) \geq \mathbf{1}_{\{u>-k\}} f\,\mathrm{d}V, \qquad \mathrm{MA}_\theta(v_k) \geq \mathbf{1}_{\{v>-k\}} g\,\mathrm{d}V.$$

Apply Lemma 1.7.3 to each mixed term in the positive expansion of $\theta^n_{tu_k+(1-t)v_k}$. On $E_k = \{u > -k\} \cap \{v > -k\}$ this gives the density on the right of (6.2). On the same set, plurifine locality identifies the left-hand side with the extended measure of $tu + (1-t)v$. As $k \to \infty$, the sets E_k exhaust the complement of the two pole sets, which have zero smooth volume. Monotone convergence on Borel sets proves the inequality. □

The same mixed inequality gives a lower bound for the full trace measure of an unbounded potential. Unlike the extended measure, the full current $\omega + \mathrm{dd^c}u$ keeps its mass on the pole set; the bound below concerns only its absolutely continuous part.

Lemma 6.4.2 *Let γ be a Hermitian form. If $u \in \mathrm{PSH}(X,\omega)$ and $0 \leq g \in L^1(\mathrm{d}V)$ satisfy $\mathrm{MA}_\omega^{\mathrm{ext}}(u) \geq g\,\mathrm{d}V$, then*

$$(\omega + \mathrm{dd^c}u) \wedge \gamma^{n-1} \geq (g\,\mathrm{d}V/\gamma^n)^{1/n}\gamma^n.$$

Proof For bounded u, Lemma 1.7.3, applied in local coordinates with $T_1 = \omega + \mathrm{dd^c}u$, $T_2 = \gamma$ and $k = 1$, gives the asserted inequality.

In general, subtract a constant so that $u \leq 0$, and put $u_k = \max(u, -k)$. Positivity and locality give

$$\mathrm{MA}_\omega(u_k) \geq \mathbf{1}_{\{u>-k\}} g\,\mathrm{d}V,$$

so the bounded case applies to u_k with the density $\mathbf{1}_{\{u>-k\}}g$. Since $u_k \to u$ in L^1, the positive measures $(\omega + \mathrm{dd^c}u_k) \wedge \gamma^{n-1}$ converge weakly to $(\omega + \mathrm{dd^c}u) \wedge \gamma^{n-1}$. The densities on the right converge in L^1, because $g^{1/n}$ is integrable and the pole set has zero smooth volume. Passing to the limit proves the assertion. □

6.5 The bounded mass property

When ω is a Kähler form, all bounded ω-plurisubharmonic functions have the same Monge–Ampère mass $\int_X \omega^n$. For a general Hermitian form, the mass can depend on the potential, as in Example 2.3.1, and the following two numbers measure its range.

Definition 6.5.1 Let ω be a Hermitian form on X. The *lower mass* and the *upper mass* of ω are

$$v_-(\omega) = \inf_{v \in \mathrm{PSH}(X,\omega)\cap L^\infty(X)} \int_X (\omega + \mathrm{dd^c} v)^n,$$
$$v_+(\omega) = \sup_{v \in \mathrm{PSH}(X,\omega)\cap L^\infty(X)} \int_X (\omega + \mathrm{dd^c} v)^n.$$

The manifold X has the *bounded mass property*, abbreviated BMP, if $v_+(\omega) < +\infty$. The form ω has *positive lower mass* if $v_-(\omega) > 0$.

Testing with $v = 0$ gives $v_-(\omega) \le \int_X \omega^n \le v_+(\omega)$. By the next proposition, the bounded mass property does not depend on the choice of ω. Since the extended measure (6.1) is built from products of bounded potentials, the upper mass also controls the extended measures of unbounded potentials (Proposition 6.5.2).

Proposition 6.5.1 *The bounded mass property is independent of the Hermitian form. Moreover, the supremum in Definition 6.5.1 is unchanged if only smooth potentials are used.*

Proof For another Hermitian form η, choose $C > 0$ such that $\eta \le C\omega$. If v is a bounded η-plurisubharmonic function, then v/C is ω-plurisubharmonic and

$$0 \le \eta + \mathrm{dd^c} v \le C\big(\omega + \mathrm{dd^c}(v/C)\big).$$

By positivity of mixed bounded products, $\int_X (\eta + \mathrm{dd^c} v)^n \le C^n v_+(\omega)$. Interchanging the two forms proves metric independence.

For the last assertion, approximate a bounded potential by Theorem 1.11.1. The smooth approximants decrease and remain uniformly bounded, so the continuity of bounded products along decreasing sequences gives convergence of their total masses. The reverse inequality between the two suprema is immediate. □

Proposition 6.5.2 *Assume $v_+(\omega) < +\infty$. If θ is a smooth real $(1,1)$-form with $\theta \le C\omega$ for some $C > 0$, and $u \in \mathrm{PSH}(X,\theta)$, then*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u)(X) \le C^n v_+(\omega).$$

Proof The comparison in Theorem 6.1.1, applied with the Hermitian form $C\omega$, gives

$$\mathbf{1}_{D_t} \mathrm{MA}_\theta^{\mathrm{ext}}(u) \le \mathbf{1}_{D_t} (C\omega + \mathrm{dd^c} u_t)^n.$$

Since u_t/C is bounded and ω-plurisubharmonic, the right-hand side has mass at most $C^n v_+(\omega)$. Let $t \to \infty$. □

6.6 Infinite mass with trivial multiplier ideals

If the bounded mass property fails, there are smooth ω-plurisubharmonic functions u_j whose masses M_j tend to infinity. In a convex combination $U = \sum_j a_j u_j$, positivity of mixed products shows that each summand contributes at least $a_j^n M_j$ to the extended measure of U. Choosing the masses M_j to outgrow a_j^{-n} therefore forces infinite mass. On the other hand, each tail $\sum_{j>N} a_j u_j$ is a small multiple of a convex combination of normalized potentials, and the uniform exponential integrability of Lemma 1.5.1 applies to it at every exponent.

Theorem 6.6.1 *If $v_+(\omega) = +\infty$, there is $U \in \mathrm{PSH}(X,\omega)$, $U \le 0$, such that*

$$\mathrm{MA}_\omega^{\mathrm{ext}}(U)(X) = +\infty, \qquad \int_X \mathrm{e}^{-pU}\,\mathrm{d}V < +\infty \quad \text{for every } p > 0.$$

In particular, $\mathcal{I}(pU) = \mathcal{O}_X$ for every $p > 0$.

Proof Set $a_j = 2^{-j}$ for $j \ge 1$. By Proposition 6.5.1, we can choose smooth ω-plurisubharmonic functions u_j with $\sup_X u_j = 0$ and

$$M_j := \int_X \omega_{u_j}^n \ge 2^{j(n+1)}.$$

The partial sums $U_N = \sum_{j\le N} a_j u_j$ decrease and satisfy

$$\omega + \mathrm{dd^c} U_N = \sum_{j\le N} a_j \omega_{u_j} + \left(1 - \sum_{j\le N} a_j\right)\omega \ge 0.$$

Their L^1 norms are bounded by (1.1), so their limit U is ω-plurisubharmonic and nonpositive.

We first prove that the mass is infinite. Fix j and write $v_j = U - a_j u_j$. Passing to the limit in the remaining partial sums gives $(1-a_j)\omega + \mathrm{dd^c} v_j \ge 0$. For $t > 0$, put

$$v_{j,t} = \max(v_j, -t), \qquad W_{j,t} = a_j u_j + v_{j,t}.$$

The function $v_{j,t}$ is a bounded potential for the positive background $(1-a_j)\omega$, so $W_{j,t}$ is bounded and ω-plurisubharmonic.

On $D_t = \{U > -t\}$, the inequality $u_j \le 0$ gives $v_j = U - a_j u_j \ge U > -t$, and hence $W_{j,t} = U = \max(U,-t)$ there. Plurifine locality and positivity of bounded mixed products yield

$$\begin{aligned}\mathbf{1}_{D_t}\omega_{\max(U,-t)}^n &= \mathbf{1}_{D_t}\left(a_j\omega_{u_j} + (1-a_j)\omega + \mathrm{dd^c} v_{j,t}\right)^n \\ &\ge a_j^n \mathbf{1}_{D_t}\omega_{u_j}^n.\end{aligned}$$

The sets D_t exhaust $X \setminus \{U = -\infty\}$. This pole set is pluripolar, hence has zero smooth volume, so the smooth measure $\omega_{u_j}^n$ gives it no mass. Letting $t \to +\infty$, we obtain

$$\mathrm{MA}_{\omega}^{\mathrm{ext}}(U)(X) \geq a_j^n M_j \geq 2^j .$$

Since j is arbitrary, the mass is infinite.

For the integrability, fix $p > 0$, let α be the exponent of Lemma 1.5.1, and take N so large that $p\delta \leq \alpha$, where $\delta = \sum_{j>N} a_j = 2^{-N}$. Write $U = A_N + V_N$ with $A_N = \sum_{j\leq N} a_j u_j$ smooth. For a finite tail ending at $m > N$, Jensen's inequality for the convex exponential function, with the unused weight assigned to the value zero, gives

$$\exp\left(-p \sum_{N<j\leq m} a_j u_j\right) \leq \sum_{N<j\leq m} \frac{a_j}{\delta} \mathrm{e}^{-p\delta u_j} + 1 - \sum_{N<j\leq m} \frac{a_j}{\delta}.$$

Because $u_j \leq 0$ and $p\delta \leq \alpha$, the integrals of the exponentials on the right are uniformly bounded. Integrating and letting $m \to +\infty$ by monotone convergence, we obtain $\int_X \mathrm{e}^{-pV_N}\,\mathrm{d}V < +\infty$. Multiplication by the bounded smooth function e^{-pA_N} proves $\int_X \mathrm{e}^{-pU}\mathrm{d}V < +\infty$.

Consequently, the constant germ 1 is locally integrable against each weight e^{-pU}, and every multiplier ideal $\mathcal{I}(pU)$ is the whole structure sheaf. □

Corollary 6.6.1 *The bounded mass property holds if and only if* $\mathrm{MA}_{\omega}^{\mathrm{ext}}(u)(X) < +\infty$ *for every* $u \in \mathrm{PSH}(X,\omega)$. *If the bounded mass property fails, there are potentials with infinite extended mass and trivial multiplier ideals* $\mathcal{I}(pu) = \mathcal{O}_X$, $p > 0$, *arbitrarily close to zero in* L^1.

Proof The first assertion follows from Proposition 6.5.2 and Theorem 6.6.1. For the second, take εU, $0 < \varepsilon \leq 1$, with U as in Theorem 6.6.1. It is ω-plurisubharmonic and has the required exponential integrability. On $D_t = \{U > -t\}$, its truncation at level εt is $\varepsilon \max(U, -t)$, and

$$\omega + \mathrm{dd}^{\mathrm{c}}\big(\varepsilon \max(U,-t)\big) = \varepsilon\omega_{\max(U,-t)} + (1-\varepsilon)\omega.$$

Positivity of mixed products bounds the restricted measure of εU below by ε^n times that of U. Its limiting mass is therefore infinite. Finally, $\|\varepsilon U\|_{L^1} \to 0$ as $\varepsilon \to 0$. □

6.7 Integrable Hessians and infinite mass

In the construction of Theorem 6.6.1, the Gauduchon identity of Proposition 4.2.1 fixes the trace integral of every positive summand $\omega + \mathrm{dd}^{\mathrm{c}} u_j$. The series defining $\omega + \mathrm{dd}^{\mathrm{c}} U$ therefore converges in the coefficient L^1 norm, although its determinant is not integrable. The trace measures converge in total variation, yet the Monge–Ampère mass is infinite. In Chapter 7, weights that decay on deep sublevel sets will control these masses.

Fix a Gauduchon form γ and set $M = \int_X \omega \wedge \gamma^{n-1}$. For a real $(1,1)$-form T with measurable coefficients, let A_T be its Hermitian matrix relative to γ, and let $|A_T| = (A_T^2)^{1/2}$ be its positive matrix absolute value. We use the norm

$$\|T\|_{L^1(\gamma)} = \frac{1}{n} \int_X \operatorname{tr} |A_T| \, \gamma^n .$$

For $T \geq 0$ this equals $\int_X T \wedge \gamma^{n-1}$. On compact X, any other smooth Hermitian form gives an equivalent norm and hence the same space of integrable coefficients. When the coefficients of T are integrable, we write $\det_\gamma T = \det A_T$; this function is defined almost everywhere, and $T^n = (\det_\gamma T)\gamma^n$ when T is smooth.

Proposition 6.7.1 *Suppose $v_+(\omega) = +\infty$. For the potential U and its smooth decreasing approximants U_N constructed in the proof of Theorem 6.6.1, the current $T = \omega + \mathrm{dd^c} U$ has integrable coefficients and*

$$\|\omega + \mathrm{dd^c} U_N - T\|_{L^1(\gamma)} \leq 2^{1-N} M .$$

Its pointwise determinant satisfies

$$\mathrm{MA}_\omega^{\mathrm{ext}}(U) \geq (\det_\gamma T)\gamma^n , \qquad \int_X (\det_\gamma T)\gamma^n = +\infty .$$

Moreover,

$$\int_X (\omega + \mathrm{dd^c} U_N)^n \longrightarrow +\infty .$$

Proof Write $T_j = \omega + \mathrm{dd^c} u_j$ for the smooth positive forms in that construction, and put

$$S_N = \sum_{j \leq N} a_j T_j , \qquad \delta_N = \sum_{j > N} a_j = 2^{-N} .$$

The smooth positive forms S_N increase pointwise, and the Gauduchon identity gives

$$\int_X S_N \wedge \gamma^{n-1} = (1 - \delta_N) M .$$

By monotone convergence of their traces, the series of matrices has a finite positive limit S almost everywhere. The coefficients of S are integrable, because in a γ-unitary frame the absolute value of every coefficient of a positive matrix is bounded by its trace. Positivity and the same trace identity give

$$\|S - S_N\|_{L^1(\gamma)} = \delta_N M .$$

In particular, $S_N \to S$ in the sense of distributions. Since

$$\omega + \mathrm{dd^c} U_N = S_N + \delta_N \omega \longrightarrow \omega + \mathrm{dd^c} U$$

in the sense of distributions, by L^1 convergence of the potentials, we obtain $T = S$. The triangle inequality now gives

$$\|\omega + \mathrm{dd^c} U_N - T\|_{L^1(\gamma)} \le \|S_N - S\|_{L^1(\gamma)} + \delta_N \|\omega\|_{L^1(\gamma)} = 2\delta_N M.$$

To compare $\mathrm{MA}_\omega^{\mathrm{ext}}(U)$ with the determinant, fix N and set $V_N = U - U_N$. The remaining partial sums give $\delta_N \omega + \mathrm{dd^c} V_N \ge 0$ and $V_N \le 0$. For $t > 0$, the function $W_{N,t} = U_N + \max(V_N, -t)$ is bounded, and its current is the sum of two positive terms:

$$\omega + \mathrm{dd^c} W_{N,t} = S_N + \bigl(\delta_N \omega + \mathrm{dd^c} \max(V_N, -t)\bigr).$$

On $D_t = \{U > -t\}$, the inequality $U_N \le 0$ gives $V_N \ge U > -t$, and consequently $W_{N,t} = U = \max(U, -t)$ there. Locality and positivity of bounded products imply

$$\mathbf{1}_{D_t} \mathrm{MA}_\omega^{\mathrm{ext}}(U) \ge \mathbf{1}_{D_t} S_N^n.$$

The smooth measure S_N^n gives no mass to the pluripolar pole set of U, so letting $t \to \infty$ proves $\mathrm{MA}_\omega^{\mathrm{ext}}(U) \ge S_N^n$. The positive matrices S_N increase to T almost everywhere, so their determinants increase to $\det_\gamma T$. Monotone convergence on every Borel set gives the asserted inequality between $\mathrm{MA}_\omega^{\mathrm{ext}}(U)$ and the determinant measure.

Finally, for every $N \ge j$, positivity gives $S_N \ge a_j T_j$. Hence both the measurable limit and the smooth approximating forms satisfy

$$\int_X (\det_\gamma T)\gamma^n \ge a_j^n \int_X T_j^n \ge 2^j, \qquad \int_X (\omega + \mathrm{dd^c} U_N)^n \ge a_j^n \int_X T_j^n \ge 2^j.$$

The first bound holds for every j, and the second for every $N \ge j$; together they prove the two assertions about infinite mass. □

Corollary 6.7.1 *If the bounded mass property fails, there are nonpositive potentials $w_\varepsilon \in \mathrm{PSH}(X, \omega)$, $0 < \varepsilon < 1$, such that*

$$\omega + \mathrm{dd^c} w_\varepsilon \ge (1 - \varepsilon)\omega, \qquad \mathcal{I}(p w_\varepsilon) = \mathcal{O}_X \quad (p > 0),$$

and such that both the integral of the pointwise determinant $\det_\gamma(\omega + \mathrm{dd^c} w_\varepsilon)$ against γ^n and the extended Monge–Ampère mass of w_ε are infinite. As $\varepsilon \downarrow 0$, the potentials converge to zero in L^1, their currents converge to ω in the coefficient L^1 norm, and their full trace measures $(\omega + \mathrm{dd^c} w_\varepsilon) \wedge \gamma^{n-1}$ converge to $\omega \wedge \gamma^{n-1}$ in total variation.

Proof Take $w_\varepsilon = \varepsilon U$, with U and $T = \omega + \mathrm{dd^c} U$ as in Proposition 6.7.1. Its current is

$$T_\varepsilon = (1 - \varepsilon)\omega + \varepsilon T.$$

The lower bound and the two L^1 convergence assertions follow immediately. The full trace measures have integrable densities, and their distance from $\omega \wedge \gamma^{n-1}$ in total variation is at most

$$\varepsilon \|T - \omega\|_{L^1(\gamma)}.$$

Every multiplier ideal is trivial by the exponential integrability of U proved in Theorem 6.6.1. Since $T_\varepsilon \ge \varepsilon T$ almost everywhere, the determinant integral of T_ε is

at least ε^n times that of T, hence infinite. The extended mass of w_ε is infinite by the proof of Corollary 6.6.1. □

For smooth potentials, the total masses can be prescribed in advance while both the currents and the exponential weights converge.

Corollary 6.7.2 *Suppose $v_+(\omega) = +\infty$. Let $(\varepsilon_j)_{j\ge1}$ and $(b_j)_{j\ge1}$ be real sequences with $0 < \varepsilon_j < 1$, $\varepsilon_j \to 0$, and $b_j > \int_X \omega^n$. There are smooth potentials $w_j \in \mathrm{PSH}(X,\omega)$ with $\sup_X w_j = 0$ such that*

$$\omega + \mathrm{dd^c} w_j \ge (1-\varepsilon_j)\omega, \qquad \int_X (\omega + \mathrm{dd^c} w_j)^n = b_j,$$
$$\|\mathrm{dd^c} w_j\|_{L^1(\gamma)} \le 2M\varepsilon_j.$$

Moreover, $w_j \to 0$ in $L^1(\mathrm{d}V)$ and $\mathrm{e}^{-pw_j} \to 1$ in $L^1(\mathrm{d}V)$ for every fixed $p > 0$. The full Gauduchon trace measures converge to $\omega \wedge \gamma^{n-1}$ in total variation.

Proof By Proposition 6.5.1, we can choose a smooth $u_j \in \mathrm{PSH}(X,\omega)$ with $\sup_X u_j = 0$ and

$$\int_X (\omega + \mathrm{dd^c} u_j)^n > \varepsilon_j^{-n} b_j.$$

Put $T_j = \omega + \mathrm{dd^c} u_j$. The polynomial

$$F_j(s) = \int_X \big((1-s)\omega + sT_j\big)^n, \qquad 0 \le s \le \varepsilon_j,$$

satisfies $F_j(0) < b_j$, and also $F_j(\varepsilon_j) \ge \varepsilon_j^n \int_X T_j^n > b_j$ by positivity of the mixed terms. The intermediate value theorem gives $s_j \in (0,\varepsilon_j)$ with $F_j(s_j) = b_j$. Set $w_j = s_j u_j$. Then $\sup_X w_j = 0$, $\omega + \mathrm{dd^c} w_j = (1-s_j)\omega + s_j T_j \ge (1-\varepsilon_j)\omega$, and w_j has the prescribed mass b_j.

The Gauduchon identity gives $\|T_j\|_{L^1(\gamma)} = \|\omega\|_{L^1(\gamma)} = M$. Hence

$$\|\mathrm{dd^c} w_j\|_{L^1(\gamma)} = s_j \|T_j - \omega\|_{L^1(\gamma)} \le 2M\varepsilon_j.$$

Since the absolute value of the trace of a Hermitian matrix is bounded by the trace of its absolute value, the same bound holds for the total variation of $\mathrm{dd^c} w_j \wedge \gamma^{n-1}$. With K_ω as in (1.1), we also have $\|w_j\|_{L^1(\mathrm{d}V)} \le K_\omega \varepsilon_j$.

Finally, let α, C be the constants of Lemma 1.5.1 for $(X,\omega,\mathrm{d}V)$, and fix $p > 0$. For all sufficiently large j, one has $ps_j \le \alpha$. Convexity of the exponential function, applied with weight ps_j/α, gives

$$0 \le \mathrm{e}^{-pw_j} - 1 \le \frac{ps_j}{\alpha}\big(\mathrm{e}^{-\alpha u_j} - 1\big).$$

Integrating, we bound the $L^1(\mathrm{d}V)$ norm of $\mathrm{e}^{-pw_j} - 1$ by $pC\varepsilon_j/\alpha$, which proves the last convergence. □

Chapter 7
Weighted Monge–Ampère measures

Let X be a connected compact complex manifold of dimension n, and let ω be a Hermitian form. Capacity refers to the capacity Cap_ω of Section 1.8. For nonpositive $u \in \mathrm{PSH}(X,\omega)$ we write

$$\mu_u = \mathrm{MA}_\omega^{\mathrm{ext}}(u)$$

for the extended non-pluripolar Monge–Ampère measure of Theorem 6.1.1, and we put

$$r_n = \max(n-2, 0).$$

By Chapter 6, the measure μ_u can have infinite mass when the bounded mass property fails. Its mass above depth t, on the superlevel set $\{u \geq -t\}$, is nevertheless bounded by a polynomial of degree r_n in t, because the masses of bounded potentials grow at most polynomially in their range. A weight that decreases sufficiently fast in the depth $-u$ compensates for this growth. If $w : [0,+\infty) \to [0,+\infty)$ is a nonincreasing function with $w(t) \to 0$ as $t \to +\infty$, we call

$$w(-u)\,\mu_u$$

the *damped Monge–Ampère measure* of u with weight w; the weight is set to zero on the pole set $\{u = -\infty\}$, which μ_u does not charge. The main examples are the exponential weights e^{-pt} and the polynomial weights $(1+t)^{-q}$. For suitable weights the damped measures are finite, uniformly absolutely continuous with respect to capacity, and continuous under convergence in capacity, a property that the extended measures themselves lack. Removing the weight requires uniform control of the mass on deep sublevel sets; we characterize this control and show by examples that such mass can persist although the potentials converge in capacity.

7.1 Range and restricted mass

We first bound the Monge–Ampère mass of a bounded potential polynomially in its range. The first mixed mass $\int_X (\omega + \mathrm{dd^c} v) \wedge \omega^{n-1}$ is bounded independently of v by the Gauduchon trace. Local Chern–Levine–Nirenberg estimates turn this into a bound of degree $j-1$ in the range for the jth mixed mass, and Stokes' theorem expresses the top mass in terms of the lower ones.

Proposition 7.1.1 *There is a constant C_ω such that, for every $A \geq 0$,*

$$\int_X (\omega + \mathrm{dd^c} v)^n \leq C_\omega (1+A)^{r_n} \quad \text{if } v \in \mathrm{PSH}(X,\omega),\ 0 \leq v \leq A.$$

Proof Choose finitely many coordinate balls whose concentric smaller balls, with compact closure in the larger ones, cover X. On each larger ball choose a fixed quadratic function q with $\mathrm{dd^c} q \geq \omega$, shifted so that $p = v + q$ is plurisubharmonic with $0 \leq p \leq A + C$. Let κ be the Euclidean form. In the identity

$$\mathrm{dd^c} p = (\omega + \mathrm{dd^c} v) + (\mathrm{dd^c} q - \omega),$$

the integral of the first term against κ^{n-1} is bounded by a fixed multiple of the global trace mass, which is bounded by Corollary 4.2.1, and the second term is smooth and fixed. Thus $\int \mathrm{dd^c} p \wedge \kappa^{n-1}$ is bounded uniformly in v and A; in dimension one, Stokes' theorem replaces the trace bound. By (1.2), on each smaller ball,

$$\int (\mathrm{dd^c} p)^j \wedge \kappa^{n-j} \leq C_j (1+A)^{j-1} \quad (1 \leq j \leq n).$$

Expand $(\omega + \mathrm{dd^c} v)^j = (\mathrm{dd^c} p + \omega - \mathrm{dd^c} q)^j$ and sum over the finite cover. Since the smooth factors have bounded coefficients, the positive mixed masses satisfy

$$0 \leq M_j(v) := \int_X (\omega + \mathrm{dd^c} v)^j \wedge \omega^{n-j} \leq C_j (1+A)^{\max(j-1,0)} \quad (0 \leq j \leq n).$$

For smooth v, the exact form $(\mathrm{dd^c} v)^n$ integrates to zero, as in the proof of Theorem 2.2.1; the regularization of Theorem 1.11.1 and the continuity of bounded products give the same identity for bounded v. Thus

$$0 = \int_X (\mathrm{dd^c} v)^n = \sum_{j=0}^{n} (-1)^{n-j} \binom{n}{j} M_j(v).$$

Since the mixed masses are nonnegative, it follows that

$$M_n(v) \leq \sum_{j=0}^{n-1} \binom{n}{j} M_j(v) \leq C_\omega (1+A)^{r_n}.$$

The largest power is $n-2$ when $n \geq 2$; for $n = 1$, only the constant term remains. □

For $n \leq 2$ the bound is uniform, so every compact complex curve or surface has the bounded mass property. In higher dimensions the bound grows with the range, and truncation turns it into a bound for the mass of an unbounded potential above a finite depth.

Lemma 7.1.1 *Let $u \in \mathrm{PSH}(X,\omega)$ be nonpositive. For $t \geq 0$ and every Borel set $E \subset X$,*

$$\mu_u(\{u \geq -t\}) \leq C_\omega (1+t)^{r_n}, \qquad \mu_u(E \cap \{u \geq -t\}) \leq (1+t)^n \operatorname{Cap}_\omega(E). \quad (7.1)$$

Proof Put $v_t = \max(u, -t-1) + t + 1$. It is ω-plurisubharmonic and takes values in $[0, t+1]$, and by plurifine locality its Monge–Ampère measure equals μ_u on $\{u \geq -t\} \subset \{u > -t-1\}$. The first estimate therefore follows from Proposition 7.1.1, after enlarging the constant. For the second, $v_t/(1+t)$ is a test function for the capacity, and positivity gives

$$(\omega + \mathrm{dd^c} v_t)^n \leq (1+t)^n \big(\omega + \mathrm{dd^c}(v_t/(1+t))\big)^n.$$

Restricting this inequality to $E \cap \{u \geq -t\}$ proves the capacity bound. □

7.2 Exponential damping

The exponential weight can be handled directly. A convex increasing function with bounded range transforms u into a bounded ω-plurisubharmonic function, and the chain rule shows that the transformed current dominates an exponential multiple of $\omega + \mathrm{dd^c} u$. The Monge–Ampère measure of the bounded transform therefore controls the damped measure.

For $a > 0$ put $F_a(t) = a^{-1} \mathrm{e}^{at}$ for $t \leq 0$, with $F_a(-\infty) = 0$. Then $0 \leq F_a \leq a^{-1}$, while $0 < F_a' \leq 1$ and $F_a'' \geq 0$ at finite arguments.

Proposition 7.2.1 *If $u \in \mathrm{PSH}(X,\omega)$ and $u \leq 0$, then $F_a(u)$ is a bounded ω-plurisubharmonic function, and*

$$\mathrm{e}^{nau} \mu_u \leq \mathrm{MA}_\omega(F_a(u)).$$

Proof First suppose that u is bounded. The chain rule (1.6) gives

$$\omega + \mathrm{dd^c} F_a(u) = \mathrm{e}^{au}(\omega + \mathrm{dd^c} u) + (1 - \mathrm{e}^{au})\omega + a\mathrm{e}^{au}\, \mathrm{d}u \wedge \mathrm{d^c} u.$$

All three summands are positive, and positivity of their bounded mixed products yields the claimed inequality.

For general u, use the truncations $u_t = \max(u, -t)$. The bounded functions $F_a(u_t)$ decrease and take values between zero and a^{-1}, so their limit $F_a(u)$ is a bounded

ω-plurisubharmonic function. On the plurifinely open set $D_t = \{u > -t\}$, it agrees with $F_a(u_t)$. Locality and the bounded case therefore give

$$\mathrm{e}^{nau}\mathbf{1}_{D_t}\mu_u \le \mathbf{1}_{D_t}\mathrm{MA}_\omega(F_a(u)).$$

Let $t \to +\infty$. The pole set is not charged by μ_u, and it has zero mass for the bounded product on the right. □

Theorem 7.2.1 *For $p > 0$, the damped measures $\nu_{p,u} = \mathrm{e}^{pu}\mu_u$ satisfy*

$$\nu_{p,u}(X) \le C_\omega(1 + p^{-1})^{r_n}, \qquad \nu_{p,u}(E) \le \max(1, n/p)^n \operatorname{Cap}_\omega(E)$$

for every Borel set $E \subset X$, uniformly over all nonpositive $u \in \mathrm{PSH}(X, \omega)$.

Proof Take $a = p/n$ in Proposition 7.2.1. Since $F_{p/n}(u)$ takes values in $[0, n/p]$, Proposition 7.1.1 with $A = n/p$ gives the total mass bound, after enlarging C_ω. For the capacity bound put $B = \max(1, n/p)$ and $v = F_{p/n}(u)$. Then v/B is a test function for the capacity, and

$$B\big(\omega + \mathrm{dd^c}(v/B)\big) = (\omega + \mathrm{dd^c}v) + (B-1)\omega \ge \omega + \mathrm{dd^c}v.$$

Consequently $\nu_{p,u} \le \mathrm{MA}_\omega(v) \le B^n\mathrm{MA}_\omega(v/B)$, which gives the second bound. The measures $\nu_{p,u}$ do not charge pluripolar sets, because μ_u does not. □

Since μ_u does not charge the pole set, multiplication by e^{-pu} recovers μ_u from $\nu_{p,u}$, including when its mass is infinite. An additive shift $u \mapsto u + c$ multiplies the damped measure by e^{pc}.

7.3 Decreasing weights and capacity continuity

For a general decreasing weight w, writing $w(s) = \int_s^\infty (-w'(t))\,\mathrm{d}t$ and integrating the finite-depth estimate (7.1) in t bounds both the total mass and the mass on deep sublevel sets. Above any fixed depth, the damped measure is a weighted product of bounded potentials, which is continuous under convergence in capacity; the tail bound then removes the restriction to a fixed depth.

Theorem 7.3.1 *Let $w : [0, +\infty) \to (0, +\infty)$ be continuously differentiable and nonincreasing, with $w(t) \to 0$ as $t \to +\infty$. For $T \geq 0$ define*

$$B_w(T) = \int_T^\infty (1+t)^{r_n} (-w'(t))\, \mathrm{d}t.$$

Assume $B_w(0) < +\infty$. For nonpositive $u \in \mathrm{PSH}(X, \omega)$, the damped measures $\nu_{w,u} = w(-u)\mu_u$ satisfy

$$\nu_{w,u}(X) \leq C_\omega B_w(0), \qquad \nu_{w,u}(\{u < -T\}) \leq C_\omega B_w(T).$$

For every Borel set E and $T \geq 0$,

$$\nu_{w,u}(E) \leq w(0)(1+T)^n \operatorname{Cap}_\omega(E) + C_\omega B_w(T).$$

In particular, these measures are uniformly absolutely continuous with respect to capacity. If nonpositive $u_j, u \in \mathrm{PSH}(X, \omega)$ satisfy $u_j \to u$ in capacity, then $\nu_{w,u_j} \rightharpoonup \nu_{w,u}$.

Proof Write $s = -u$. Since $w(s) = \int_s^\infty (-w'(t))\, \mathrm{d}t$ for finite s, and since μ_u does not charge the pole set $\{s = +\infty\}$, Tonelli's theorem and Lemma 7.1.1 give

$$\int_X w(s)\, \mathrm{d}\mu_u = \int_0^\infty (-w'(t))\mu_u(\{s \leq t\})\, \mathrm{d}t \leq C_\omega B_w(0).$$

Restricting the integral to $\{s > T\}$ gives the same bound with $B_w(T)$ in place of $B_w(0)$, since the inner set is then $\{T < s \leq t\}$, which is empty unless $t > T$.

For the capacity bound, the second estimate in (7.1) gives

$$\int_{E \cap \{s \leq T\}} w(s)\, \mathrm{d}\mu_u \leq w(0)(1+T)^n \operatorname{Cap}_\omega(E).$$

Adding the tail estimate for $\{s > T\}$ proves the asserted bound. Since $B_w(T) \to 0$, choosing first T large and then the capacity small gives uniform absolute continuity.

To prove continuity, fix a continuous nonincreasing $\eta : [0, +\infty) \to [0, 1]$, equal to one on $[0, 1]$ and zero on $[2, +\infty)$, and put $\eta_T(s) = \eta(s/T)$. For fixed $T > 0$, set $v_{j,T} = \max(u_j, -2T)$ and $g_T(t) = \eta_T(-t)w(-t)$ on $[-2T, 0]$. Since $g_T(-2T) = 0$, locality gives

$$\eta_T(-u_j)w(-u_j)\mu_{u_j} = g_T(v_{j,T})\, \mathrm{MA}_\omega(v_{j,T}). \tag{7.2}$$

Truncation preserves convergence in capacity. The functions $g_T(v_{j,T})$ are uniformly bounded and quasi-continuous, and they converge in capacity to the corresponding function for u. The weighted continuity of bounded products in Sections 1.6 and 1.8 therefore gives weak convergence of the measures in (7.2) for each fixed T. The measure $(1 - \eta_T(-u_j))\nu_{w,u_j}$ is carried by $\{u_j < -T\}$, so by the tail bound its integral against a continuous test function f is at most $C_\omega B_w(T)\|f\|_\infty$, uniformly in j; the same holds for u. Letting $T \to \infty$ completes the proof. □

For $w(t) = \mathrm{e}^{-pt}$, $p > 0$, the integral $B_w(0)$ is finite because the exponential dominates the polynomial factor. Thus the exponentially damped measures of Theorem 7.2.1 are continuous under convergence in capacity. By that theorem, their tails also satisfy

$$\nu_{p,u}(\{u < -T\}) \le \mathrm{e}^{-pT/2}\nu_{p/2,u}(X) \le C_p\mathrm{e}^{-pT/2}.$$

For polynomial weights, the general estimate takes the following explicit form.

Theorem 7.3.2 *For every $q > r_n$, the damped measures*

$$\sigma_{q,u} := (1-u)^{-q}\mu_u$$

have uniformly bounded mass for $u \in \mathrm{PSH}(X,\omega)$, $u \le 0$. More precisely,

$$\sigma_{q,u}(\{u < -T\}) \le C\frac{q}{q-r_n}(1+T)^{r_n-q} \quad (T \ge 0),$$

where C depends only on ω. There is also a constant C_q such that, for every Borel set $E \subset X$,

$$\sigma_{q,u}(E) \le C_q\,\mathrm{Cap}_\omega(E)^{(q-r_n)/(q+n-r_n)}.$$

Proof For $w(t) = (1+t)^{-q}$, direct integration gives

$$B_w(T) = q\int_T^\infty (1+t)^{r_n-q-1}\,\mathrm{d}t = \frac{q}{q-r_n}(1+T)^{r_n-q}.$$

Thus Theorem 7.3.1 gives the mass and tail estimates. For the capacity bound put $\delta = \mathrm{Cap}_\omega(E)$. If $0 < \delta \le 1$, choose $T = \delta^{-1/(q+n-r_n)} \ge 1$ in that theorem. Both $T^n\delta$ and T^{r_n-q} equal $\delta^{(q-r_n)/(q+n-r_n)}$, so its two terms have the required bound. If $\delta = 0$, let $T \to \infty$; if $\delta > 1$, use the total mass bound. □

For $n \ge 2$, the capacity exponent is $1 - n/(q+2)$. The threshold $q > n-2$ comes from the mixed-mass estimate in Proposition 7.1.1.

Logarithmic factors give weights at the threshold. For $n \ge 3$ and $a > 1$, put $r = n-2 > 0$ and

$$w(t) = (1+t)^{-r}[\log(\mathrm{e}+t)]^{-a}.$$

Differentiation gives

$$(1+t)^r(-w'(t)) = \frac{r}{(1+t)[\log(\mathrm{e}+t)]^a} + \frac{a}{(\mathrm{e}+t)[\log(\mathrm{e}+t)]^{a+1}}.$$

The ratios $(\mathrm{e}+t)/(1+t)$ are bounded. The substitution $y = \log(\mathrm{e}+t)$ therefore bounds the integrals of the two terms over $[T,+\infty)$ by fixed multiples of $[\log(\mathrm{e}+T)]^{1-a}$ and $[\log(\mathrm{e}+T)]^{-a}$, respectively. Since $a > 1$ and $\log(\mathrm{e}+T) \ge 1$, we obtain $B_w(T) \le C_{n,a}[\log(\mathrm{e}+T)]^{1-a}$. Hence, by Theorem 7.3.1, the damped measures $(1-u)^{-(n-2)}[\log(\mathrm{e}-u)]^{-a}\mu_u$ have uniformly bounded mass, their mass on $\{u < -T\}$ is at most a constant times $[\log(\mathrm{e}+T)]^{1-a}$, and they are continuous under convergence

in capacity. In dimensions one and two, $r_n = 0$ and $B_w(T) = w(T)$, so every weight satisfying the monotonicity, differentiability and vanishing conditions of Theorem 7.3.1 can be used.

Damping can restore convergence when every undamped measure has infinite mass. When the bounded mass property fails, take the potential U constructed in the proof of Theorem 6.6.1, whose current has integrable coefficients by Proposition 6.7.1, and normalize it by $\sup_X U = 0$. For $0 < \varepsilon < 1$, the potentials εU converge to zero in capacity as $\varepsilon \downarrow 0$: by (1.15), the capacity of $\{\varepsilon U < -\delta\}$ is at most $C\varepsilon/\delta$ for each fixed $\delta > 0$ and small ε. Consequently, for $p > 0$ and $q > r_n$,

$$e^{p\varepsilon U}\mu_{\varepsilon U} \rightharpoonup \omega^n, \qquad (1 - \varepsilon U)^{-q}\mu_{\varepsilon U} \rightharpoonup \omega^n,$$

although $\mu_{\varepsilon U}(X) = +\infty$ for every $0 < \varepsilon < 1$. The full currents also converge to ω in the coefficient L^1 norm, and their Gauduchon traces converge in total variation.

7.4 Uniform tails and undamped convergence

On deep sublevel sets the damping weight tends to zero, so convergence of the weighted measures can leave their undamped mass uncontrolled. Uniformly vanishing deep tails supply the additional control: the following condition gives a finite limit measure and weak convergence of the undamped measures μ_{u_j}. It can equivalently be expressed by an increasing integrability weight.

Theorem 7.4.1 *Let $u_j, u \in \mathrm{PSH}(X, \omega)$ be nonpositive and suppose $u_j \to u$ in capacity. Assume*

$$\lim_{T\to\infty} \sup_j \mu_{u_j}(\{u_j < -T\}) = 0.$$

Then μ_u is finite and $\mu_{u_j} \rightharpoonup \mu_u$.

Proof Choose T_0 such that every tail $\mu_{u_j}(\{u_j < -T\})$ with $T \geq T_0$ is at most one. By Lemma 7.1.1, $\mu_{u_j}(X) \leq C(1 + T_0)^{r_n} + 1$, so the tail condition already gives a uniform bound for the total masses.

With the cutoffs η_T of (7.2), the fixed-level argument in the proof of Theorem 7.3.1, applied with $w \equiv 1$, gives

$$\eta_T(-u_j)\mu_{u_j} \rightharpoonup \eta_T(-u)\mu_u \quad \text{for every fixed } T > 0.$$

The masses of the measures on the left are bounded by the uniform bound for the total masses. Since $\eta_T(-u)$ increases to one off the pole set as $T \to \infty$, monotone convergence proves $\mu_u(X) < +\infty$.

For a continuous test function $f : X \to \mathbb{R}$, the error made by inserting $\eta_T(-u_j)$ is at most $\|f\|_\infty \mu_{u_j}(\{u_j < -T\})$, which is small for large T, uniformly in j. For the limit potential, the corresponding error tends to zero because μ_u is finite and does not charge the pole set. Let first $j \to \infty$ with T fixed, and then $T \to \infty$. □

Let $\chi : [0, +\infty) \to [1, +\infty)$ be continuous, nondecreasing and unbounded. For a nonpositive potential $u \in \mathrm{PSH}(X, \omega)$ define

$$J_{\chi,\omega}(u) = \int_X \chi(-u)\, \mathrm{d}\mu_u,$$

with the value $+\infty$ allowed. Since $\chi(T) \to +\infty$, a uniform bound for this functional forces the sublevel tails to vanish uniformly.

Corollary 7.4.1 *Let $u_j, u \in \mathrm{PSH}(X, \omega)$ be nonpositive. If $u_j \to u$ in capacity and $\sup_j J_{\chi,\omega}(u_j) \le C$, then*

$$J_{\chi,\omega}(u) \le C, \qquad \mu_{u_j} \rightharpoonup \mu_u.$$

Proof Since $\chi \ge 1$, the total masses are at most C, and

$$\mu_{u_j}(\{u_j < -T\}) \le C/\chi(T).$$

Thus Theorem 7.4.1 applies. For the bound on $J_{\chi,\omega}(u)$, use (7.2) with the compactly supported continuous function $s \mapsto \chi(s)\eta_T(s)$ in place of $w\eta_T$. The corresponding weighted integrals converge for each fixed T, and they are at most C. Let $T \to \infty$ and use monotone convergence. □

Proposition 7.4.1 *For a family of nonpositive potentials in $\mathrm{PSH}(X, \omega)$, the uniform tail condition of Theorem 7.4.1 is equivalent to a uniform bound on $J_{\chi,\omega}$ for some continuous nondecreasing unbounded function $\chi \ge 1$.*

Proof One implication was proved in Corollary 7.4.1. Conversely, write the family as $(u_i)_{i\in I}$. As in the proof of Theorem 7.4.1, the tail condition and Lemma 7.1.1 give a uniform bound for the total masses. Choose numbers $T_k \to +\infty$, with $T_{k+1} > T_k + 1$, such that $\mu_{u_i}(\{-u_i > T_k\}) \le 2^{-k}$ for every $i \in I$. Let ρ_k be a continuous nondecreasing function, equal to zero on $[0, T_k]$ and to one on $[T_k + 1, +\infty)$, and define

$$\chi(s) = 1 + \sum_{k\ge 1} \rho_k(s).$$

The sum is locally finite, so χ is continuous, nondecreasing and unbounded. Tonelli's theorem gives

$$J_{\chi,\omega}(u_i) \le \mu_{u_i}(X) + \sum_{k\ge 1} \mu_{u_i}(\{-u_i > T_k\}) \le \sup_{i\in I} \mu_{u_i}(X) + 1,$$

so this weight gives a uniform integrability bound for the whole family. □

7.5 Mass concentration

The tail condition excludes mass carried by sublevel sets that disappear in the capacity limit. On a curve this mass can concentrate at a pole of the limit. When the bounded mass property fails, it can also persist along smooth potentials converging to zero.

Example 7.5.1 On $X = \mathbb{P}^1$, let z be the standard affine coordinate and let δ_0 denote the unit Dirac measure at its origin. Take the Fubini–Study form

$$\omega = \mathrm{dd^c} \log(1 + |z|^2), \qquad \int_X \omega = 1,$$

and the global nonpositive potential

$$u(z) = \log \frac{|z|^2}{1 + |z|^2}, \qquad u_j = \max(u, -j).$$

At infinity, in the coordinate $\zeta = 1/z$, the function u equals $-\log(1 + |\zeta|^2)$, so it is smooth there. The Poincaré–Lelong formula gives

$$\omega + \mathrm{dd^c} u = \delta_0, \qquad \mathrm{MA}_\omega^{\mathrm{ext}}(u) = 0.$$

The second identity holds because the extended measure discards the pole set and the current vanishes on its complement.

Each u_j is bounded and ω-plurisubharmonic. Its measure $\mu_j = \mu_{u_j} = \omega + \mathrm{dd^c} u_j$ has mass one by Stokes' theorem, and $\mu_j = 0$ on the open set $\{u > -j\}$ by locality. Hence

$$\operatorname{supp} \mu_j \subset \{u \le -j\} = \left\{ |z|^2 \le \frac{\mathrm{e}^{-j}}{1 - \mathrm{e}^{-j}} \right\}.$$

These disks shrink to the origin, so $\mu_j \rightharpoonup \delta_0$.

On their supports, $u_j = -j$. Consequently, for $j > T$,

$$\mu_j(\{u_j < -T\}) = 1, \qquad \mathrm{e}^{p u_j} \mu_j = \mathrm{e}^{-pj} \mu_j \rightharpoonup 0 \quad (p > 0).$$

Nevertheless, $u_j \to u$ in capacity. Indeed, outside any neighborhood of the origin the functions eventually agree with u, and the origin has arbitrarily small neighborhoods of arbitrarily small capacity. Thus bounded mass and capacity convergence do not prevent the undamped measures from acquiring mass at a pole of the limit. The damped limit is the extended measure of u, as predicted by Theorem 7.3.1.

We return to a general compact Hermitian manifold (X, ω).

Corollary 7.5.1 *Assume $v_+(\omega) = +\infty$ and put $V_\omega = \int_X \omega^n$. Fix a real number $b > V_\omega$ and a sequence $0 < \varepsilon_j < 1$ tending to zero. The smooth potentials w_j of Corollary 6.7.2, chosen with mass b, converge to zero in capacity. For every $T > 0$,*

$$\bigl\|\mathbf{1}_{\{w_j \geq -T\}}(\omega + \mathrm{dd^c} w_j)^n - \omega^n\bigr\|_{\mathrm{TV}} \longrightarrow 0, \qquad \int_{\{w_j < -T\}} (\omega + \mathrm{dd^c} w_j)^n \longrightarrow b - V_\omega.$$

After passage to a subsequence, there is a positive measure σ of mass $b - V_\omega$ such that

$$(\omega + \mathrm{dd^c} w_j)^n \rightharpoonup \omega^n + \sigma, \qquad \mathbf{1}_{\{w_j < -T\}}(\omega + \mathrm{dd^c} w_j)^n \rightharpoonup \sigma \quad \textit{for every } T > 0.$$

Proof The construction in Corollary 6.7.2 gives $w_j = s_j u_j$, where u_j is smooth and ω-plurisubharmonic, $\sup_X u_j = 0$ and $0 < s_j < \varepsilon_j$. The sublevel estimate (1.15) gives, for every fixed $\delta > 0$ and all sufficiently large j,

$$\mathrm{Cap}_\omega(\{|w_j| > \delta\}) = \mathrm{Cap}_\omega(\{u_j < -\delta/s_j\}) \leq C s_j/\delta \longrightarrow 0.$$

Put $\mu_j = (\omega + \mathrm{dd^c} w_j)^n$. Fix $T > 0$ and write $E_{j,T} = \{w_j \geq -T\}$. The lower bound in Corollary 6.7.2 gives

$$\mathbf{1}_{E_{j,T}} \mu_j \geq \lambda_{j,T} := (1 - \varepsilon_j)^n \mathbf{1}_{E_{j,T}} \omega^n.$$

Since $w_j \to 0$ in L^1, the smooth volume of $X \setminus E_{j,T}$ tends to zero, and hence $\lambda_{j,T} \to \omega^n$ in total variation. For every $p > 0$, Theorem 7.3.1 gives $\int_X \mathrm{e}^{p w_j}\, \mathrm{d}\mu_j \to V_\omega$, and therefore

$$\limsup_j \mu_j(E_{j,T}) \leq \mathrm{e}^{pT} \lim_j \int_X \mathrm{e}^{p w_j}\, \mathrm{d}\mu_j = \mathrm{e}^{pT} V_\omega.$$

Letting $p \downarrow 0$ and combining with the lower bound, we obtain $\mu_j(E_{j,T}) \to V_\omega$. Positivity now yields

$$\begin{aligned} \|\mathbf{1}_{E_{j,T}} \mu_j - \omega^n\|_{\mathrm{TV}} &\leq \mu_j(E_{j,T}) - \lambda_{j,T}(X) + \|\lambda_{j,T} - \omega^n\|_{\mathrm{TV}} \\ &\longrightarrow 0. \end{aligned}$$

Subtracting this shallow mass from $\mu_j(X) = b$ proves the assertion about the mass on $\{w_j < -T\}$.

The positive measures μ_j have fixed mass on the compact manifold X, so a subsequence converges weakly to a measure ν of mass b. The inequality $\mu_j \geq (1 - \varepsilon_j)^n \omega^n$ gives $\nu \geq \omega^n$. Set $\sigma = \nu - \omega^n$. For each $T > 0$, subtracting the total-variation limit of the shallow restrictions from $\mu_j \rightharpoonup \nu$ gives the last assertion along the same subsequence, for every T. □

Thus the defect σ in Corollary 7.5.1 carries the whole excess mass $b - V_\omega$, although the currents $\omega + \mathrm{dd^c} w_j$ converge to ω in the coefficient L^1 norm and their

Gauduchon traces converge in total variation. The location of σ is constrained by the limits of the intermediate powers of $\mathrm{dd^c} w_j$, as we now show.

7.5.1 Intermediate currents of a shrinking sequence

We formulate the result for a connected compact complex manifold Y of dimension $n \geq 1$ with a Hermitian form h, since it will be applied with different metrics in Chapter 8. Consider smooth functions

$$v_j = s_j u_j, \qquad u_j \in \mathrm{PSH}(Y, h), \qquad \sup_Y u_j = 0, \qquad 0 < s_j \longrightarrow 0.$$

Suppose that their Monge–Ampère masses $\int_Y (h + \mathrm{dd^c} v_j)^n$ equal a fixed number b and that

$$(h + \mathrm{dd^c} v_j)^n \rightharpoonup h^n + \sigma.$$

The lower bound $h + \mathrm{dd^c} v_j \geq (1 - s_j)h$ shows that σ is positive. Although $\mathrm{dd^c} v_j \to 0$ in the trace norm, its intermediate powers can have nonzero limits, and these limits determine σ.

Proposition 7.5.1 *After passage to a common subsequence, the positive forms*

$$H_j = \mathrm{dd^c} v_j + s_j h = s_j (h + \mathrm{dd^c} u_j)$$

satisfy $H_j^k \rightharpoonup K_k$ *for* $1 \leq k \leq n$. *The currents* K_k *are positive and closed, and* $K_1 = K_n = 0$. *For every smooth real* $(n-k, n-k)$*-form* η *with* $\mathrm{d}\eta = 0$ *or* $\mathrm{dd^c}\eta = 0$,

$$\int_Y K_k \wedge \eta = 0.$$

Moreover,

$$\sigma = \sum_{k=2}^{n-1} \binom{n}{k} h^{n-k} \wedge K_k. \tag{7.3}$$

If ϑ *is a smooth closed semipositive* $(1,1)$*-form on* Y, *then* σ *is supported on* $\{\vartheta^n = 0\}$. *In dimension three the same conclusion holds for every smooth semipositive* $(1,1)$*-form* ϑ *with* $\mathrm{dd^c}\vartheta = 0$.

Proof For $s_j < 1/2$, positivity in the expansion

$$(h + \mathrm{dd^c} v_j)^n = \sum_{k=0}^{n} \binom{n}{k} (1 - s_j)^{n-k} h^{n-k} \wedge H_j^k$$

gives a uniform bound for each $\int_Y h^{n-k} \wedge H_j^k$. In local unitary coordinates, the coefficient matrix of the smooth positive form H_j^k on exterior powers is positive semidefinite, so its entries are bounded in absolute value by its trace, up to a

dimensional constant. The trace bounds therefore bound every coefficient in total variation, and weak compactness of measures gives a common subsequence and positive limits K_k.

For $n \geq 2$, choose a Gauduchon form γ. By Proposition 4.2.1,

$$\int_Y H_j \wedge \gamma^{n-1} = s_j \int_Y h \wedge \gamma^{n-1}.$$

Since γ and h are equivalent smooth metrics, it follows that $H_j \to 0$ in coefficient total variation. For $n = 1$ the same conclusion follows from $\int_Y H_j = s_j \int_Y h$. Thus $K_1 = 0$ in all dimensions. Since $\mathrm{d}H_j = s_j \mathrm{d}h$,

$$\mathrm{d}(H_j^k) = k s_j \mathrm{d}h \wedge H_j^{k-1} \longrightarrow 0$$

as currents, because the preceding trace bounds control multiplication by the fixed smooth form $\mathrm{d}h$. Hence every K_k is closed.

The smooth form $(\mathrm{dd^c} v_j)^k$ is both d-exact and $\mathrm{dd^c}$-exact:

$$(\mathrm{dd^c} v_j)^k = \mathrm{d}\big(\mathrm{d^c} v_j \wedge (\mathrm{dd^c} v_j)^{k-1}\big) = \mathrm{dd^c}\big(v_j (\mathrm{dd^c} v_j)^{k-1}\big).$$

Its integral against either kind of test form η in the statement is therefore zero by Stokes' formula. Expanding $\mathrm{dd^c} v_j = H_j - s_j h$ gives

$$\int_Y \eta \wedge H_j^k = -\sum_{r=0}^{k-1} \binom{k}{r} (-s_j)^{k-r} \int_Y \eta \wedge h^{k-r} \wedge H_j^r = O(s_j).$$

Each integral on the right is bounded by the trace bound for H_j^r. Taking $k = n$ and $\eta = 1$ shows that the positive measures H_j^n tend to zero in total variation, which proves $K_n = 0$; the other vanishing integrals follow by weak convergence. Finally, letting $j \to \infty$ in the positive expansion above, the terms with $k = 0$ tend to h^n and those with $k = 1$ and $k = n$ vanish in the limit, which proves (7.3).

For closed semipositive ϑ, apply the vanishing integrals to $\eta = \vartheta^{n-k}$. The measure $K_k \wedge \vartheta^{n-k}$ is positive and has zero mass. On every relatively compact open set where $\vartheta > 0$, it dominates a positive multiple of the trace measure of K_k, so K_k vanishes there. The decomposition gives the asserted support. In dimension three only K_2 occurs, and the same argument applies to the $\mathrm{dd^c}$-closed test form ϑ itself. □

In dimensions at most two the decomposition forces $\sigma = 0$. A threefold carrying a pluriclosed Hermitian metric, that is, a Hermitian form ϑ with $\mathrm{dd^c}\vartheta = 0$, has no nonzero defect σ of this form either. In higher dimensions, the vanishing integrals impose necessary conditions on each intermediate current; they do not by themselves produce a smooth sequence with prescribed intermediate limits.

7.6 Damping for a smooth background

For a general smooth background θ, truncation at a constant level may fail to preserve θ-plurisubharmonicity. A larger Hermitian form makes the truncations plurisubharmonic and dominates the extended measure, and the local expansion of the θ-product gives continuity at each fixed truncation level.

Theorem 7.6.1 *Let θ be a smooth real $(1,1)$-form, and for nonpositive $u \in \mathrm{PSH}(X,\theta)$ put $\mu_{\theta,u} = \mathrm{MA}_\theta^{\mathrm{ext}}(u)$. The mass bounds, capacity estimates and capacity-continuity statements for damped measures in this chapter, including Theorem 7.3.1, hold for the measures $\mu_{\theta,u}$ in place of μ_u, with constants depending on θ and ω. In particular, for $p > 0$ and $q > r_n$,*

$$\int_X \mathrm{e}^{pu}\,\mathrm{d}\mu_{\theta,u} \le C(1+p^{-1})^{r_n}, \qquad \int_X (1-u)^{-q}\,\mathrm{d}\mu_{\theta,u} \le C_q.$$

The undamped tail criterion of Theorem 7.4.1 and the integrability criterion of Corollary 7.4.1 also hold with $\mu_{\theta,u}$ in place of μ_u.

Proof Choose $C_0 \ge 1$ such that $\theta \le \Omega := C_0\omega$. Then $u \in \mathrm{PSH}(X,\Omega)$, and Theorem 6.1.1 gives

$$0 \le \mu_{\theta,u} \le \mathrm{MA}_\Omega^{\mathrm{ext}}(u).$$

All the mass, tail and capacity bounds therefore follow from the estimates already proved for Ω. The metric comparison in Section 1.8 gives, for every Borel set $E \subset X$,

$$\mathrm{Cap}_\omega(E) \le \mathrm{Cap}_\Omega(E) \le C_0^n\,\mathrm{Cap}_\omega(E).$$

For continuity, let nonpositive $u_j, u \in \mathrm{PSH}(X,\theta)$ converge in capacity, and use (7.2) with the θ-product. The truncations are bounded and Ω-plurisubharmonic. The weighted capacity continuity of Sections 1.6 and 1.8 applies term by term to the local expansion of their signed θ-products, with the same bounded quasi-continuous coefficients. Since the cutoff vanishes at the truncation level, the result is exactly the restricted positive measure. The uniform tails obtained from the domination by $\mathrm{MA}_\Omega^{\mathrm{ext}}$ remove the cutoff. Domination also gives the sublevel estimate, so the preceding proofs of the undamped tail and integrability criteria apply without change. □

Chapter 8
Unbounded mass on Hopf manifolds

By Proposition 7.1.1, every compact complex curve or surface has the bounded mass property. The property can fail in dimension three even when the metric is Gauduchon. We prove this on a Hopf threefold, then extend the construction to every scalar Hopf manifold of dimension at least three.

The threefold mass formula provides the starting point. Its linear term vanishes for a Gauduchon metric, and for the standard Hopf metric the quadratic term is a positive multiple of the Dirichlet energy along the elliptic fibers over $\mathbb{P}^2$. We therefore seek smooth potentials with large vertical energy whose perturbed forms stay positive. A fiber heat kernel supplies the concentration. Varying its time across the base controls the mixed derivatives; a function of the base then restores positivity without changing the vertical energy. The higher-dimensional extension follows by comparing the angular densities.

We next use the fiber structure to study minimum mass, damping and weak limits. Fiber averaging identifies the bounded potentials of minimum mass. For normalized potentials invariant under unitary rotations of the last two coordinates, a positive fiber flux yields the sharp square-root damping threshold; concentration at the endpoint separates individual finiteness from uniform tails and capacity continuity. Finally, we classify the excess measures produced by shrinking smooth potentials. They are exactly the lifts of base measures by the normalized area measures on the elliptic fibers, for the standard metric and for every other Hermitian metric on this threefold.

Theorem 8.0.1 (Xia–Zhang) *The compact threefold*

$$X = (\mathbb{C}^3 \setminus \{0\})/\langle z \mapsto \mathrm{e}^{-1} z \rangle$$

admits a Gauduchon form ω and smooth real functions V_j such that

$$\omega + \mathrm{dd^c} V_j > 0, \qquad \int_X (\omega + \mathrm{dd^c} V_j)^3 \longrightarrow +\infty.$$

In particular, X does not have the bounded mass property.

8.1 The Hopf metric and its mass

The projection to $\mathbb{P}^2$ separates the horizontal and vertical parts of the metric. We normalize the fiber measure to have mass one; this fixes the constants in the mass formula.

On the covering space $\mathbb{C}^3 \setminus \{0\}$, with coordinates $z = (z_0, z_1, z_2)$, put

$$s = \log |z|^2, \qquad \alpha = \mathrm{dd^c} s, \qquad \beta = \mathrm{d}s \wedge \mathrm{d^c} s = \frac{\mathrm{i}}{2\pi} \partial s \wedge \bar{\partial} s, \qquad \omega = \alpha + \beta.$$

The contraction $z \mapsto \mathrm{e}^{-1} z$ changes s by the constant -2, so these forms descend to X. A closed spherical shell between two successive radii is a compact fundamental domain; this also proves that the quotient is compact. Let ω_{FS} be the Fubini–Study form on $\mathbb{P}^2$, given by $\mathrm{dd^c} \log(1 + |\xi|^2)$ in affine coordinates $\xi = (\xi_1, \xi_2)$. Projectivization gives a holomorphic map

$$\pi : X \longrightarrow \mathbb{P}^2, \qquad \alpha = \pi^* \omega_{\mathrm{FS}}, \qquad \int_{\mathbb{P}^2} \omega_{\mathrm{FS}}^2 = 1.$$

The form α has rank two and is positive transversally to the fibers, while the rank-one form β is positive on the vertical line. Their kernels intersect only in zero, and therefore $\omega > 0$.

We shall use the identities

$$\alpha^3 = 0, \quad \beta^2 = 0, \quad \mathrm{d}\alpha = 0, \quad \mathrm{dd^c}\beta = -\alpha^2, \quad \mathrm{dd^c}(\omega^2) = 0. \tag{8.1}$$

The first three follow from the definitions and the dimension of the base. For the fourth, differentiating $\beta = \mathrm{i}\partial s \wedge \bar{\partial} s/(2\pi)$ gives $\mathrm{dd^c}\beta = (\partial\bar{\partial} s)^2/(4\pi^2) = -\alpha^2$. Finally, $\omega^2 = \alpha^2 + 2\alpha \wedge \beta$, so $\mathrm{dd^c}(\omega^2) = -2\alpha^3 = 0$. Thus ω is Gauduchon, although $\mathrm{dd^c}\omega = -\alpha^2 \neq 0$.

On the affine base chart $U_0 = \{[z_0 : z_1 : z_2] \in \mathbb{P}^2 : z_0 \neq 0\} \simeq \mathbb{C}^2$ write

$$\xi_j = z_j/z_0 \quad (j = 1, 2), \qquad w = \log z_0.$$

The choice of logarithm and the contraction change w by elements of $\Lambda = \mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z}$. Hence

$$\pi^{-1}(U_0) \simeq U_0 \times E, \qquad E = \mathbb{C}/\Lambda, \qquad \mathrm{d}A_E = \frac{\mathrm{i}}{4\pi} \mathrm{d}w \wedge \mathrm{d}\bar{w}, \quad \int_E \mathrm{d}A_E = 1.$$

On another base chart the fiber coordinate changes by a holomorphic function of the base. Consequently, the vertical derivative ∂_w and the fiber integral below are globally defined. For a smooth function V on X, write $V_w = \partial V/\partial w$.

Proposition 8.1.1 *For every $V \in C^\infty(X, \mathbb{R})$,*

$$\int_X (\omega + \mathrm{dd^c} V)^3 = 6 + 6 \int_{\mathbb{P}^2} \left(\int_{\pi^{-1}(y)} |V_w|^2 \, \mathrm{d}A_E \right) \omega_{\mathrm{FS}}^2(y). \tag{8.2}$$

In particular, positivity of $\omega + \mathrm{dd^c} V$ is not required.

Proof Since β restricts to $2\mathrm{d}A_E$ on each fiber,

$$\int_X \omega^3 = 3 \int_X \alpha^2 \wedge \beta = 6.$$

By (2.1) and (8.1), followed by an integration by parts against the closed form α^2,

$$\begin{aligned} \int_X (\omega + \mathrm{dd^c} V)^3 - \int_X \omega^3 &= 3 \int_X V \mathrm{dd^c} \omega \wedge \mathrm{dd^c} V \\ &= -3 \int_X V \alpha^2 \wedge \mathrm{dd^c} V = 3 \int_X \mathrm{d}V \wedge \mathrm{d^c} V \wedge \alpha^2. \end{aligned}$$

Wedging with α^2 removes every component of $\mathrm{d}V \wedge \mathrm{d^c} V$ except the vertical one, which is $\mathrm{i}|V_w|^2 \mathrm{d}w \wedge \mathrm{d}\bar{w}/(2\pi) = 2|V_w|^2 \mathrm{d}A_E$. Integration over the fibers proves the formula. □

8.2 The radial–vertical block

We look for potentials that depend on the base point only through its distance from the origin of the affine chart. In a suitable frame, the matrix of $\omega + \mathrm{dd^c} V$ then consists of one tangential horizontal coefficient and a two-by-two radial–vertical block, whose Schur complement isolates the mixed derivative that must be controlled. Subscripts denote partial derivatives in the indicated variables.

For $\xi \neq 0$ introduce

$$x = \log |\xi|^2, \qquad \mu = \frac{\mathrm{e}^x}{1 + \mathrm{e}^x}, \qquad \mu_x = \mu(1 - \mu).$$

We use smooth real functions $V : \mathbb{R} \times E \to \mathbb{R}$, written $V = V(x, w)$, that are independent of x for x near $-\infty$ and constant in both variables for x near $+\infty$. These conditions allow V to be extended smoothly across $\xi = 0$, and over the complement of the affine chart by the same constant. The region of the base where V is nonconstant may depend on V.

Lemma 8.2.1 *For such a function, at $\xi \neq 0$ the inequality $\omega + \mathrm{dd^c} V > 0$ is equivalent to*

$$1 + V_{w\bar{w}} > 0, \qquad \mu + V_x > 0, \qquad Q[V] := V_{xx} + \mu - \frac{|\mu + V_{x\bar{w}}|^2}{1 + V_{w\bar{w}}} > 0. \tag{8.3}$$

At $\xi = 0$, the inequality $\omega + \mathrm{dd^c} V > 0$ is equivalent to $1 + V_{w\bar{w}} > 0$.

Proof In these coordinates,

$$s = w + \bar{w} + \log(1 + \mathrm{e}^x), \qquad \partial s = \mathrm{d}w + \mu \partial x,$$

and

$$2\pi\alpha = \mathrm{i}\mu\partial\bar{\partial}x + \mathrm{i}\mu(1-\mu)\partial x \wedge \bar{\partial}x.$$

Choose horizontal vectors of unit length for $2\pi\alpha$, one orthogonal to the radial direction and the other

$$e_r = \frac{\xi_1 \partial_{\xi_1} + \xi_2 \partial_{\xi_2}}{\sqrt{\mu(1-\mu)}}.$$

Adjoin the vertical vector ∂_w. In this frame the matrix of $2\pi(\omega + \mathrm{dd^c} V)$ is

$$\begin{pmatrix} (\mu + V_x)/\mu & 0 & 0 \\ 0 & (\mu + V_{xx})/[\mu(1-\mu)] & (\mu + V_{x\bar{w}})/\sqrt{\mu(1-\mu)} \\ 0 & (\mu + V_{wx})/\sqrt{\mu(1-\mu)} & 1 + V_{w\bar{w}} \end{pmatrix}.$$

Taking the Schur complement of the last diagonal entry gives (8.3). At $\xi = 0$, the derivatives of V in the base directions vanish and $\partial s = \mathrm{d}w$, which gives the last assertion. □

A rapid cutoff of a concentrated fiber potential can make the mixed derivative $V_{x\bar{w}}$ too large for this criterion. We therefore spread the concentration by the heat equation before cutting off, so that the fiber derivatives are already exponentially small in the cutoff region.

8.3 Heat potentials and the mixed derivative

The fiber potential will be built from the heat kernel of E. It has large vertical energy at small times and decays at large times, where it can be cut off, and a lower bound for its logarithmic Hessian controls vertical positivity. To control the radial–vertical block when the time varies, we also need an estimate relating the kernel to its logarithmic gradient.

For $t > 0$ define

$$k_t(w) = \frac{2}{t} \sum_{\lambda \in \Lambda} \exp\left(-\frac{|w - \lambda|^2}{t}\right). \tag{8.4}$$

This is a smooth positive Λ-periodic function of integral one: unfolding the integral reduces it to the Gaussian integral on $\mathbb{C}$, since $\mathrm{d}A_E = \mathrm{d}a\,\mathrm{d}b/(2\pi)$ for $w = a + \mathrm{i}b$. For $(p, q) \in \mathbb{Z}^2$ set

$$\nu_{p,q} = p + \frac{\mathrm{i}q}{2\pi}, \qquad \chi_{p,q}(w) = \mathrm{e}^{2\pi \mathrm{i} p \operatorname{Re} w + \mathrm{i} q \operatorname{Im} w}.$$

These characters form an orthonormal basis of $L^2(E, \mathrm{d}A_E)$. Computing the Fourier coefficients by the same unfolding gives

$$k_t = \sum_{p,q} \mathrm{e}^{-\pi^2 |\nu_{p,q}|^2 t} \chi_{p,q}, \qquad \partial_t k_t = \partial_w \partial_{\bar{w}} k_t. \tag{8.5}$$

All differentiated series converge locally uniformly for $t > 0$.

Lemma 8.3.1 *Let $0 < \eta < 1/10$ and define*

$$F_\eta(t, w) = -\eta \int_t^\infty (k_r(w) - 1)\,\mathrm{d}r.$$

Then F_η is smooth and real, and

$$(F_\eta)_t = (F_\eta)_{w\bar{w}} = \eta(k_t - 1), \tag{8.6}$$

$$(\log k_t)_{w\bar{w}} \geq -1/t, \tag{8.7}$$

$$\int_E |(F_\eta)_w(t, w)|^2 \mathrm{d}A_E = 2\eta^2 \log(1/t) + O(\eta^2) \quad (0 < t \leq 1). \tag{8.8}$$

The error term in (8.8) is uniform in t and η. For fixed nonnegative integers a, m there is also a uniform estimate

$$\|\partial_t^a F_\eta(t, \cdot)\|_{C^m(E)} \leq C_{a,m} \eta \mathrm{e}^{-t/4} \quad (t \geq 1). \tag{8.9}$$

Proof Integrating the nonconstant Fourier modes gives

$$F_\eta(t, w) = -\frac{\eta}{\pi^2} \sum_{(p,q) \neq (0,0)} \frac{\mathrm{e}^{-\pi^2 |\nu_{p,q}|^2 t}}{|\nu_{p,q}|^2} \chi_{p,q}(w).$$

This proves smoothness, reality and (8.6). The least nonzero value of $\pi^2 |\nu_{p,q}|^2$ is $1/4$, and any fixed number of differentiations introduces coefficients of polynomial growth in $|\nu_{p,q}|$. Factoring out $\mathrm{e}^{-t/4}$ for $t \geq 1$ therefore leaves a convergent Gaussian series, which proves (8.9).

To prove (8.7), fix a lift of w and give Λ the probability weights

$$P_\lambda = \frac{\mathrm{e}^{-|w-\lambda|^2/t}}{\sum_{\lambda'} \mathrm{e}^{-|w-\lambda'|^2/t}}.$$

Logarithmic differentiation of the Gaussian sum yields

$$t\partial_{\bar w}\log k_t = -\sum_{\lambda}(w-\lambda)P_\lambda,$$

and one more derivative gives

$$(\log k_t)_{w\bar w} = -\frac{1}{t} + \frac{1}{t^2}\left(\sum_{\lambda}|w-\lambda|^2 P_\lambda - \left|\sum_{\lambda}(w-\lambda)P_\lambda\right|^2\right).$$

The expression in parentheses is a variance and is nonnegative.

Finally, Parseval's identity gives, with $\mathcal{E}_\eta(t)$ denoting the energy in (8.8),

$$\mathcal{E}_\eta(t) = \frac{\eta^2}{\pi^2}\sum_{(p,q)\neq(0,0)}\frac{\mathrm{e}^{-2\pi^2|\nu_{p,q}|^2 t}}{|\nu_{p,q}|^2}, \qquad \mathcal{E}_\eta'(t) = -2\eta^2(k_{2t}(0)-1).$$

The Gaussian formula at the origin implies

$$k_{2t}(0) = \frac{1}{t} + O\left(t^{-1}\mathrm{e}^{-1/(4t)}\right) \quad (0<t\le 1).$$

To see this, isolate the zero lattice vector and use $\mathrm{e}^{-|\lambda|^2/(2t)} \le \mathrm{e}^{-1/(4t)}\mathrm{e}^{-|\lambda|^2/4}$ for $\lambda \neq 0$. The error term is integrable near $t=0$, and $\mathcal{E}_\eta(1) = O(\eta^2)$. Integrating the derivative between t and 1 proves (8.8). □

The Schur complement subtracts a square involving the mixed derivative. When the time parameter is allowed to vary, the heat equation produces a compensating positive square, and the following bound relating the heat kernel to its logarithmic gradient controls the region where that square is small.

Lemma 8.3.2 *For a constant $C_0 \ge 1$ depending only on E,*

$$t k_t(w) \le C_0 \exp\left(-\frac{|t\partial_{\bar w}\log k_t(w)|^2}{C_0 t}\right) \quad (0<t\le 1). \tag{8.10}$$

Proof Choose a nearest lattice point λ_0, and put $d = |w-\lambda_0|$ and $s_\lambda = |w-\lambda|^2 - d^2 \ge 0$. The distance d is bounded by the diameter of a fundamental rectangle. By the triangle inequality, $s_\lambda \ge |\lambda-\lambda_0|^2/4 - C$, and outside a fixed finite set of λ we have $s_\lambda \ge |\lambda-\lambda_0|^2/8$. Consequently,

$$\sum_{\lambda}(1+|w-\lambda|)\mathrm{e}^{-s_\lambda/t} \le C, \qquad t k_t(w) \le C\mathrm{e}^{-d^2/t}.$$

The probability formula in the previous proof gives, with $G = |t\partial_{\bar w}\log k_t|$,

$$G \le d + \sum_{\lambda\neq\lambda_0}|w-\lambda|\mathrm{e}^{-s_\lambda/t}.$$

If $d \geq 1/4$, this is at most Cd. If $d < 1/4$, the nonzero lattice distances are at least one and

$$s_\lambda \geq |\lambda - \lambda_0|(|\lambda - \lambda_0| - 2d) \geq \tfrac{1}{2}|\lambda - \lambda_0|^2.$$

Summing the resulting Gaussian bound gives $G \leq C(d + \mathrm{e}^{-c/t})$ in all cases. When $G > 2C\mathrm{e}^{-c/t}$, we have $d \geq G/(2C)$, and the bound $tk_t \leq C\mathrm{e}^{-d^2/t}$ gives (8.10). In the remaining case G^2/t is bounded, and (8.10) follows from $tk_t \leq C$ after increasing C_0. □

Lemma 8.3.3 *There is a constant C depending only on E with the following property. For $0 < \kappa < 1/(200C_0)$, $0 < \eta < 1/10$, $0 < t \leq 1$ and $1/2 \leq \mu \leq 1$, define $\sigma > 0$ and the functions h, ζ of $w \in E$ by*

$$\sigma^2 = \frac{2\kappa}{\eta} \log \frac{1}{\eta t}, \qquad h = \eta k_t, \qquad \zeta = \frac{\sigma}{\mu}\, t\partial_{\bar{w}} \log k_t.$$

Then

$$\kappa t k_t - \frac{\mu^2(1-\eta)h}{1-\eta+h}\left|\zeta - \frac{1}{1-\eta}\right|^2 \leq C\kappa \exp\left(-\frac{1}{C\sigma^2 t}\right). \tag{8.11}$$

Proof If $\sigma^2 t \geq 1/100$, the bound $tk_t \leq C_0$ gives (8.11) after enlarging C. Assume therefore that $\sigma^2 t < 1/100$. If $|\zeta - (1-\eta)^{-1}| \geq 1/4$, the subtracted expression is at least $h/[100(1+h)]$. Since $\log(1/(\eta t)) > 2$, the definition of σ gives

$$\kappa t(1+h) \leq \frac{\eta}{400} + C_0\kappa\eta < \frac{\eta}{100}.$$

Multiplication by $k_t/(1+h)$ shows that the left side of (8.11) is nonpositive.

Otherwise $|\zeta| \geq 3/4$, so

$$|t\partial_{\bar{w}} \log k_t| = \frac{\mu|\zeta|}{\sigma} \geq \frac{3}{8\sigma}.$$

Discarding the nonnegative square and applying Lemma 8.3.2 gives (8.11) in this case as well. □

8.4 Variation of the heat time

The heat time will remain small on a fixed base ball and then increase with the radial variable until the fiber potential can be cut off. We choose its rate of increase so that the negative part of the Schur complement has small integral in the radial variable. Fix κ as in Lemma 8.3.3.

All estimates below concern the limit $\eta \downarrow 0$, with κ fixed. Write

$$L = \log(1/\eta), \quad \varepsilon = \eta^{1/\eta^2}, \quad q_0 = \sqrt{\log \frac{1}{\eta\varepsilon}}, \quad a = \sqrt{\frac{\kappa}{2\eta}}.$$

Fix a smooth nondecreasing $\chi : \mathbb{R} \to [0,1]$, independent of η, equal to zero on $(-\infty, 0]$ and one on $[1, +\infty)$, with $\int_0^1 \chi = 1/2$. Define

$$q(x) = q_0 - \int_0^{ax} \chi(s)\,\mathrm{d}s, \qquad t(x) = \eta^{-1}\mathrm{e}^{-q(x)^2}. \tag{8.12}$$

Thus $t = \varepsilon$ on $x \le 0$, and $q = q_0 + 1/2 - ax$ on $x \ge a^{-1}$. Put

$$b = \frac{q_0 - 1/2}{a}, \qquad x_* = \frac{q_0 + 1/2}{a}.$$

For small η, we have $0 < a^{-1} < b < x_*$, with

$$q(b) = 1, \quad q(x_*) = 0, \quad b, x_* = O\big(\sqrt{L/\eta}\big), \quad \eta b = o(1). \tag{8.13}$$

Fix also a smooth cutoff $\vartheta : \mathbb{R} \to [0,1]$, independent of η, zero on $(-\infty, 0]$ and one on $[1, +\infty)$, and define

$$W(x, w) = \vartheta(q(x)) F_\eta(t(x), w).$$

This function equals $F_\eta(\varepsilon, w)$ for $x \le 0$ and vanishes for $x \ge x_*$. Moreover, by (8.6),

$$1 + W_{w\bar w} = 1 + \vartheta(q)\eta(k_t - 1) > 1 - \eta. \tag{8.14}$$

Lemma 8.4.1 *For the functions just constructed, let*

$$d_\eta(x) = \max_{w \in E} \max\{-Q[W](x, w), 0\}.$$

For all sufficiently small η, the function d_η is continuous, supported in $[0, b]$, and

$$\int_{\mathbb{R}} d_\eta(x)\,\mathrm{d}x = o(1), \qquad \sup_{\mathbb{R}\times E} \max\{-W_x, 0\} = o(1). \tag{8.15}$$

On $[-2, -1] \times E$, one also has $Q[W] \ge 2/27$.

Proof We first derive an exact formula for $Q[W]$ on $[0, b]$, then bound its negative part separately on $[0, a^{-1}]$ and on $[a^{-1}, b]$, integrate these bounds, and finally examine the ends of the radial line.

Step 1: the Schur complement on $[0, b]$. Write $F = F_\eta$ for the heat potential. On $[0, b]$ we have $q \ge 1$, hence $\vartheta(q) = 1$ and $W = F(t(x), w)$. Set

$$h = \eta k_t, \qquad \sigma = (\log t)_x, \qquad \zeta = \frac{\sigma t}{\mu}\partial_{\bar w} \log k_t.$$

The heat equation gives $F_t = h - \eta$, and the chain rule gives

$$W_x = \sigma t F_t, \quad W_{xx} = (\sigma_x + \sigma^2) t F_t + \sigma^2 t^2 F_{tt}, \quad W_{x\bar w} = \sigma t F_{t\bar w}.$$

Substituting these in $Q[W]$, using $h_t = h((\log k_t)_{w\bar w} + |\partial_{\bar w} \log k_t|^2)$, and completing the square, we obtain the exact identity

$$\begin{aligned} Q[W] = \sigma^2 t\{h[1 + t(\log k_t)_{w\bar w}] - \eta\} + \sigma_x t F_t + \mu(1-\mu) - \frac{\mu^2\eta}{1-\eta} \\ + \frac{\mu^2(1-\eta)h}{1-\eta+h}\left|\zeta - \frac{1}{1-\eta}\right|^2. \end{aligned} \tag{8.16}$$

By (8.7), the part $\sigma^2 t h[1 + t(\log k_t)_{w\bar w}]$ is nonnegative.

Step 2: the initial interval $[0, a^{-1}]$. Here

$$\sigma = 2aq\chi(ax), \qquad \sigma_x = -\frac{\kappa}{\eta}\chi(ax)^2 + \frac{\kappa}{\eta} q\chi'(ax).$$

Moreover $q_0 - 1/2 \le q \le q_0$ and $t \le \varepsilon e^{q_0}$, and the latter tends to zero faster than any power of η. In particular,

$$\kappa q\chi'(ax)t \le \eta, \qquad \sigma^2 t \le \eta^2.$$

At each point where $\chi(ax) > 0$, apply Lemma 8.3.3 with $\kappa\chi(ax)^2$ in place of κ; its constant is uniform in x. The positive square in (8.16) then absorbs the negative term $-\kappa\chi^2 t k_t$ coming from $\sigma_x t F_t$. The remaining part of $\sigma_x t F_t$, which involves χ', is at least $-\eta$, because $F_t \ge -\eta$. The other negative terms in (8.16) are $O(\eta)$, and so is the exponential error of Lemma 8.3.3, since $\sigma^2 t \le \eta^2$. Thus $d_\eta \le C\eta$ on this interval. At points where $\chi(ax) = 0$, the smooth nonnegative function χ has a minimum, so $\chi'(ax) = 0$ and directly

$$Q[W] = \mu - \frac{\mu^2}{1-\eta+h} > 0,$$

since $\mu \le \mu(a^{-1}) < 1 - \eta$ for small η.

Step 3: the interval $[a^{-1}, b]$. Here the formulas simplify to

$$\sigma = 2aq, \qquad \sigma_x = -\kappa/\eta, \qquad \mathrm{d}x = -\frac{\mathrm{d}q}{a} = \sqrt{\frac{\eta}{2\kappa}}\frac{\mathrm{d}t}{tq}. \tag{8.17}$$

For $t \le 1$, Lemma 8.3.3 and (8.16) give

$$d_\eta(x) \le 2\eta + 2\kappa q^2 t + C\kappa \exp\left(-\frac{\eta}{C\kappa q^2 t}\right). \tag{8.18}$$

Indeed, $-\eta\sigma^2 t = -2\kappa q^2 t$ and $\sigma_x t F_t = -\kappa t k_t + \kappa t$; these are the two terms for which the scale was chosen. When $t \ge 1$, we insert the exponential derivative estimates (8.9) directly in the definition of Q. The denominator stays above $1 - \eta$, and the chain rule gives

$$d_\eta(x) \le C\kappa q^2 t^2 e^{-t/4}. \tag{8.19}$$

The perturbing derivatives are bounded by constants times $\eta e^{-t/4}$, $\eta\sigma t e^{-t/4}$ and $\eta[(|\sigma_x| + \sigma^2)t + \sigma^2 t^2]e^{-t/4}$. Since $q, t \geq 1$ here, each is bounded by a constant times the right side of (8.19). Since $1 + W_{w\bar{w}} \geq 1 - \eta$, subtracting the two quotients gives

$$|Q[W] - Q[0]| \leq |W_{xx}| + C\big(|W_{x\bar{w}}| + |W_{x\bar{w}}|^2 + |W_{w\bar{w}}|\big).$$

The square of the mixed derivative is at most $C\kappa\eta q^2 t^2 e^{-t/2}$, so it satisfies the same bound. Since $Q[0] > 0$, this proves (8.19).

Step 4: integration of the negative part. The constant 2η and the initial interval contribute $O(\eta b) = o(1)$, by (8.13). In the small-time region, $q \geq \sqrt{L}$ and $t = \eta^{-1} e^{-q^2}$. Therefore

$$\int 2\kappa q^2 t \, dx \leq \frac{2\kappa}{a\eta} \int_{\sqrt{L}}^{\infty} q^2 e^{-q^2} \, dq \leq C\sqrt{\eta L} = o(1).$$

For the exponential term the integral is at most

$$\frac{C\kappa}{a} \int_{\sqrt{L}}^{q_0} \exp\left(-\frac{\eta^2 e^{q^2}}{C\kappa q^2}\right) dq.$$

The interval $[\sqrt{L}, 2\sqrt{L}]$ has length $O(\sqrt{L})$. For $q \geq 2\sqrt{L}$ and sufficiently small η, $\eta^2 e^{q^2}/q^2 \geq e^{q^2/4}$. The integrand on this remaining interval is bounded by $\exp(-e^{q^2/4}/(C\kappa))$, which is integrable on $[1, +\infty)$. The prefactor is $O(\sqrt{\eta})$, and the initial interval contributes $O(\sqrt{\eta L})$, so the full expression is $o(1)$. In the large-time region, (8.17) gives

$$\int d_\eta(x) \, dx \leq C\sqrt{\eta} \int_1^{1/(e\eta)} qte^{-t/4} \, dt \leq C\sqrt{\eta L} \int_1^{\infty} te^{-t/4} \, dt = o(1).$$

This proves the integral assertion on $[0, b]$.

Step 5: the radial slope. The negative part of W_x is uniformly small as well. For $t \leq 1$, we have $F_t \geq -\eta$ and $0 \leq \sigma \leq 2aq$, so

$$\max\{-W_x, 0\} \leq \sqrt{2\kappa\eta}\, t \sqrt{\log \frac{1}{\eta t}} \leq C\sqrt{\eta L}.$$

The last inequality follows because $t\sqrt{L + \log(1/t)}$ is increasing on $(0, 1]$ when $L > 1$. For $t \geq 1$ and $q \geq 1$, use $|W_x| \leq C\sqrt{\eta}\, qte^{-t/4}$ and $q \leq \sqrt{L}$.

Step 6: the ends. It remains to consider the two ends, including the cutoff region. If $b \leq x \leq x_*$, then $0 \leq q \leq 1$ and $1/(e\eta) \leq t \leq 1/\eta$. The derivatives of the cutoffs and scale have at most polynomial growth in η^{-1}. Thus (8.9) implies

$$\sup_w \big(|W_x| + |Q[W] - Q[0]|\big) \leq Ce^{-1/(5e\eta)}.$$

But $Q[0] = \mu(1-\mu) \geq \mathrm{e}^{-x_*}/4$ on this interval, and (8.13) shows that the error is $o(\mathrm{e}^{-x_*})$. Hence $Q[W] > 0$ there. For $x \geq x_*$, $W = 0$ and positivity is immediate. For $x \leq 0$, $W_x = 0$ and

$$Q[W] \geq \mu\left(1 - \frac{\mu}{1-\eta}\right) > 0,$$

since $\mu \leq 1/2$. On $[-2,-1]$, the bounds $1/9 \leq \mu \leq 3/10$ and $1-\eta \geq 9/10$ give $Q[W] \geq 2/27$. Finally, $Q[W]$ is continuous, with positive denominator, so the maximum of its negative part over the compact fiber E is continuous in x. This proves the assertions about support and continuity, and completes the proof. □

8.5 A base correction and unbounded mass

Adding a function of x alone changes $Q[W]$ by its second derivative and leaves the vertical energy unchanged. The integral bound for d_η lets us choose this second derivative larger than d_η and compensate its integral on an interval where $Q[W]$ is uniformly positive. The correction has small first derivative, so the remaining horizontal coefficient stays positive as well.

Proof (of Theorem 8.0.1) Choose a smooth function $r_\eta \geq 0$ supported in $(-1/2, b+1/2)$ with

$$r_\eta > d_\eta \text{ on } [0,b], \qquad m_\eta := \int_{\mathbb{R}} r_\eta \,\mathrm{d}x \leq \int_{\mathbb{R}} d_\eta \,\mathrm{d}x + \eta = o(1).$$

Such a majorant exists by uniform approximation of the compactly supported continuous function d_η, followed by adding a positive bump on $[0,b]$; for each fixed η the approximation error can be chosen small enough for the integral bound. Fix a smooth $\psi \geq 0$ supported in $(-2,-1)$ with integral one and set

$$g_\eta(x) = \int_{-\infty}^{x} (x-s)(r_\eta(s) - m_\eta\psi(s)) \,\mathrm{d}s, \qquad V_\eta = W + g_\eta.$$

The negative part of g_η'' lies to the left of its positive part, and their integrals agree. Consequently,

$$-m_\eta \leq g_\eta' \leq 0, \qquad g_\eta' = 0 \text{ for } x \leq -2 \text{ and for } x \geq b + 1/2.$$

Thus g_η vanishes for $x \leq -2$ and is constant for $x \geq b+1/2$, and V_η has the properties at the two ends required for smooth extension to X.

Since g_η is independent of w, the Schur complement changes by exactly its second derivative:

$$Q[V_\eta] = Q[W] + r_\eta - m_\eta\psi.$$

This is positive on $[0,b]$ because $r_\eta > d_\eta$ there. On $(-2,-1)$ it is at least $2/27 - m_\eta\|\psi\|_\infty > 0$ for small η. Elsewhere $Q[W] > 0$, $\psi = 0$ and $r_\eta \geq 0$. The vertical

coefficient remains above $1-\eta$ by (8.14). For the remaining coefficient, if $x \le -2$, both W_x and g'_η vanish; if $-2 \le x \le 0$, then $W_x = 0$ and $\mu \ge \mu(-2) > 0$, while $|g'_\eta| \le m_\eta = o(1)$; and if $x \ge 0$, then $\mu \ge 1/2$ and $W_x \ge -o(1)$. In all cases $\mu + (V_\eta)_x > 0$ for sufficiently small η. Therefore Lemma 8.2.1 gives $\omega + \mathrm{dd^c} V_\eta > 0$ on X.

On the fixed ball $B = \{|\xi|^2 < \mathrm{e}^{-3}\} \Subset U_0$, one has $V_\eta = F_\eta(\varepsilon, w)$, including at $\xi = 0$. Thus

$$\int_{\pi^{-1}(y)} |(V_\eta)_w|^2 \mathrm{d}A_E = 2\eta^2 \log(1/\varepsilon) + O(\eta^2) = 2\log(1/\eta) + O(\eta^2) \longrightarrow +\infty$$

uniformly for $y \in B$. Since $\int_B \omega_{\mathrm{FS}}^2 > 0$, the mass identity (8.2) shows that $\int_X (\omega + \mathrm{dd^c} V_\eta)^3 \to +\infty$, and the theorem follows by taking $V_j = V_{\eta_j}$ along any sequence $\eta_j \downarrow 0$. □

8.6 Higher-dimensional Hopf manifolds

The threefold mass formula locates the source of unbounded mass, but it does not by itself give a construction in higher dimension. The same heat potentials do work there: the radial–vertical block is unchanged, and each extra angular direction contributes a factor whose lower bound is uniform where the threefold mass diverges.

For $n \ge 3$, let

$$H_n = (\mathbb{C}^n \setminus \{0\})/\langle z \mapsto \mathrm{e}^{-1} z \rangle, \qquad p_n : H_n \longrightarrow \mathbb{P}^{n-1}.$$

Put $s = \log|z|^2$, $\alpha_n = \mathrm{dd^c} s = p_n^* \omega_{\mathrm{FS}}$, $\beta_n = \mathrm{d}s \wedge \mathrm{d^c} s$ and $\omega_n = \alpha_n + \beta_n$, where $\int_{\mathbb{P}^{n-1}} \omega_{\mathrm{FS}}^{n-1} = 1$. The forms descend and ω_n is positive for the same reasons as in dimension three. The fiber is the same elliptic curve E, with $\int_E \beta_n = 2$. Since α_n has rank $n-1$ and $\beta_n^2 = 0$,

$$\int_{H_n} \omega_n^n = 2n, \qquad \mathrm{dd^c}(\omega_n^{n-1}) = -(n-1)\alpha_n^n = 0.$$

Thus ω_n is Gauduchon.

On the affine chart write $\xi \in \mathbb{C}^{n-1}$, $x = \log|\xi|^2$, $w = \log z_0 \pmod{\Lambda}$ and $\mu = \mathrm{e}^x/(1+\mathrm{e}^x)$ as before. For a smooth real function $V(x,w)$ with the endpoint properties of Lemma 8.2.1, let $J_n(V;x,w)$ be the density obtained by integrating $(\omega_n + \mathrm{dd^c} V)^n$ over the angular variables, with angular probability measure. Thus

$$\int_{H_n} (\omega_n + \mathrm{dd^c} V)^n = \int_{\mathbb{R}\times E} J_n(V;x,w)\, \mathrm{d}x\, \mathrm{d}A_E.$$

The endpoints and the complement of the affine chart have zero smooth volume.

Lemma 8.6.1 *The positivity criterion* (8.3) *holds in every dimension $n \geq 3$, and*

$$J_n(V; x, w) = \frac{n(n-1)}{6}(\mu + V_x)^{n-3} J_3(V; x, w). \tag{8.20}$$

Here J_3 is evaluated for the same function V on the threefold.

Proof Choose $n-2$ horizontal angular vectors, one horizontal radial vector and the vertical vector ∂_w. In the normalization of the proof of Lemma 8.2.1, each angular entry is $A = (\mu + V_x)/\mu$, and the radial–vertical block is

$$K_V = \begin{pmatrix} (\mu + V_{xx})/[\mu(1-\mu)] & (\mu + V_{x\bar{w}})/\sqrt{\mu(1-\mu)} \\ (\mu + V_{wx})/\sqrt{\mu(1-\mu)} & 1 + V_{w\bar{w}} \end{pmatrix}.$$

This follows by differentiating $s = w + \bar{w} + \log(1 + \mathrm{e}^x)$: the radial part of $\partial\bar{\partial}x$ is zero, whereas its angular part contributes V_x/μ. The Schur complement of the last entry gives the stated positivity criterion. At $\xi = 0$ the same endpoint argument as in dimension three applies.

Set $d = n - 1$. The radial Fubini–Study probability density is $d\mu^{d-1}\mathrm{d}\mu = d\mu^d(1-\mu)\mathrm{d}x$; it follows from the polar-coordinate determinant of $\mathrm{dd^c}\log(1 + |\xi|^2)$ and its integral is one. The background block K_0 has determinant one. Using the fiber mass two, therefore,

$$J_n(V) = 2nd\mu^d(1-\mu)A^{n-2}\det K_V.$$

For $n = 3$ this is $12\mu^2(1-\mu)A\det K_V$. Comparing the two expressions proves (8.20). □

Theorem 8.6.1 *For every $n \geq 3$, the Gauduchon metric ω_n admits smooth potentials V_η with $\omega_n + \mathrm{dd^c}V_\eta > 0$ whose total Monge–Ampère masses tend to infinity as $\eta \downarrow 0$.*

Proof Use exactly the functions $V_\eta = W + g_\eta$ constructed in the proof of Theorem 8.0.1, including the heat scale $\varepsilon = \eta^{1/\eta^2}$. Their endpoint properties give smooth potentials on every H_n, and Lemma 8.6.1 gives strict positivity. The slope bounds in Lemma 8.4.1 and $-m_\eta \leq g'_\eta \leq 0$ imply

$$\mu + (V_\eta)_x \geq \tfrac{1}{4} \qquad (x \geq 0)$$

for all sufficiently small η.

We must first localize the divergent threefold mass to this region. On $x < 0$, the heat potential is $W = F_\eta(\varepsilon, w)$ and has no x derivatives. The determinant formula in the preceding proof and $\int_E F_{w\bar{w}}\,\mathrm{d}A_E = 0$ give

$$\int_E J_3(V_\eta; x, w)\,\mathrm{d}A_E = 12(\mu + g'_\eta)\big(g''_\eta + \mu(1-\mu)\big).$$

Here $0 < \mu + g'_\eta \leq \mu$, and $g''_\eta = r_\eta - m_\eta\psi$ with $\int r_\eta = m_\eta$ and $\int \psi = 1$. Hence

$$\int_{x<0} J_3(V_\eta)\,\mathrm{d}x\,\mathrm{d}A_E \le 12\int_{-\infty}^{0}\mu^2(1-\mu)\,\mathrm{d}x + 12\int_{\mathbb{R}}|g_\eta''|\,\mathrm{d}x \le \tfrac{3}{2} + 24m_\eta.$$

No bound on the amplitude of the fiber Hessian is required; its mean has been integrated exactly. Since the total threefold mass tends to infinity, its mass on $x \ge 0$ tends to infinity. The dimensional comparison now gives

$$\int_{H_n}(\omega_n + \mathrm{dd^c}V_\eta)^n \ge \frac{n(n-1)}{6}\,4^{-(n-3)}\int_{x\ge 0} J_3(V_\eta)\,\mathrm{d}x\,\mathrm{d}A_E \longrightarrow +\infty.$$

Corollary 8.6.1 *Every Hermitian metric on H_n, $n \ge 3$, fails the bounded mass property.*

Proof For a Hermitian form h, compactness gives $h \ge c\omega_n$ for some $c > 0$. The potentials cV_η satisfy $h + \mathrm{dd^c}(cV_\eta) \ge c(\omega_n + \mathrm{dd^c}V_\eta) > 0$, and positivity of determinants bounds their masses below by c^n times the divergent masses in Theorem 8.6.1. □

8.7 Minimum mass and fiber averaging

We return to the threefold $X = H_3$ and its form ω.

Averaging along the elliptic fibers removes the variation measured by (8.2). The Poincaré inequality on the fibers bounds the distance from a potential to its average by the excess mass. Bounded regularization preserves this inequality, which therefore identifies all bounded potentials of minimal mass and shows that potentials of almost minimal mass are close to them.

Let E act on X by scalar multiplication: $\tau_a[z] = [\mathrm{e}^a z]$ for $a \in E$. The action preserves α, β and ω, and $\mathrm{d}A_E$ is the Haar probability measure of E. For a bounded Borel function $u : X \to \mathbb{R}$, set

$$\mathrm{d}\nu = \frac{\omega^3}{6} = \frac{1}{2}\alpha^2 \wedge \beta, \qquad Au(p) = \int_E u(\tau_a(p))\,\mathrm{d}A_E(a) \quad (p \in X).$$

Thus Au is constant on each fiber, and ν is the probability measure whose disintegration along π has fiber measures $\mathrm{d}A_E$ and base measure ω_{FS}^2.

Proposition 8.7.1 *For every $u \in \mathrm{PSH}(X,\omega)\cap L^\infty(X)$, the average Au is the pullback of a bounded ω_{FS}-plurisubharmonic function on $\mathbb{P}^2$, and*

$$\|u - Au\|^2_{L^2(X,\nu)} \le \frac{2}{3}\left(\int_X(\omega + \mathrm{dd^c}u)^3 - 6\right). \tag{8.21}$$

The coefficient $2/3$ is optimal, even for smooth u with $\omega + \mathrm{dd^c}u > 0$. Moreover,

$$\int_X(\omega + \mathrm{dd^c}u)^3 = 6 \quad\Longleftrightarrow\quad u = \pi^*v \quad \text{for some } v \in \mathrm{PSH}(\mathbb{P}^2,\omega_{\mathrm{FS}})\cap L^\infty(\mathbb{P}^2).$$

Proof First suppose that u is smooth and $\omega + \mathrm{dd}^{\mathrm{c}} u > 0$. Averaging the positive forms $\tau_a^*(\omega + \mathrm{dd}^{\mathrm{c}} u)$ gives $\omega + \mathrm{dd}^{\mathrm{c}} Au > 0$. Since Au is smooth and constant on the fibers, $Au = \pi^* v$ for a smooth function v on $\mathbb{P}^2$. At each point, the kernel of ∂s maps isomorphically onto the tangent space of the base, and β vanishes on it. Restricting $\omega + \mathrm{dd}^{\mathrm{c}} Au = \pi^*(\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}} v) + \beta$ to this kernel therefore shows that $\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}} v > 0$.

For a smooth function $f : E \to \mathbb{R}$, the nonconstant Fourier characters in (8.5), indexed by $(p, q) \in \mathbb{Z}^2 \setminus \{(0, 0)\}$, have eigenvalues $\pi^2 p^2 + q^2/4 \geq 1/4$ for $-\partial_w \partial_{\bar{w}}$. Parseval's identity therefore gives

$$\int_E \left| f - \int_E f \, \mathrm{d}A_E \right|^2 \mathrm{d}A_E \leq 4 \int_E |f_w|^2 \, \mathrm{d}A_E .$$

Applying this inequality on every fiber, integrating against ω_{FS}^2 and using the mass identity (8.2), we obtain (8.21).

For bounded u, choose uniformly bounded smooth functions $u_j \downarrow u$ with $\omega + \mathrm{dd}^{\mathrm{c}} u_j > 0$ by Theorem 1.11.1. Their averages decrease pointwise to Au by dominated convergence. The corresponding smooth base potentials v_j decrease to a bounded ω_{FS}-plurisubharmonic function v, so $Au = \pi^* v$. Dominated convergence gives $u_j \to u$ and $Au_j \to Au$ in $L^2(X, \nu)$, while bounded Bedford–Taylor continuity gives convergence of the total masses. Thus (8.21) passes to u.

If the mass is 6, the inequality gives $u = Au$ almost everywhere. Since both functions are bounded and quasi-plurisubharmonic, Lemma 1.3.4 gives equality everywhere. Conversely, if $u = \pi^* v$ with bounded $v \in \mathrm{PSH}(\mathbb{P}^2, \omega_{\mathrm{FS}})$, choose smooth $v_j \downarrow v$ with $\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}} v_j > 0$ by Theorem 1.11.1. The pullbacks decrease to u and are uniformly bounded. They are strictly ω-plurisubharmonic because the base forms are positive and β is positive on the vertical line. Their vertical derivatives vanish, so (8.2) gives mass 6 for each of them. Bounded Bedford–Taylor continuity gives the same mass for u.

It remains to prove that the constant $2/3$ is optimal. Choose a nonzero real $\rho \in C_c^\infty(U_0)$. For $\delta \in \mathbb{R}$, the function

$$u(\xi, w) = \delta \rho(\xi) \cos(\mathrm{Im}\, w)$$

extends by zero to a smooth function on X. For sufficiently small nonzero real δ, it satisfies $\omega + \mathrm{dd}^{\mathrm{c}} u > 0$. Its fiber average is zero, and its only fiber frequencies are $(p, q) = (0, \pm 1)$, with eigenvalue $1/4$. Hence equality holds in the fiber inequality, and therefore in (8.21), with nonzero left-hand side. No smaller coefficient can hold. □

Corollary 8.7.1 *The Hopf metric satisfies*

$$v_-(\omega) = 6, \qquad v_+(\omega) = +\infty .$$

Proof The lower bound $v_-(\omega) \geq 6$ follows from (8.21), and it is attained by constants. Theorem 8.0.1 gives $v_+(\omega) = +\infty$. □

In particular, for any sequence of bounded potentials whose masses tend to 6, the differences from their fiber averages tend to zero in $L^2(X, \nu)$. This controls only

the variation along the fibers; the averaged potentials can still be arbitrary bounded potentials on the base.

For nonpositive $u \in \mathrm{PSH}(X, \omega)$ on this threefold, Theorem 7.3.1 gives finite damped measures for the weight $(1-u)^{-1}[\log(\mathrm{e}-u)]^{-a}$, $a > 1$, at the threshold $r_3 = 1$, with uniform tails and capacity continuity. The optimal damping rate for all normalized potentials on this threefold remains open. Under unitary rotations of the last two coordinates, Theorem 8.8.3 gives the exact square-root threshold.

8.8 Sharp damping under unitary rotations

The general damping estimate controls mass by the depth of a potential. On the standard Hopf threefold, unitary symmetry gives a stronger estimate: after integration along the elliptic fibers, a positive radial flux has total mass one. A semiconvexity estimate bounds the remaining radial coefficient by the square root of the depth. The resulting damping threshold is sharp, and at its endpoint finite measures can still concentrate on a pole divisor.

We retain the standard threefold X, form ω, projection $\pi : X \to \mathbb{P}^2$, fiber E and probability area $\mathrm{d}A_E$ of this chapter. Let $\mathcal{R}$ be the class of $u \in \mathrm{PSH}(X, \omega)$ with $\sup_X u = 0$ invariant under

$$(z_0, z') \longmapsto (z_0, Az'), \qquad A \in U(2), \quad z' = (z_1, z_2).$$

This holomorphic action preserves ω. The class includes bounded and unbounded potentials. For a positive C^1 nonincreasing function $W : [0, +\infty) \to (0, +\infty)$ tending to zero, write

$$\mu_u = \mathrm{MA}_\omega^{\mathrm{ext}}(u), \qquad \nu_{W,u} = W(-u)\mu_u,$$
$$Q_T(W) = \sup_{t \geq T} (1 + \sqrt{2t})W(t), \qquad Q(W) = Q_0(W).$$

The weighted measure gives zero mass to the pole set, as does the extended nonpluripolar measure. Capacity always means Cap_ω of Section 1.8.

8.8.1 Positive fiber flux

Let V be a smooth invariant ω-plurisubharmonic function with $V \leq 0$. In the affine chart it has the form $V(x, w)$. The matrix calculation in the proof of Lemma 8.2.1 applies at every finite x, without assuming the special endpoint behavior of the heat family. Put

$$A_V = \mu + V_x, \qquad B_V = 1 + V_{w\bar{w}}, \qquad R_V = \mu + V_{xx},$$
$$C_V = \mu + V_{x\bar{w}}, \qquad \Delta_V = B_V R_V - |C_V|^2.$$

Let $\mathrm{d}\Omega$ be probability angular area in $\mathbb{C}^2$. The radial Fubini–Study measure is $2\mu^2(1-\mu)\,\mathrm{d}x\,\mathrm{d}\Omega$, and $\omega^3 = 6\omega_{\mathrm{FS}}^2 \mathrm{d}A_E$. Semipositivity gives $A_V, B_V, R_V, \Delta_V \geq 0$ and, without dividing by B_V,

$$\mathrm{MA}_\omega(V) = 12 A_V \Delta_V \,\mathrm{d}x\,\mathrm{d}\Omega\,\mathrm{d}A_E. \tag{8.22}$$

The complement of these radial coordinates has zero mass for a smooth top form.

Lemma 8.8.1 *For every smooth invariant ω-plurisubharmonic function,*

$$\int_{\mathbb{R}\times E} \Delta_V \,\mathrm{d}x\,\mathrm{d}A_E = 1.$$

If in addition $V \leq 0$, then

$$|V_x|^2 \leq -2V, \qquad 0 \leq A_V \leq 1 + \sqrt{-2V}.$$

Proof Set $m(x) = \int_E V\,\mathrm{d}A_E$ and $e(x) = \int_E |V_w|^2\,\mathrm{d}A_E$. Periodic integration by parts gives

$$\int_E V_{w\bar{w}} V_{xx}\,\mathrm{d}A_E = -\operatorname{Re}\int_E V_{\bar{w}} V_{xxw}\,\mathrm{d}A_E,$$
$$e'' = 2\int_E |V_{xw}|^2\,\mathrm{d}A_E + 2\operatorname{Re}\int_E V_{\bar{w}} V_{xxw}\,\mathrm{d}A_E.$$

The mean of every fiber derivative vanishes. Expanding Δ_V yields

$$\int_E \Delta_V\,\mathrm{d}A_E = m'' + \mu(1-\mu) - \tfrac{1}{2}e''.$$

Thus $f(x) = \log(1+\mathrm{e}^x) + m(x) - e(x)/2$ is convex.

Both m and e are smooth global functions on the projective base: local fiber coordinates change by holomorphic translations, preserving fiber Haar area, the vertical derivative and the Dirichlet integral. They are $U(2)$-invariant. Smoothness and radial invariance at $\xi = 0$ give $m', e' \to 0$ at the negative end. At the positive end use a normal coordinate z_0/z_1 to the hyperplane $\{z_0 = 0\}$ on the base. The invariant base functions are constant along this hyperplane and smooth across it; their x derivatives tend to zero. This does not require that the pointwise potential be constant on its elliptic fibers at that end. Consequently $f'(-\infty) = 0$ and $f'(+\infty) = 1$. Integrating the nonnegative f'' proves the flux identity.

For each fixed w, $R_V \geq 0$ implies $V_{xx} \geq -1$ on all of $\mathbb{R}$. Hence for every real h,

$$V(x+h, w) \geq V(x, w) + hV_x(x, w) - h^2/2.$$

Taking $h = V_x(x, w)$ and using $V \le 0$ proves the derivative bound. Finally $\mu \le 1$ proves the bound for A_V. □

Combining the positive density with Lemma 8.8.1 proves

$$\int_X W(-V)\mathrm{MA}_\omega(V) \le 12Q(W), \qquad \int_{\{-V>T\}} W(-V)\mathrm{MA}_\omega(V) \le 12Q_T(W). \tag{8.23}$$

The positive flux supplies the reference integral even though the unweighted Monge–Ampère masses are unbounded.

Lemma 8.8.2 *Every bounded invariant ω-plurisubharmonic function u, with $-L \le u \le 0$, admits smooth invariant ω-plurisubharmonic approximants with the same bounds converging to u in capacity.*

Proof The compact group $G = U(3) \times (\mathbb{R}/\mathbb{Z})$ acts transitively and holomorphically on X by unitary transformations and positive scalar multiplication. It preserves ω. Choose a nonnegative smooth central approximate identity ρ_ϵ on G, supported near its identity, and put

$$u_\epsilon(p) = \int_G u(gp)\rho_\epsilon(g)\,\mathrm{d}g.$$

Convolution on a compact homogeneous space is smooth. Averaging preserves the current inequality and the bounds, and centrality makes convolution commute with the $U(2)$ action. Transporting the bounded tests defining capacity shows that Cap_ω is G-invariant.

Suppose $L > 0$. By quasi-continuity, choose an open set O of arbitrarily small capacity such that u is continuous on $X \setminus O$. When g is sufficiently close to the identity, $u(gp)$ and $u(p)$ are uniformly close whenever both points lie outside O. Thus, outside O and for small kernel support,

$$\{|u_\epsilon - u| > \delta\} \subset \{P_\epsilon \mathbf{1}_O > \delta/(4L)\}, \qquad P_\epsilon \mathbf{1}_O(p) = \int_G \mathbf{1}_O(gp)\rho_\epsilon(g)\,\mathrm{d}g.$$

Markov's inequality, followed by capacity invariance, gives

$$\begin{aligned}\mathrm{Cap}_\omega\{P_\epsilon \mathbf{1}_O > \delta/(4L)\} &\le \frac{4L}{\delta} \sup_{0\le v\le 1} \int_X P_\epsilon \mathbf{1}_O\,(\omega + \mathrm{dd^c} v)^3 \\ &\le \frac{4L}{\delta}\,\mathrm{Cap}_\omega(O),\end{aligned}$$

where the supremum runs over $v \in \mathrm{PSH}(X, \omega)$. Letting the capacity of O tend to zero proves the claim. If $L = 0$, $u = 0$ and no approximation is needed. □

Proposition 8.8.1 *For every $u \in \mathcal{R}$ and $T \geq 0$,*

$$\nu_{W,u}(X) \leq 12Q(W), \qquad \nu_{W,u}(\{-u > T\}) \leq 12Q_T(W). \tag{8.24}$$

If $\sqrt{t}\,W(t) \to 0$, the family $\{\nu_{W,u} : u \in \mathcal{R}\}$ is uniformly absolutely continuous with respect to capacity, and $u \mapsto \nu_{W,u}$ is continuous from convergence in capacity to weak convergence of finite measures.

Proof For bounded $u \leq 0$, apply Lemma 8.8.2. The bounded capacity continuity of products and quasi-continuous coefficients in Sections 1.6 and 1.8 passes the total estimate (8.23) to u. For the tail at $T > 0$, use continuous depth cutoffs majorizing $\mathbf{1}_{\{-u>T\}}$ and supported in $\{-u > T - \delta\}$, where $0 < \delta < T$. The same product continuity gives a bound by $12Q_{T-\delta}(W)$. Continuity of $(1 + \sqrt{2t})W(t)$ gives $Q_{T-\delta}(W) \to Q_T(W)$. For $T = 0$, use the total estimate.

For unbounded u, the canonical truncations $u^K = \max(u, -K)$ remain bounded and invariant. On $\{u > -K\}$ their measures agree with the finite-level restrictions defining μ_u. These restrictions increase to μ_u, so monotone convergence proves (8.24).

Splitting at depth T and rescaling u^T into a capacity test gives, for every Borel set B,

$$\nu_{W,u}(B) \leq W(0)(1+T)^3\,\mathrm{Cap}_\omega(B) + 12Q_T(W). \tag{8.25}$$

Indeed $\omega + \mathrm{dd^c}u^T \leq (1+T)(\omega + \mathrm{dd^c}(u^T/(1+T)))$, and the latter potential has range of length at most one. If $\sqrt{t}\,W(t) \to 0$, then $Q_T(W) \to 0$. Taking first T large and then the capacity small proves uniform absolute continuity.

Suppose $u_j \to u$ in capacity in $\mathcal{R}$. For fixed K, the truncations u_j^K converge in capacity to u^K, and their weighted bounded products converge weakly. Outside $\{u \leq -K\}$, locality identifies ν_{W,u^K} with $\nu_{W,u}$. Both measures give this exceptional set mass at most $12Q_{K-1}(W)$ when $K > 1$, by their tail estimates; this also includes any truncation mass on $\{u = -K\}$. Hence

$$\|\nu_{W,u^K} - \nu_{W,u}\|_{\mathrm{TV}} \leq 24Q_{K-1}(W)$$

uniformly over $u \in \mathcal{R}$. Letting $K \to +\infty$ removes the truncations and proves the claimed continuity. □

8.8.2 Heat concentration at large depth

The flux estimate suggests the depth scale at which a counterexample must place its mass. A faster initial heat time than in the unbounded-mass construction gives mass of order η^{-1} at depth of order η^{-2}. Its integrated radial defect remains small after a fixed parameter is chosen, but no longer tends to zero. We therefore need a correction with a small fixed total slope.

We use the heat kernel k_t of (8.4) and its potential F_η of Lemma 8.3.1. The following value estimates complement the derivative bounds already proved.

Lemma 8.8.3 *Uniformly in η and w, $F_\eta(t,w) \le C\eta$ for $t > 0$, and $F_\eta(t,w) \ge -2\eta\log(1/t) - C\eta$ for $0 < t \le 1$. Uniformly on $\sqrt{t} \le |w| \le 2\sqrt{t}$ near the origin of E, as $t \to 0$,*

$$\begin{aligned} F_\eta(t,w) &= 2\eta\log t + O(\eta),\\ tk_t(w) &= 2\mathrm{e}^{-|w|^2/t} + O(\mathrm{e}^{-1/(Ct)}),\\ t\partial_{\bar w}\log k_t(w) &= -w + O(\mathrm{e}^{-1/(Ct)}). \end{aligned}$$

Proof For the upper bound use $k_r \ge 0$ on $(0,1]$ and (8.9). The nonnegative Fourier coefficients imply $k_r(w) \le k_r(0)$, and Gaussian summation gives $k_r(0) \le 2/r + Cr^{-1}\mathrm{e}^{-1/(2r)}$ for $r \le 1$. Its integrable error proves the lower bound. On the indicated annulus the nonzero-lattice terms and their derivatives are exponentially small relative to the zero-lattice term, proving the last two identities. For the first, split the defining integral at a fixed small r_0. On $[t, r_0]$ the nonzero-lattice contributions have bounded integral, and the difference between $(2/r)\mathrm{e}^{-|w|^2/r}$ and $2/r$ has integral at most $2|w|^2/t \le 8$. The remaining integral is uniformly bounded. □

Theorem 8.8.1 *There are $A, B, D, \eta_0 > 0$ such that for every $0 < \eta < \eta_0$ there exist $u_\eta \in C^\infty(X,\mathbb{R}) \cap \mathcal{R}$ and a measurable $K_\eta \subset X$ satisfying*

$$\sup_X u_\eta = 0, \qquad \omega + \mathrm{dd^c} u_\eta > 0, \qquad 0 \le -u_\eta \le B\eta^{-2} \quad \text{on } X,$$

$$A\eta^{-2} \le -u_\eta \le B\eta^{-2} \quad \text{on } K_\eta, \qquad \int_{K_\eta} (\omega + \mathrm{dd^c} u_\eta)^3 \ge D\eta^{-1}.$$

Proof Fix κ as in Lemma 8.3.3, also with $\kappa < 1/100$. Choose a small fixed $c > 0$ later and set

$$\varepsilon = \mathrm{e}^{-c\eta^{-3}}, \qquad q_0 = \sqrt{c\eta^{-3} + \log(1/\eta)}, \qquad a = \sqrt{\kappa/(2\eta)},$$

$$q(x) = q_0 - \int_0^{ax} \chi(s)\,\mathrm{d}s, \qquad t(x) = \eta^{-1}\mathrm{e}^{-q(x)^2},$$

$$b = (q_0 - 1/2)/a, \qquad x_* = (q_0 + 1/2)/a, \qquad Z_\eta(x,w) = \vartheta(q(x))F_\eta(t(x),w).$$

Use the cutoffs χ and ϑ from the earlier heat-time construction. Then $Z_\eta = F_\eta(\varepsilon,\cdot)$ for $x \le 0$, $Z_\eta = 0$ for $x \ge x_*$, and

$$\eta b, \eta x_* \longrightarrow \ell := \sqrt{2c/\kappa}, \qquad 1 + (Z_\eta)_{w\bar w} > 1 - \eta.$$

The larger value of q_0 changes the integrated positivity defect; we estimate it at this scale. Write $r_- = \max(-r, 0)$ for the negative part of a real number r.

On $[0,b]$ we have $\vartheta = 1$. Write $F = F_\eta$ and put $\sigma = (\log t)_x$, $h = \eta k_t$ and $\zeta = \sigma t\partial_{\bar w}\log k_t/\mu$. The identity (8.16) applies to Z_η on this interval. The contribution involving $h[1 + t(\log k_t)_{w\bar w}]$ is nonnegative. On $[0, a^{-1}]$,

$$\sigma = 2aq\chi(ax), \quad \sigma_x = -\frac{\kappa}{\eta}\chi(ax)^2 + \frac{\kappa}{\eta}q\chi'(ax), \quad t \le \varepsilon\mathrm{e}^{q_0}.$$

This upper bound for t is smaller than every power of η. Thus $\kappa q\chi' t \le \eta$ and $\sigma^2 t \le \eta^2$. Use (8.11) with $\kappa\chi^2$ where $\chi > 0$, and $F_t \ge -\eta$ for the χ' term. It follows that $[Q[Z_\eta]]_- \le C\eta$. Where $\chi = 0$ also $\chi' = 0$, and $Q[Z_\eta] = \mu - \mu^2/(1-\eta+h) > 0$, since $x \le a^{-1} = o(1)$.

On $[a^{-1}, b]$, $\sigma = 2aq$, $\sigma_x = -\kappa/\eta$, $\mathrm{d}x = -\mathrm{d}q/a$. For $t \le 1$, (8.16) and (8.11) give

$$[Q[Z_\eta]]_- \le 2\eta + 2\kappa q^2 t + C\kappa \exp\left(-\frac{\eta}{C\kappa q^2 t}\right).$$

For $t \ge 1$, (8.9) gives instead $[Q[Z_\eta]]_- \le C\kappa q^2 t^2 \mathrm{e}^{-t/4}$. Put $L = \log(1/\eta)$. Integrating the $q^2 t$ term uses $\int_{\sqrt{L}}^\infty q^2 \mathrm{e}^{-q^2}\,\mathrm{d}q \le C\sqrt{L}\eta$. For the exponential term split at $2\sqrt{L}$: the initial interval has length $O(\sqrt{L})$, and on the rest $\eta^2 \mathrm{e}^{q^2}/q^2 \ge \mathrm{e}^{q^2/4}$ for small η. Its remaining integral is uniformly bounded even with upper endpoint infinity. For large time use $\mathrm{d}x = \sqrt{\eta/(2\kappa)}\,\mathrm{d}t/(tq)$, $q \le \sqrt{L}$, and the integrability of $t\mathrm{e}^{-t/4}$. Including the constant term and initial interval yields

$$\int_0^b \max_{w\in E} [Q[Z_\eta](x,w)]_-\,\mathrm{d}x \le C\eta b + C\sqrt{\eta L} \le C\ell + o(1). \tag{8.26}$$

All constants here are independent of q_0, c, η with fixed κ. The bound is small after choosing c, although it need not tend to zero.

Also $\sup[(Z_\eta)_x]_- = O(\sqrt{\eta L})$: for $t \le 1$ use $F_t \ge -\eta$ and $t\sqrt{L + \log(1/t)} \le \sqrt{L}$; for $t \ge 1$ use (8.9). On $[b, x_*]$, $0 \le q \le 1$ and $(\mathrm{e}\eta)^{-1} \le t \le \eta^{-1}$, so differentiated cutoffs and (8.9) give

$$\sup_w \big(|(Z_\eta)_x| + |Q[Z_\eta] - Q[0]|\big) \le C\mathrm{e}^{-1/(5\mathrm{e}\eta)}.$$

Choose c so that $\ell < 1/(10\mathrm{e})$. Since $Q[0] = \mu(1-\mu) \ge \mathrm{e}^{-x_*}/4$ here, this implies $Q[Z_\eta] > 0$ on the cutoff interval. For $x \le 0$ use $Q[Z_\eta] \ge \mu(1 - \mu/(1-\eta)) > 0$, and for $x \ge x_*$ use $Z_\eta = 0$. On $[-2, -1]$ the same formula gives $Q[Z_\eta] \ge 2/27$.

The continuous defect $d_\eta(x) = \max_w [Q[Z_\eta]]_-$ is therefore supported in $[0, b]$. Choose a smooth nonnegative r_η, supported in $(-1/2, b + 1/2)$, with $r_\eta > d_\eta$ on $[0, b]$ and $m_\eta := \int r_\eta \le \int d_\eta + \eta$. Uniform approximation and a positive bump give this choice for each fixed η; no uniform derivative bound is needed. Fix a smooth probability bump ψ supported in $(-2, -1)$ and put

$$g_\eta(x) = \int_{-\infty}^x (x - s)(r_\eta(s) - m_\eta\psi(s))\,\mathrm{d}s, \qquad V_\eta = Z_\eta + g_\eta.$$

The support order implies $-m_\eta \le g_\eta' \le 0$; $g_\eta = 0$ at the negative end and is constant at the positive end. Furthermore $g_\eta \le 0$ and $|g_\eta| \le m_\eta(b+3) = O_c(\eta^{-1})$. Shrink the fixed c so that (8.26) ensures

$$m_\eta < \min\{\mu(-2)/2,\ 1/8,\ 1/(27\|\psi\|_\infty)\}$$

for all sufficiently small η. Now $Q[V_\eta] = Q[Z_\eta] + r_\eta - m_\eta\psi > 0$ everywhere: use the majorant on $[0, b]$, the margin $2/27$ on $(-2, -1)$, and the established positivity elsewhere. The vertical coefficient is above $1 - \eta$. For the horizontal coefficient, derivatives vanish for $x \le -2$; on $[-2, 0]$ use $\mu \ge \mu(-2) > m_\eta$; on $[0, \infty)$ use $\mu \ge 1/2$ and $(Z_\eta)_x \ge -o(1)$. Thus (8.3) gives a smooth globally strictly positive potential.

On $x < -3$, $V_\eta = F_\eta(\varepsilon, \cdot)$ has fiber mean zero, so $0 \le \sup_X V_\eta \le C\eta$ by Lemma 8.8.3 and $g_\eta \le 0$. Set $u_\eta = V_\eta - \sup_X V_\eta$. Where the cutoff is nonzero $t \ge \varepsilon$, giving

$$0 \le -u_\eta \le 2c\eta^{-2} + O_c(\eta^{-1}) + O(\eta). \tag{8.27}$$

Multiplication by a cutoff between zero and one preserves this lower bound for Z_η, including where F_η is positive.

Mass and depth on the concentration region. Let K_η consist of all radial angular directions and

$$q_0/2 \le q(x) \le 3q_0/4, \qquad \sqrt{t(x)} \le |w| \le 2\sqrt{t(x)},$$

using the small lift near zero in E. This lies in the linear transport region, with $\vartheta = 1$, $x \asymp_c \eta^{-1} \to \infty$, $\sigma = 2aq \asymp_c \eta^{-2}$, and superexponentially small t. Lemma 8.8.3 gives, uniformly,

$$0 < c_1 \le tk_t \le 3, \quad h \to \infty, \quad \zeta \to 0, \quad \eta\sigma^2 t \to 0, \quad \mu \to 1.$$

In (8.16) the first h contribution is nonnegative, $\sigma_x t F_t = -\kappa t(k_t - 1) \ge -3\kappa$, and the completed square tends to one. Its other negative terms tend to zero. Thus $Q[Z_\eta] \ge 1/4$ for small η. On the core $\psi = 0$ and $g_\eta'' = r_\eta \ge 0$, so $Q[V_\eta] \ge 1/4$. Also

$$\mu + (V_\eta)_x \ge c_2\eta\sigma, \qquad 1 + (V_\eta)_{w\bar w} \ge c_1\eta/t.$$

Indeed $(Z_\eta)_x = \eta\sigma(tk_t - t)$ and $\mu + g_\eta' > 0$ here; the vertical inequality follows from $1 - \eta + \eta k_t$.

In (8.22), $\Delta_{V_\eta} = (1 + (V_\eta)_{w\bar w})Q[V_\eta]$. The fiber annulus has area $3t/2$. Integrating the preceding lower bounds and using $\sigma\,\mathrm{d}x = -2q\,\mathrm{d}q$ yields

$$\int_{K_\eta} (\omega + \mathrm{dd^c} u_\eta)^3 \ge c_3\eta^2 \int_{q_0/2}^{3q_0/4} 2q\,\mathrm{d}q = c_4\eta^2 q_0^2 \ge c_5\eta^{-1}.$$

The annular value estimate also gives

$$-u_\eta = 2\eta q^2 + O_c(\eta^{-1}) + O(\eta\log(1/\eta)).$$

As $\eta q_0^2 = c\eta^{-2} + \eta\log(1/\eta)$, this is bounded above and below by fixed positive multiples of η^{-2} on the core. Together with (8.27), this proves the asserted mass and depth bounds. All these potentials are bounded: truncations beyond their individual depth equal them everywhere, so the defining extended product equals (8.22).

Corollary 8.8.1 *Let $W : [0,\infty) \to (0,\infty)$ be nonincreasing. A uniform bound for the weighted masses*

$$\int_X W(-u)\mathrm{MA}_\omega^{\mathrm{ext}}(u)$$

over all normalized ω-psh potentials requires

$$\sup_{T\gg 1} \sqrt{T}\, W(T) < \infty.$$

Uniform deep tails over that class require $\sqrt{T}\, W(T) \to 0$.

Proof On K_η, monotonicity of W gives

$$\int_X W(-u_\eta)\mathrm{MA}_\omega^{\mathrm{ext}}(u_\eta) \geq D\eta^{-1}W(B\eta^{-2}).$$

Every sufficiently large T equals $B\eta^{-2}$ for some sufficiently small η, proving the necessary bound. Also $K_\eta \subset \{-u_\eta > A\eta^{-2}/2\}$, so uniform deep tails force this lower bound to tend to zero. □

Theorem 8.8.2 *Suppose W is positive and nonincreasing, finite on compact intervals, and*

$$\sup_{T\gg 1} \sqrt{T}W(T) = \infty.$$

Then there is a single $U \in \mathcal{R}$ such that

$$\int_X W(-U)\mathrm{MA}_\omega^{\mathrm{ext}}(U) = \infty.$$

Proof First select the correction with additional local control. Put

$$x_{\mathrm{pre}} = (q_0 + 1/2 - 2\sqrt{L})/a.$$

Then $t(x_{\mathrm{pre}}) = \eta^3$, $x_{\mathrm{pre}} \to \infty$, and $b - x_{\mathrm{pre}} = O(\sqrt{\eta L}) \to 0$. For a fixed large K the preceding defect estimates give $d_\eta \leq (K/2)\eta$ on $[0, x_{\mathrm{pre}}]$: on the linear portion $q^2 t \leq 4L\eta^3$, and the exponential error is $O(\exp(-1/(C\kappa\eta^2 L))) = o(\eta)$. On the initial portion use the previously proved $C\eta$ bound. The integral of d_η on $[x_{\mathrm{pre}}, b]$ tends to zero by the same integrated estimates and this interval's length.

Choose a fixed left cutoff, zero for $x \leq -1/2$ and one for $x \geq -1/4$, and a translated right cutoff, one for $x \leq x_{\mathrm{pre}}$ and zero for $x \geq x_{\mathrm{pre}} + 1/4$. Let r_η^0 be $K\eta$ times their product. It strictly exceeds d_η on $[0, x_{\mathrm{pre}}]$. The continuous function $e_\eta = \max(d_\eta - r_\eta^0, 0)$ is supported in $[x_{\mathrm{pre}}, b]$. Add a smooth nonnegative majorant $s_\eta > e_\eta$ on that interval, supported in $(x_{\mathrm{pre}} - 1/4, b + 1/2)$, with $\int s_\eta \leq \int e_\eta + \eta$. Set $r_\eta = r_\eta^0 + s_\eta$. Then

$$r_\eta > d_\eta \quad \text{on } [0, b], \qquad m_\eta = \int r_\eta \leq K\eta b + O(\sqrt{\eta L}) + O(\eta).$$

After shrinking the fixed c, this is bounded by a fixed m_0 within all the positivity tolerances above. The conclusions of Theorem 8.8.1 therefore hold for this choice, with fixed A, B, D. On every fixed compact interval $I \Subset (0,\infty)$, for sufficiently small η we have $r_\eta = K\eta$ and exactly

$$g_\eta(x) = -m_\eta(x-\mu_\psi) + K\eta(x^2/2 + b_0 x + b_1), \qquad \mu_\psi = \int s\psi(s)\,\mathrm{d}s. \tag{8.28}$$

Here b_0, b_1 depend only on the fixed left cutoff. Globally $0 \le -g_\eta(x) \le m_0(x+2)$ for $x \ge 0$.

Let $G(w) = -\int_0^\infty (k_r(w) - 1)\,\mathrm{d}r$ for $w \ne 0$ on E. Gaussian integration gives the uniform bound

$$-F_\eta(t,w) \le C\eta\big(1 + \log^+(1/\mathrm{dist}_E(w,0)^2)\big), \quad t > 0. \tag{8.29}$$

Indeed the nearest Gaussian has integral bounded by $C + 2\log^+(1/\mathrm{dist}_E(w,0)^2)$ on $(0,1]$; the other lattice terms have bounded integral and large times decay. The same bound applies after the cutoff. On a fixed $I \Subset (0,\infty)$, $\vartheta = 1$ for small η and $t_\eta(x) \le \exp(-c/(2\eta^3))$. Every fixed x derivative of t_η has this bound times a polynomial in η^{-1}. On compact fiber sets away from zero,

$$F_\eta(t_\eta(x), w)/\eta \longrightarrow G(w) \quad \text{in } C^\ell \text{ for every fixed } \ell.$$

To verify derivatives, subtract G from $G_t = F_\eta(t,\cdot)/\eta$: $G_t - G = \int_0^t (k_r - 1)\,\mathrm{d}r = -t + O(\exp(-d^2/(Ct)))$ when d stays positive. Differentiated Gaussian errors have only polynomial factors in t^{-1}, and repeated x differentiation preserves their decay. Together with (8.28) and $0 \le \sup V_\eta \le C\eta$, this gives uniform C^ℓ bounds for u_η on each such fixed compact product set, for all sufficiently small η. The threshold may depend on the set and derivative order.

Fix $a_j = 2^{-j-2}$, $j \ge 1$, so $\sum a_j = 1/4$. Choose scales $\eta_j \downarrow 0$ recursively and write $u_j = u_{\eta_j}$, $K_j = K_{\eta_j}$. Require the minimum x on K_j to exceed every earlier $x_{*,i}$ by two. Choose a relatively compact product neighborhood O_j of K_j, with positive x interval and fiber closure away from zero, on which the earlier u_i are constant. The K_j are pairwise disjoint. With $E_j = \sum_{i<j} a_i \|u_i\|_\infty$, impose

$$E_j \le a_j \eta_j^{-2}, \qquad \eta_j \le a_j,$$
$$a_j \eta_j \le 2^{-j} a_i \eta_i \quad (i < j).$$

For each earlier O_i, require the preceding uniform derivative bounds to hold for u_j through order j. All are finite constraints at stage j, achievable by making η_j smaller. They ensure that the future series $\sum_{k>i} a_k u_k$ converges in C^∞ on compact subsets of O_i: for every fixed derivative order the sufficiently late terms have a uniform bound there, and $\sum a_k < \infty$.

These constraints also give $\sum_{k>j} a_k \eta_k \le a_j \eta_j$. On K_j the coordinate and distance estimates are

$$x \le C_c \eta_j^{-1}, \qquad \log^+(1/\operatorname{dist}_E(w,0)^2) \le C_c \eta_j^{-3}.$$

Using (8.29), the global slope bound on g_k, and the supremum constants, the future depth is at most

$$C_c \eta_j^{-3} \sum_{k>j} a_k \eta_k + C_c \eta_j^{-1} \sum_{k>j} a_k \le C_c a_j \eta_j^{-2} + C_c \eta_j^{-1}/4.$$

The last term is at most a fixed multiple of $a_j \eta_j^{-2}$ since $\eta_j \le a_j$. Including the earlier and current terms, there is a fixed $C_* > 0$, independent of the scales, such that

$$-\sum_i a_i u_i \le C_* a_j \eta_j^{-2} \quad \text{on } K_j. \tag{8.30}$$

Fix this constant before the scale choice. Since $\sqrt{T}W(T)$ is unbounded, at each stage choose arbitrarily large T_j such that

$$\frac{D}{\sqrt{C_*}} a_j^{5/2} \sqrt{T_j} W(T_j) \ge 1, \qquad \eta_j = \sqrt{C_* a_j / T_j},$$

and so small a scale that all finite preceding constraints hold. Such values occur arbitrarily far out because W is finite on compact intervals. Thus the recursive choice is possible.

The smooth nonpositive partial sums $v_N = \sum_{j \le N} a_j u_j$ decrease, and

$$\omega + \mathrm{dd^c} v_N = (1 - \sum_{j \le N} a_j)\omega + \sum_{j \le N} a_j(\omega + \mathrm{dd^c} u_j) \ge \tfrac{3}{4}\omega.$$

By Theorem 1.4.1, $\int_X (-v_N)\,\mathrm{d}V \le C \sum_j a_j < +\infty$. Thus Corollary 1.4.1 gives a ω-plurisubharmonic limit v with $\omega + \mathrm{dd^c} v \ge 3\omega/4$. Its supremum is finite and nonpositive.

On O_j the earlier terms are constant and the future series converges smoothly. Thus v is smooth there and $\omega + \mathrm{dd^c} v \ge a_j(\omega + \mathrm{dd^c} u_j)$ pointwise. The determinant inequality for positive Hermitian matrices gives on K_j

$$\mathrm{MA}_\omega^{\mathrm{ext}}(v) \ge a_j^3 (\omega + \mathrm{dd^c} u_j)^3.$$

On these sets the extended product is the smooth product: on a compact neighborhood of K_j all sufficiently deep canonical truncations equal v. Set $U = v - \sup_X v$. Since $\sup v \le 0$, $-U \le -v$, and its local currents are unchanged. Monotonicity of W and (8.30) give

$$\int_{K_j} W(-U)\mathrm{MA}_\omega^{\mathrm{ext}}(U) \ge D a_j^3 \eta_j^{-1} W(C_* a_j \eta_j^{-2}) = \frac{D}{\sqrt{C_*}} a_j^{5/2} \sqrt{T_j} W(T_j) \ge 1.$$

The disjoint K_j prove infinite total mass for this single potential. They lie in its smooth locus, so no mass is assigned to poles. □

8.8.3 Concentration at the critical weight

Lemma 8.8.4 *Suppose $\sqrt{t}\,W(t)$ is bounded but does not tend to zero. There are smooth $u_j \in \mathcal{R}$ converging in capacity to $g \in \mathcal{R}$ such that a weak cluster measure of ν_{W,u_j} gives positive mass to the pole divisor*

$$H = \pi^{-1}\{[z_0 : z_1 : z_2] : z_0 = 0\},$$

whereas $\nu_{W,g}(H) = 0$.

Proof Use the correction chosen in the proof of Theorem 8.8.2. Its plateau and its late supplement satisfy

$$\int r_\eta^0 = K\eta x_{\mathrm{pre}} + O(\eta), \qquad \int s_\eta = O(\sqrt{\eta L}) + O(\eta), \qquad \eta x_{\mathrm{pre}} \to \ell.$$

Therefore $m_\eta \to m := K\ell > 0$. Shrink the fixed c so that m satisfies all the established positivity margins. On each fixed finite x interval, r_η and all its derivatives tend to zero; the late supplement escapes the interval. Thus g_η converges smoothly there to

$$g(x) = -m \int_{-\infty}^{x} (x - s)\psi(s)\,\mathrm{d}s.$$

It is zero for $x \le -2$ and equals $-m(x - \mu_\psi)$ for $x \ge -1$. The same margins give $\mu + g' > 0$ and $g'' + \mu(1 - \mu) \ge 0$ at finite x. Across H, its extension has logarithmic singularity of coefficient m: a local defining function ζ gives $g = m \log|\zeta|^2 + O(1)$. Its upper semicontinuous extension is ω-plurisubharmonic, has supremum zero and belongs to $\mathcal{R}$.

The bound (8.29) and $F_\eta \le C\eta$ imply that, on compact base sets away from H, each fixed-depth exceptional set lies in an exponentially shrinking tube about the local holomorphic zero section $w = 0$. These tubes have capacity tending to zero. Indeed, on a relatively compact coordinate chart, $\log|w|^2$ is locally integrable and plurisubharmonic; the weighted Chern–Levine–Nirenberg estimate of Section 1.6 bounds the relative capacity of $\{\log|w|^2 < -T\}$ by C/T. A finite cover and the local capacity comparison transfer this estimate to Cap_ω.

The corrections converge uniformly on compact base sets away from H, including $\xi = 0$, and the supremum normalization is $O(\eta)$. Since g has its logarithmic pole on H, the estimate (1.15) gives neighborhoods of H with arbitrarily small capacity. Removing one such neighborhood proves $u_\eta \to g$ in capacity.

Assume $\sqrt{t}\,W(t)$ is bounded but does not tend to zero. Choose the preceding sequence of cores with weighted mass bounded below by $c_0 > 0$. The proved upper bound makes their full weighted measures uniformly finite, so a subsequence has a weak cluster measure ν. For each fixed closed neighborhood H_r of H, all sufficiently late cores lie in H_r. Portmanteau gives $\nu(H_r) \ge c_0$; decreasing continuity of the finite measure gives $\nu(H) \ge c_0$. But $\nu_{W,g}(H) = 0$ by its defining non-pluripolar truncation. □

Theorem 8.8.3 *Within $\mathcal{R}$ the following assertions hold.*

(1) *Every individual $\nu_{W,u}$ is finite if and only if $\sup_{t\gg 1}\sqrt{t}\,W(t) < \infty$. This is also equivalent to a uniform total-mass bound. In this case*

$$\sup_{u\in\mathcal{R}} \nu_{W,u}(X) \le 12Q(W).$$

If the condition fails there is one $u \in \mathcal{R}$ with infinite measure.

(2) *Uniform deep tails hold if and only if $\sqrt{t}\,W(t) \to 0$. For all $u \in \mathcal{R}$ and $T \ge 0$,*

$$\nu_{W,u}(\{-u > T\}) \le 12Q_T(W).$$

The inequality is understood in the extended sense.

(3) *Uniform absolute continuity relative to Cap_ω holds if and only if $\sqrt{t}\,W(t) \to 0$.*

(4) *The assignment $u \mapsto \nu_{W,u}$ is a map into finite measures and is continuous from capacity convergence in $\mathcal{R}$ to weak measure convergence if and only if $\sqrt{t}\,W(t) \to 0$. When $\sqrt{t}\,W(t)$ is bounded but does not tend to zero, there are smooth $u_j \in \mathcal{R}$ converging in capacity to $g \in \mathcal{R}$, whose weighted measures have a weak cluster measure charging the pole divisor of g.*

Proof The sufficient conditions are Proposition 8.8.1. The necessary uniform mass and tail conditions follow from Corollary 8.8.1, whose smooth potentials are invariant. If $\sqrt{t}\,W(t)$ is unbounded, Theorem 8.8.2 disproves universal individual finiteness and prevents a map into finite measures.

For uniform absolute continuity, the concentration regions of Theorem 8.8.1 lie in $\{x \ge c_1/\eta\}$ for a fixed $c_1 > 0$, hence in shrinking neighborhoods of H. The globally defined $h_H = \log(|z_0|^2/|z|^2)$ has supremum zero and $\omega + \mathrm{dd^c} h_H = \beta + [H] \ge 0$. Its sublevel estimate (1.15) shows that these neighborhoods have capacity tending to zero. If $\limsup_{t\to+\infty}\sqrt{t}\,W(t) > 0$, choose the scales so that $D\eta^{-1}W(B\eta^{-2})$ stays bounded below. The weighted masses on these regions then violate uniform absolute continuity. Finally, Lemma 8.8.4 disproves capacity-to-weak continuity whenever $\sqrt{t}\,W(t)$ is bounded but does not tend to zero. □

Corollary 8.8.2 *For a weight W satisfying the assumptions of this section and agreeing for large t with*

$$W_{p,a}(t) = (1+t)^{-p}[\log(\mathrm{e}+t)]^{-a},$$

universal individual finiteness and uniform total-mass bounds in $\mathcal{R}$ hold exactly when $p > 1/2$, or $p = 1/2$ and $a \ge 0$. Uniform deep tails, uniform capacity absolute continuity and capacity-to-weak continuity hold exactly when $p > 1/2$, or $p = 1/2$ and $a > 0$.

Proof Apply Theorem 8.8.3 to $\sqrt{t}\,W_{p,a}(t) \sim t^{1/2-p}(\log t)^{-a}$. A smooth decreasing modification on a compact interval changes none of these conditions. □

The necessary conditions and the single infinite-measure example also apply to the class of all normalized potentials on X. The sufficient conditions proved here use

the $U(2)$ symmetry. For the unrestricted class, Theorem 7.3.1 still gives the sufficient condition $\int_0^{+\infty}(1+t)(-W'(t))\,\mathrm{d}t < +\infty$; its optimal damping rate remains open.

8.9 Limits of shrinking smooth potentials

When the bounded mass property fails, Corollary 7.5.1 produces smooth potentials converging to zero whose Monge–Ampère measures keep an excess mass in the limit. On the Hopf threefold we can determine exactly which excess measures occur: they are the lifts of arbitrary base measures by the fiber probability measures. The proof combines the intermediate currents of Proposition 7.5.1 with averaging over the automorphism group.

On a general Hermitian manifold, the restrictions on the intermediate currents in Proposition 7.5.1 are still necessary; we do not know whether they are sufficient, or what the support and pluripolar behavior of shrinking defects can be in general.

We keep the Hopf threefold X, its projection $\pi : X \to \mathbb{P}^2$, and the forms $\omega = \alpha + \beta$ of the previous sections. For $p \in \mathbb{P}^2$, let h_p be the Haar probability measure on the elliptic fiber $\pi^{-1}(p)$, that is, the measure $\mathrm{d}A_E$ transported by the action of E. For a finite positive measure μ on the base, define its *fiberwise lift* $\mathcal{L}\mu$ by

$$\int_X \varphi\,\mathrm{d}\mathcal{L}\mu = \int_{\mathbb{P}^2}\left(\int_{\pi^{-1}(p)}\varphi\,\mathrm{d}h_p\right)\mathrm{d}\mu(p), \qquad \varphi \in C(X).$$

Since fiber integrals of continuous functions are continuous in p, the map $\mathcal{L}$ is weakly continuous. The normalization $\int_{\pi^{-1}(p)}\beta = 2$ gives

$$\mathcal{L}\mu = \tfrac{1}{2}\beta \wedge \pi^*\mu, \qquad \mathcal{L}(\omega_{\mathrm{FS}}^2) = \tfrac{1}{6}\omega^3. \tag{8.31}$$

Here $\pi^*\mu$ denotes the pullback of a top-degree current by the submersion π; locally it is the base measure with constant coefficients in the fiber directions.

For a Hermitian form Ω on X, put

$$M_\Omega(f) = \int_X (\Omega + \mathrm{dd^c} f)^3, \qquad V_\Omega = \int_X \Omega^3$$

for smooth real f, and let b be a real number. A positive measure σ on X is called a *shrinking defect* for (Ω, b) if, for every sequence $0 < \varepsilon_j < 1$ tending to zero, there are smooth $U_j \in \mathrm{PSH}(X,\Omega)$ and numbers $0 < r_j < \varepsilon_j$ such that

$$\sup_X U_j = 0, \qquad w_j = r_j U_j, \qquad M_\Omega(w_j) = b, \qquad (\Omega + \mathrm{dd^c} w_j)^3 \rightharpoonup \Omega^3 + \sigma. \tag{8.32}$$

Here weak convergence means convergence against every continuous function on X. We first classify the shrinking defects for the metric ω, for which $V_\omega = 6$; we then write $m = b - 6 > 0$. Afterwards we pass to an arbitrary Hermitian form.

8.9.1 Positive quadratic measures

The mass formula of Proposition 8.1.1 gives

$$M_\omega(\lambda f) - 6 = \lambda^2\big(M_\omega(f) - 6\big)$$

for every smooth real f and real λ. To use this scalar identity in a weak limit, we also need a positive measure that represents the quadratic term.

Lemma 8.9.1 *Let f be smooth, $0 < t < 1$, and $\mathrm{dd^c} f \geq -t\omega$. Set $H = \mathrm{dd^c} f + t\omega$, $d = M_\omega(f) - 6$, and $\nu = 3\omega \wedge H^2$. Then $d \geq 0$ and*

$$\int_X \omega^2 \wedge H = 6t, \qquad \int_X \omega \wedge H^2 = d/3 + 6t^2, \qquad \int_X H^3 = td + 6t^3,$$
$$\big\|(\omega + \mathrm{dd^c} f)^3 - \omega^3 - \nu\big\|_{\mathrm{TV}} \leq 36t + 2td + 24t^3.$$

Proof The Gauduchon identity $\mathrm{dd^c}\omega^2 = 0$ gives $\int_X \omega^2 \wedge \mathrm{dd^c} f = 0$, and Stokes' formula gives $\int_X (\mathrm{dd^c} f)^3 = 0$. Expanding the three integrals with these identities proves the asserted values, and Proposition 8.1.1 gives $d \geq 0$. The identity of measures

$$(\omega + \mathrm{dd^c} f)^3 = (1-t)^3\omega^3 + 3(1-t)^2\omega^2 \wedge H + (1-t)\nu + H^3$$

has four positive terms. After subtracting $\omega^3 + \nu$, the total masses of the remaining terms bound the total variation by $18t + 18t + t(d + 18t^2) + td + 6t^3$, as asserted. □

8.9.2 Orbital mixtures

Averaging a shrinking defect over automorphisms of X produces new shrinking defects. The compact group $G = U(3) \times (\mathbb{R}/\mathbb{Z})$ acts transitively on X by the holomorphic maps $g[z] = [\mathrm{e}^t Az]$, $g = (A, t)$, and preserves ω. Let h_G be its Haar probability measure. For a probability measure ρ on G and a finite measure σ on X, write

$$\mathcal{A}_\rho \sigma = \int_G g^*\sigma \, \mathrm{d}\rho(g).$$

Here the pullback of a measure is defined by $\int_X \varphi \, \mathrm{d}(g^*\sigma) = \int_X \varphi \circ g^{-1} \, \mathrm{d}\sigma$. In particular, transitivity gives

$$\int_G g^*\zeta \, \mathrm{d}h_G(g) = \frac{\zeta(X)}{6}\omega^3$$

for every finite measure ζ on X.

Proposition 8.9.1 *If σ is a shrinking defect for $(\omega, 6 + m)$, then so is $\mathcal{A}_\rho\sigma$ for every probability measure ρ on G.*

Proof Fix a sequence ε_j as in the definition. Take a sequence $f_k = t_k u_k$ realizing σ as in (8.32), so that f_k has mass $6+m$, and put $H_k = \mathrm{dd}^{\mathrm{c}} f_k + t_k \omega$. By Lemma 8.9.1, the positive measures $\nu_k = 3\omega \wedge H_k^2$ have masses $m + 18 t_k^2$ and converge weakly to σ.

The idea is to replace f_k by a normalized sum of N random translates. First suppose that ρ has density at most L relative to h_G. Choose N independent random group elements $g_1, \dots, g_N$ with law ρ, and set

$$W = N^{-1/2} \sum_{a=1}^{N} f_k \circ g_a, \qquad \tau = t_k \sqrt{N}, \qquad K = \mathrm{dd}^{\mathrm{c}} W + \tau\omega = N^{-1/2} \sum_{a=1}^{N} g_a^* H_k \geq 0.$$

The quadratic measure of W is

$$3\omega \wedge K^2 = D + C, \qquad D = N^{-1} \sum_{a=1}^{N} g_a^* \nu_k, \qquad C = \frac{6}{N} \sum_{a<c} \omega \wedge g_a^* H_k \wedge g_c^* H_k \geq 0.$$

Averaging $u_k \circ g$ against h_G gives a constant, hence $\int_G g^* H_k \, \mathrm{d}h_G = t_k \omega$. Consequently $B = \int_G g^* H_k \, \mathrm{d}\rho \leq L t_k \omega$, and independence gives

$$\mathbb{E}[C(X)] = 3(N-1) \int_X \omega \wedge B^2 \leq 18 (N-1) L^2 t_k^2.$$

For any real $\varphi \in C(X)$ with $\|\varphi\|_\infty \leq 1$, the variance of $D(\varphi)$ is at most $(m + 18 t_k^2)^2 / N$.

For general ρ, convolve it with the normalized restrictions of h_G to shrinking neighborhoods of the identity, which have positive Haar measure. This gives probability measures $\rho_j \rightharpoonup \rho$ with bounded densities L_j. Fix a countable dense set (φ_l) in the real unit ball of $C(X)$ and numbers $0 < \delta_j < \min(1, m/4)$ tending to zero. Choose N_j large enough that

$$\frac{j (m+18)^2}{N_j \delta_j^2} < \frac{1}{4}.$$

Next choose k_j large enough that $t_{k_j} < 1$, $\tau_j = t_{k_j} \sqrt{N_j} < \min(\varepsilon_j/4, 1/j, 1/4)$, $18 N_j t_{k_j}^2 < m/4$, and the expected cross-term mass is less than $\delta_j / 4$. Chebyshev's inequality for the first j test functions and Markov's inequality for $C(X)$ show that some choice of N_j group elements satisfies

$$|D_j(\varphi_l) - (\mathcal{A}_{\rho_j} \nu_{k_j})(\varphi_l)| < \delta_j \quad (l \leq j), \qquad C_j(X) < \delta_j.$$

We may also arrange $k_j \to \infty$. For each fixed test function φ, the family $\{\varphi \circ g^{-1} : g \in G\}$ is compact in $C(X)$, so a finite uniform net and the bounded masses of ν_k show that $\int \varphi \circ g^{-1} \, \mathrm{d}\nu_k \to \int \varphi \circ g^{-1} \, \mathrm{d}\sigma$ uniformly in g. It follows that $\mathcal{A}_{\rho_j} \nu_{k_j} \rightharpoonup \mathcal{A}_\rho \sigma$. The dense test functions and the bounded masses now imply $D_j \rightharpoonup \mathcal{A}_\rho \sigma$, while $C_j \to 0$ in total variation.

By the integral identity of Lemma 8.9.1,

$$d_j = M_\omega(W_j) - 6 = m + C_j(X) - 18(N_j - 1)t_{k_j}^2 \longrightarrow m, \qquad d_j > 3m/4.$$

Put $\lambda_j = \sqrt{m/d_j}$, so $\lambda_j \to 1$ and $\lambda_j < 2$. The average $a_j = N_j^{-1} \sum_a u_{k_j} \circ g_a$ is smooth and ω-plurisubharmonic. With

$$U_j = a_j - \sup_X a_j, \qquad r_j = \lambda_j \tau_j < \varepsilon_j,$$

the potential $r_j U_j$ differs from $\lambda_j W_j$ by a constant and has exact mass $6+m$. Its positive quadratic measure is $\lambda_j^2(D_j + C_j)$. The total-variation estimate of Lemma 8.9.1, with parameter r_j, proves the required weak limit. □

Since $v_+(\omega) = +\infty$, Corollary 7.5.1 gives a sequence with some defect of mass m. Passing to a further subsequence meets any prescribed bounds ε_j without changing the defect, so a shrinking defect of mass m exists. Applying Proposition 8.9.1 with $\rho = h_G$ shows that $(m/6)\omega^3$ is a shrinking defect. In particular, the excess mass can persist as a smooth limiting density.

8.9.3 Fiber measures

The intermediate currents force every shrinking defect to be a lift of a base measure, and the automorphisms of X realize all such lifts.

Lemma 8.9.2 *Let $f_j = t_j u_j$, where $u_j \in \mathrm{PSH}(X, \omega)$ are smooth, $\sup_X u_j = 0$ and $0 < t_j \to 0$. Suppose that $M_\omega(f_j) = 6 + m$ and $(\omega + \mathrm{dd^c} f_j)^3 \rightharpoonup \omega^3 + \sigma$. Then there is a unique positive measure μ on $\mathbb{P}^2$, of mass m, such that*

$$\sigma = \mathcal{L}\mu, \qquad (\mathrm{dd^c} f_j + t_j\omega)^2 \rightharpoonup \tfrac{1}{6}\pi^*\mu.$$

Proof Put $H_j = \mathrm{dd^c} f_j + t_j\omega$. By Proposition 7.5.1, applied with $h = \omega$ and $n = 3$, every convergent subsequence of H_j^2 has a positive closed limit K with $\sigma = 3\omega \wedge K$; moreover $\alpha \wedge K = 0$, because α is closed and semipositive, so that $\alpha \wedge K$ is a positive measure with $\int_X \alpha \wedge K = 0$. In holomorphic coordinates (ξ_1, ξ_2, w) on a local trivialization of the elliptic bundle, the coefficient matrix of K on the three exterior pairs is positive semidefinite as a matrix of measures. To see this directly, note that positivity of the matrices of H_j^2 passes to the limit when they are tested against constant vectors, and take Radon–Nikodym derivatives with respect to the diagonal trace. Since α is strictly positive in the horizontal directions, the identity $\alpha \wedge K = 0$ makes both diagonal entries containing $\mathrm{d}w$ vanish. Positivity then makes their rows and columns vanish, so only the horizontal top-degree coefficient remains.

Since K is closed, both real fiber derivatives of that coefficient vanish in the sense of distributions. Testing against a compactly supported base function times a nonconstant Fourier mode on $E = \mathbb{C}/(\mathbb{Z} + 2\pi\mathrm{i}\mathbb{Z})$ shows that every such mode

vanishes. By density of trigonometric polynomials in $C(E)$, the coefficient is a base measure times the constant fiber area. Changes of bundle coordinates translate w by a holomorphic function of the base and preserve that area. Thus $K = \pi^*\tau$ for a positive measure τ on $\mathbb{P}^2$.

Since $\alpha \wedge K = 0$, (8.31) gives $\sigma = 3\beta \wedge \pi^*\tau = \mathcal{L}(6\tau)$. Therefore $\mu = 6\tau = \pi_*\sigma$ is uniquely determined by σ, and it has mass m. In particular, every subsequential limit of H_j^2 is the same, which proves convergence of the entire sequence. □

Lemma 8.9.3 *For every $p \in \mathbb{P}^2$, the measure mh_p is a shrinking defect for $(\omega, 6+m)$.*

Proof Start with smooth $f_j = t_j u_j$ realizing the shrinking defect $(m/6)\omega^3 = \mathcal{L}(m\,\omega_{\mathrm{FS}}^2)$, and put $H_j = \mathrm{dd}^{\mathrm{c}} f_j + t_j\omega$. By Lemma 8.9.2, $H_j^2 \rightharpoonup (m/6)\alpha^2$, while H_j has trace mass $O(t_j)$. Fix $A \in GL(3,\mathbb{C})$, regarded as an automorphism of X, and let a be the induced projective transformation of $\mathbb{P}^2$. Choose $C_A \geq 1$ with $A^*\omega \leq C_A\omega$, and put

$$R_A = C_A\omega - A^*\omega \geq 0, \qquad H_j^A = \mathrm{dd}^{\mathrm{c}}(f_j \circ A) + C_A t_j\omega = A^*H_j + t_j R_A.$$

For this fixed A, the trace mass of A^*H_j is $O_A(t_j)$, and the positive difference $(H_j^A)^2 - A^*(H_j^2)$ has trace mass $O_A(t_j^2)$. Since $\alpha = \pi^*\omega_{\mathrm{FS}}$, it follows that

$$(H_j^A)^2 \rightharpoonup \frac{m}{6}\pi^*(a^*\omega_{\mathrm{FS}}^2), \qquad 3\omega \wedge (H_j^A)^2 \rightharpoonup \mathcal{L}(ma^*\omega_{\mathrm{FS}}^2).$$

The limiting measure has mass m, so the integral identity of Lemma 8.9.1, applied with the parameter $C_A t_j$, gives $d_j^A = M_\omega(f_j \circ A) - 6 \to m$. For large j, multiply $f_j \circ A$ by $\sqrt{m/d_j^A} \to 1$. The mass is then exactly $6 + m$, and the weak limit is unchanged. The underlying normalized potential is $u_j \circ A/C_A \in \mathrm{PSH}(X,\omega)$, with parameter $C_A t_j\sqrt{m/d_j^A} \to 0$. The total-variation estimate of Lemma 8.9.1 therefore shows that $\mathcal{L}(m\,a^*\omega_{\mathrm{FS}}^2)$ is a shrinking defect; any prescribed bounds ε_j are met by passing to a sufficiently late subsequence.

Now take $A_l = \mathrm{diag}(R_l^{-1}, 1, 1)$, $R_l \to +\infty$. Since

$$a_l^*\omega_{\mathrm{FS}}^2 = (a_l^{-1})_*\omega_{\mathrm{FS}}^2,$$

and $a_l^{-1}[q_0 : q_1 : q_2] = [R_l q_0 : q_1 : q_2] \to [1 : 0 : 0]$ outside the hyperplane $\{q_0 = 0\}$, which has zero volume, dominated convergence gives $a_l^*\omega_{\mathrm{FS}}^2 \rightharpoonup \delta_{[1:0:0]}$. By weak continuity of $\mathcal{L}$, the shrinking defects $\mathcal{L}(m\,a_l^*\omega_{\mathrm{FS}}^2)$ converge to $mh_{[1:0:0]}$. For each l, choose one corrected potential for A_l, sufficiently late in its sequence that its parameter is less than ε_l and its measure differs from the corresponding limit by less than $1/l$ on the first l functions of a fixed dense sequence of test functions. This diagonal sequence has the exact mass $6 + m$ and the limit $\omega^3 + mh_{[1:0:0]}$. Unitary automorphisms move this fiber to any prescribed fiber. □

Theorem 8.9.1 *For $b > 6$, the shrinking defects for (ω, b) are exactly $\mathcal{L}\mu$, where μ ranges over all positive measures on $\mathbb{P}^2$ of mass $b - 6$. Each such defect has support $\pi^{-1}(\operatorname{supp}\mu)$ and has no point atoms. It charges no pluripolar sets if and only if μ charges no pluripolar sets on $\mathbb{P}^2$.*

Proof Put $m = b - 6$. Necessity follows from Lemma 8.9.2. Finite convex combinations of the measures mh_p are shrinking defects by Lemma 8.9.3 and Proposition 8.9.1, the latter applied to an atomic measure ρ supported on unitary maps that move a fixed fiber to the desired fibers. Approximate an arbitrary base measure of mass m by finite atomic measures of the same mass, using finite partitions of diameter tending to zero. Weak continuity of $\mathcal{L}$ and the diagonal choice on dense test functions used in the preceding proof give a realizing sequence for every prescribed sequence ε_j.

Every nonempty open subset of a fiber has positive Haar measure. Local trivializations therefore show that $\mathcal{L}\mu$ has support $\pi^{-1}(\operatorname{supp}\mu)$, and the fiber measures have no point atoms. If B is a pluripolar subset of the base, local plurisubharmonic functions whose pole sets contain B pull back by the submersion to such functions on X. Hence $\pi^{-1}(B)$ is pluripolar, and $\mathcal{L}\mu(\pi^{-1}(B)) = \mu(B)$; thus $\mathcal{L}\mu$ charges a pluripolar set whenever μ does.

Conversely, suppose that μ charges no pluripolar subset of the base. Cover a pluripolar set in X by countably many local product charts, each carrying a plurisubharmonic function $q(\xi, w) \not\equiv -\infty$ whose pole set contains the part of the set in that chart. For a relatively compact disk D in the fiber direction, the function

$$F(\xi) = \frac{1}{|D|}\int_D q(\xi, w)\, \mathrm{d}A(w)$$

is plurisubharmonic and not identically $-\infty$ on a smaller base chart. Indeed, local integrability of q and Fubini's theorem show that F is locally integrable, and in particular finite almost everywhere; a common upper bound and the reverse Fatou lemma give upper semicontinuity; and integrating the submean inequalities in the base directions gives the submean property. The restriction of q to a fiber is either subharmonic with a pole set of zero area or identically $-\infty$. The fibers of the second kind lie over the pluripolar set $\{F = -\infty\}$, which has zero μ-measure. Integrating the Haar measures of the fibers against μ therefore shows that each local pole set has zero $\mathcal{L}\mu$-measure, and the countable cover proves the assertion for this pluripolar set. For arbitrary pluripolar subsets, the same argument applies to Borel pole sets containing them, with outer measure. Similarly, for the first implication, a Borel $\mathcal{L}\mu$-null set containing $\pi^{-1}(B)$ has a measurable fiber-mass function equal to one on B, which gives the corresponding outer-measure statement. □

For every nonempty closed set $F \subseteq \mathbb{P}^2$, a measure $m\sum_{l\ge 1} 2^{-l}\delta_{p_l}$ carried by a countable dense subset $\{p_l\}$ of F has support F. Thus every closed set of the form $\pi^{-1}(F)$ is the support of a shrinking defect. The fibers themselves are pluripolar in a global sense: for the fiber over $[1 : 0 : 0]$, the function

$$\psi = \log\frac{|z_1|^2 + |z_2|^2}{|z|^2}, \qquad \mathrm{dd}^{\mathrm{c}}\psi \ge -\alpha, \qquad \omega + \mathrm{dd}^{\mathrm{c}}\psi \ge \beta \ge 0.$$

is ω-plurisubharmonic, and its pole set is exactly that fiber; unitary maps give the other fibers. In particular, for $0 \le \lambda \le 1$ and $p \in \mathbb{P}^2$, the measure

$$m\lambda h_p + \frac{m(1-\lambda)}{6}\omega^3$$

is a shrinking defect. It gives mass $m\lambda$ to the pluripolar fiber $\pi^{-1}(p)$, while every pluripolar set has mass at most $m\lambda$. For $0 < \lambda < 1$ its support is all of X, despite this positive mass on a pluripolar set.

8.9.4 Changing the Hermitian metric

For a general Hermitian form, the fiber Haar measures are replaced by the normalized area measures of the form. Let Ω be any Hermitian form on the Hopf threefold X. Its restriction to each elliptic fiber has positive area

$$A_\Omega(p) = \int_{\pi^{-1}(p)} \Omega.$$

These areas depend smoothly on p and are bounded above and below by positive constants. Define the probability measures $h_p^\Omega = \Omega|_{\pi^{-1}(p)}/A_\Omega(p)$ on the fibers, and define the lift $\mathcal{L}_\Omega\mu$ of a finite positive measure μ on $\mathbb{P}^2$ by the formula defining $\mathcal{L}\mu$, with h_p^Ω in place of h_p.

Theorem 8.9.2 *For every Hermitian form Ω on X and every $b > V_\Omega$, the shrinking defects for (Ω, b) are exactly*

$$\mathcal{L}_\Omega\mu, \qquad \mu \ge 0, \qquad \mu(\mathbb{P}^2) = b - V_\Omega.$$

Their supports are $\pi^{-1}(\operatorname{supp}\mu)$, they have no point atoms, and they charge no pluripolar sets exactly when μ charges no base pluripolar sets. Moreover, $v_+(\Omega) = +\infty$.

Proof Put $m = b - V_\Omega > 0$. For necessity, let σ be a shrinking defect for (Ω, b). Proposition 7.5.1, applied with $h = \Omega$, gives a positive closed limit K of the squares of the intermediate forms with $\sigma = 3\Omega \wedge K$, and $\alpha \wedge K = 0$ as in the proof of Lemma 8.9.2. The local coefficient and Fourier argument of that proof gives $K = \pi^*\tau$ for a positive measure τ on $\mathbb{P}^2$. Consequently

$$\sigma = \mathcal{L}_\Omega\mu, \qquad \mu = 3A_\Omega\tau = \pi_*\sigma,$$

and μ has mass m.

Conversely, fix such a μ and set $\tau = \mu/(3A_\Omega)$. By Theorem 8.9.1, choose a sequence $f_j = t_j u_j$ realizing the shrinking defect $\mathcal{L}(6\tau)$ for ω. The positive forms $H_j = \mathrm{dd}^c f_j + t_j\omega$ have trace mass $O(t_j)$, and $H_j^2 \rightharpoonup \pi^*\tau$ by Lemma 8.9.2. Choose $C \ge 1$ with $\omega \le C\Omega$, and put

$$R = C\Omega - \omega \geq 0, \qquad G_j = \mathrm{dd}^{\mathrm{c}} f_j + Ct_j\Omega = H_j + t_j R \geq 0.$$

The trace mass of G_j is $O(t_j)$, and $G_j^2 - H_j^2$ has trace mass $O(t_j^2)$. Thus $G_j^2 \rightharpoonup \pi^*\tau$ and $3\Omega \wedge G_j^2 \rightharpoonup \mathcal{L}_\Omega \mu$.

Unlike ω, the form Ω need not be Gauduchon, so the mass polynomial may have a linear term. Define

$$\ell_j = 3\int_X \Omega^2 \wedge \mathrm{dd}^{\mathrm{c}} f_j = O(t_j), \qquad q_j = 3\int_X \Omega \wedge (\mathrm{dd}^{\mathrm{c}} f_j)^2 \longrightarrow m.$$

These estimates follow by expanding $\mathrm{dd}^{\mathrm{c}} f_j = G_j - Ct_j\Omega$ and using the preceding trace bounds. Stokes' formula removes the cubic integral, so

$$M_\Omega(\lambda f_j) = V_\Omega + \lambda \ell_j + \lambda^2 q_j.$$

For large j, $q_j > 0$. The positive root

$$\lambda_j = \frac{-\ell_j + \sqrt{\ell_j^2 + 4mq_j}}{2q_j} \longrightarrow 1 \tag{8.33}$$

gives $M_\Omega(\lambda_j f_j) = b$. The normalized function $U_j = u_j/C$ is Ω-plurisubharmonic, and $w_j = \lambda_j f_j = r_j U_j$ with $r_j = \lambda_j C t_j \to 0$.

To identify the full weak limit, first note that expanding $G_j = \mathrm{dd}^{\mathrm{c}} f_j + Ct_j\Omega$ gives

$$\int_X G_j^3 = Ct_j q_j + (Ct_j)^2 \ell_j + (Ct_j)^3 V_\Omega = O(t_j).$$

Hence $G_j^3 \to 0$ in total variation. The positive expansion

$$(\Omega + \mathrm{dd}^{\mathrm{c}} w_j)^3 = (1-r_j)^3\Omega^3 + 3(1-r_j)^2\lambda_j\Omega^2 \wedge G_j + 3(1-r_j)\lambda_j^2\Omega \wedge G_j^2 + \lambda_j^3 G_j^3$$

converges weakly to $\Omega^3 + \mathcal{L}_\Omega\mu$, since the second and fourth terms tend to zero in total variation. Given prescribed bounds ε_j, pass to a sufficiently late subsequence with $r_j < \varepsilon_j$ at every index. This preserves the normalization, the exact mass and the weak limit.

The fiber probabilities h_p^Ω have smooth densities relative to h_p that are bounded above and below by positive constants, uniformly in p. Thus $\mathcal{L}_\Omega\mu$ and $\mathcal{L}\mu$ are bounded by fixed positive multiples of each other, and the assertions about support, point atoms and pluripolar sets follow from Theorem 8.9.1. The global functions with fiber poles also remain available: if $\Omega \geq c\omega$, then $c\psi \in \mathrm{PSH}(X, \Omega)$.

Finally, for smooth $u \in \mathrm{PSH}(X, \omega)$ and $c > 0$ with $\Omega \geq c\omega$,

$$\Omega + \mathrm{dd}^{\mathrm{c}}(cu) \geq c(\omega + \mathrm{dd}^{\mathrm{c}} u), \qquad M_\Omega(cu) \geq c^3 M_\omega(u).$$

Since $v_+(\omega) = +\infty$ by Corollary 8.7.1 and the supremum may be computed over smooth potentials (Proposition 6.5.1), it follows that $v_+(\Omega) = +\infty$. □

Part II
Monge–Ampère and Hessian equations

Chapter 9
Smooth Monge–Ampère equations

Throughout this chapter, ω is a Hermitian form on X and $\mathrm{d}V$ is a smooth positive volume form. Given $F \in C^\infty(X, \mathbb{R})$, we seek a smooth real potential u and a scalar $b \in \mathbb{R}$ satisfying

$$\omega_u^n = \mathrm{e}^{F+b}\mathrm{d}V, \qquad \omega_u > 0. \tag{9.1}$$

Here $\omega_u = \omega + \mathrm{dd}^{\mathrm{c}}u$, and adding a constant to u does not change the equation. For a closed background, integration determines b from the prescribed density. For a Hermitian background, the total mass can depend on u, so the potential and the scalar must be found together.

The existence proof combines weighted integration, which bounds the normalized potential, with a trace estimate for the complex Hessian, which gives uniform ellipticity. The adjoint probability measure of Proposition 4.8.1 supplies the compatibility condition for the linearized equation. Including b as an unknown removes this obstruction, and the estimates give the compactness needed for the continuity method. A positive exponential of the potential instead makes the equation strictly monotone and gives existence without an additional scalar.

After proving existence, we differentiate the solution with respect to the prescribed logarithmic density. The same adjoint probability measure gives the first and second variations of b, proving concavity and a Lipschitz bound. On the Hopf threefold of Chapter 8, the fiber-energy formula measures exactly how its normalization differs from the closed-background formula.

The last part of the chapter concerns a different variation of the metric. For $n \geq 2$, we deform its $(n-1)$st power through a scalar Aeppli ansatz. If the initial metric is Gauduchon, this deformation preserves both the Gauduchon condition and its Aeppli class. The first-order torsion terms have a specific matrix structure, which makes the second-derivative estimate possible; rescaling then reduces the gradient bound to a Liouville theorem on $\mathbb{C}^n$. The resulting uniqueness concerns the scalar ansatz. We finish by studying the variation of its normalization constant.

9.1 Scalar bounds and uniqueness

Evaluating the equation at the extrema of the potential bounds the normalization scalar in terms of the prescribed data. Applied to the difference of two solutions, the same argument shows that their scalars agree, and ellipticity then determines the potential up to a constant. The scalar bounds will also give uniform control along the continuity path.

Theorem 9.1.1 (Tosatti–Weinkove) *For every smooth real F, (9.1) has a unique pair $(u, b) \in C^\infty(X, \mathbb{R}) \times \mathbb{R}$ with $\sup_X u = 0$.*

In dimension one, integration determines $\mathrm{e}^b = \int_X \omega / \int_X \mathrm{e}^F \mathrm{d}V$, and the remaining equation $\mathrm{dd^c} u = \mathrm{e}^{F+b}\mathrm{d}V - \omega$ is a Poisson equation whose right-hand side has integral zero, so it has a smooth solution, unique up to a constant; positivity of ω_u is automatic. Thus the theorem holds in that dimension, and we prove it for $n \geq 2$ at the end of Section 9.5.

Proposition 9.1.1 *Every solution of (9.1) satisfies*

$$\inf_X \left(\log \frac{\omega^n}{\mathrm{d}V} - F \right) \leq b \leq \sup_X \left(\log \frac{\omega^n}{\mathrm{d}V} - F \right).$$

Proof At a maximum point x_+ of u, the real $(1,1)$-form $\mathrm{dd^c} u$ is nonpositive, so $0 < \omega_u \leq \omega$ there. Hence $\omega_u^n(x_+) \leq \omega^n(x_+)$, and $b \leq \log(\omega^n/\mathrm{d}V)(x_+) - F(x_+)$. At a minimum point the reverse argument gives the lower bound. □

When $\mathrm{d}\omega = 0$, integration gives the familiar explicit formula

$$b = \log \frac{\int_X \omega^n}{\int_X \mathrm{e}^F \mathrm{d}V}. \tag{9.2}$$

The same formula holds whenever the mass-invariance criterion of Theorem 2.2.2 is satisfied. In general, integrating the equation gives only

$$\mathrm{e}^b = \frac{\mathrm{M}_\omega(u)}{\int_X \mathrm{e}^F \mathrm{d}V},$$

where $\mathrm{M}_\omega(u) = \int_X \omega_u^n$ is the mass of Theorem 2.2.1; the numerator depends on the unknown potential.

Proposition 9.1.2 *Suppose (u, b) and (v, c) are smooth solutions of (9.1) with the same F and $\mathrm{d}V$. Then $b = c$ and $u - v$ is constant.*

Proof At a maximum of $u - v$, one has $\omega_u \leq \omega_v$, so the equations give $\mathrm{e}^b \leq \mathrm{e}^c$. At a minimum one obtains $\mathrm{e}^b \geq \mathrm{e}^c$. Therefore $b = c$.

Put $h = u - v$ and $\eta_t = \omega_v + t\mathrm{dd^c} h = (1-t)\omega_v + t\omega_u$ for $0 \leq t \leq 1$. These forms are strictly positive. Subtracting the logarithms of the two equations and writing the difference as the integral of its derivative along the segment, we obtain

$$0 = \int_0^1 n \, \frac{\mathrm{d}\mathrm{d}^{\mathrm{c}} h \wedge \eta_t^{n-1}}{\eta_t^n} \, \mathrm{d}t.$$

The right-hand side is a linear second-order operator applied to h. Its coefficients are smooth, its principal part is uniformly elliptic on the compact manifold, and it has no zeroth-order term. The strong maximum principle therefore implies that h is constant. □

9.2 The potential bound from weighted integration

We now show that an upper bound for the density controls the normalized potential, following the method of Cherrier. Integrating the equation against e^{-pu} produces a gradient term and mixed weighted masses; a finite recurrence absorbs the latter together with the torsion error. Moser iteration then gives a set of uniformly positive volume near the minimum, and normalized L^1 compactness bounds that minimum. Norms below are computed with respect to the fixed metric ω.

Lemma 9.2.1 *There is a constant C depending on ω such that, for every positive $(1,1)$-form η, every smooth real f, every $\delta > 0$, and $0 \le k \le n-2$,*

$$|\mathrm{d}^{\mathrm{c}} f \wedge \mathrm{d}\omega \wedge \eta^k \wedge \omega^{n-k-2}| \le \frac{C}{\delta} \, \mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}} f \wedge \eta^k \wedge \omega^{n-k-1} + C\delta \, \eta^k \wedge \omega^{n-k}.$$

Here the absolute value of a top-degree form is the absolute value of its coefficient relative to the positive volume form ω^n.

Proof At a given point, choose an ω-unitary frame in which η is diagonal, with positive eigenvalues $\lambda_1, \dots, \lambda_n$. Expand η^k as a sum over k-element subsets I of $\{1, \dots, n\}$, with coefficients that are positive dimensional multiples of $\lambda_I = \prod_{i \in I} \lambda_i$. After wedging with $\mathrm{d}^{\mathrm{c}} f \wedge \mathrm{d}\omega \wedge \omega^{n-k-2}$, each surviving term is a bounded coefficient of $\mathrm{d}\omega$ times λ_I times one first derivative f_a with $a \notin I$. Young's inequality bounds its absolute value by

$$C\lambda_I |f_a| \le (C/\delta)\lambda_I |f_a|^2 + C\delta\lambda_I.$$

The sum of the first terms is bounded by a fixed multiple of the first form on the right of the assertion, whose diagonal expansion consists of the terms $\lambda_I |f_a|^2$ with $a \notin I$. The second form on the right contains all the λ_I. Since there are finitely many indices and $\mathrm{d}\omega$ is bounded, the constant C is uniform. □

Lemma 9.2.2 *Suppose u is smooth, $\eta = \omega + \mathrm{d}\mathrm{d}^{\mathrm{c}} u > 0$, and $\eta^n \le \Lambda \omega^n$ for a fixed $\Lambda > 0$. There are constants $p_0 \ge 1$ and C depending only on ω and Λ such that*

$$\int_X \mathrm{d}(\mathrm{e}^{-pu/2}) \wedge \mathrm{d}^{\mathrm{c}}(\mathrm{e}^{-pu/2}) \wedge \omega^{n-1} \le Cp \int_X \mathrm{e}^{-pu} \omega^n \quad (p \ge p_0).$$

Proof For a fixed real $p \geq 1$, define M_k for $0 \leq k \leq n$ and J_k for $0 \leq k \leq n-1$ by

$$M_k = \int_X \mathrm{e}^{-pu} \eta^k \wedge \omega^{n-k}, \qquad J_k = \int_X \mathrm{e}^{-pu} \mathrm{d}u \wedge \mathrm{d}^{\mathrm{c}} u \wedge \eta^k \wedge \omega^{n-k-1}, \quad J = \sum_{k=0}^{n-1} J_k.$$

All these numbers are nonnegative. The proof first bounds pJ in terms of the masses M_k, and then bounds these masses by a recurrence. Let $T = \sum_{k=0}^{n-1} \eta^k \wedge \omega^{n-k-1}$, so that $\eta^n - \omega^n = \mathrm{d}\mathrm{d}^{\mathrm{c}} u \wedge T$. Since $\mathrm{d}\eta = \mathrm{d}\omega$, differentiation gives

$$\mathrm{d}T = n \sum_{k=0}^{n-2} \eta^k \wedge \omega^{n-k-2} \wedge \mathrm{d}\omega.$$

The sum is empty when $n = 1$. Stokes' theorem gives the exact identity

$$\begin{aligned} \int_X \mathrm{e}^{-pu} (\eta^n - \omega^n) &= \int_X \mathrm{e}^{-pu} \mathrm{d}\mathrm{d}^{\mathrm{c}} u \wedge T \\ &= pJ + \int_X \mathrm{e}^{-pu} \mathrm{d}^{\mathrm{c}} u \wedge \mathrm{d}T. \end{aligned}$$

The density assumption bounds the left-hand side above by $(\Lambda + 1) M_0$. Apply Lemma 9.2.1 to the last integral, with $\delta = K/p$ for a sufficiently large fixed K. The contribution proportional to J/δ is then at most $pJ/2$, and after absorbing it we obtain

$$pJ \leq C M_0 + \frac{C}{p} \sum_{k=0}^{n-2} M_k. \tag{9.3}$$

This estimate alone does not suffice, because the mixed weighted masses on the right have not yet been bounded.

For $1 \leq k \leq n-2$, a second integration by parts gives

$$M_k - M_{k-1} = pJ_{k-1} + R_k, \qquad R_k = \int_X \mathrm{e}^{-pu} \mathrm{d}^{\mathrm{c}} u \wedge \mathrm{d}(\eta^{k-1} \wedge \omega^{n-k}). \tag{9.4}$$

The derivative in R_k has two terms, with coefficients $k-1$ and $n-k$. Applying the pointwise estimate with $\delta = 1/p$ to each of them, and omitting terms with negative indices, we obtain

$$|R_k| \leq Cp(J_{k-2} + J_{k-1}) + \frac{C}{p}(M_{k-2} + M_{k-1}), \qquad M_{-1} = J_{-1} = 0.$$

Consequently, for $p \geq 1$,

$$M_k \leq C(M_{k-1} + M_{k-2} + pJ).$$

Induction over the finitely many values of k proves

$$\sum_{k=0}^{n-2} M_k \le C(M_0 + pJ).$$

For $n = 2$ this is immediate, and for $n = 1$ the sum is empty. Inserting this bound in (9.3) gives $pJ \le CM_0 + C'J$. For $p \ge 2C'$ the last term can be absorbed, and $pJ \le CM_0$.

Finally,

$$\int_X \mathrm{d}(\mathrm{e}^{-pu/2}) \wedge \mathrm{d}^{\mathrm{c}}(\mathrm{e}^{-pu/2}) \wedge \omega^{n-1} = \frac{p^2}{4} J_0 \le \frac{p^2}{4} J \le CpM_0.$$

This proves the claimed estimate for all $p \ge p_0$. □

Theorem 9.2.1 *For each $\Lambda > 0$ there is C_Λ such that every smooth u with*

$$\omega + \mathrm{dd}^{\mathrm{c}} u > 0, \qquad \sup_X u = 0, \qquad (\omega + \mathrm{dd}^{\mathrm{c}} u)^n \le \Lambda \omega^n$$

satisfies $\|u\|_\infty \le C_\Lambda$.

Proof Let $\mathrm{d}\mu = \omega^n / \int_X \omega^n$. The Sobolev inequality for the Riemannian metric of ω gives, for some $\beta > 1$ and every smooth real function w,

$$\left(\int_X |w|^{2\beta} \, \mathrm{d}\mu \right)^{1/\beta} \le C \left(\int_X \mathrm{d}w \wedge \mathrm{d}^{\mathrm{c}} w \wedge \omega^{n-1} + \int_X |w|^2 \, \mathrm{d}\mu \right).$$

We may take $\beta = n/(n-1)$ if $n \ge 2$, and for example $\beta = 2$ if $n = 1$. Choose p_0 as in Lemma 9.2.2. Applying the Sobolev inequality to $w = \mathrm{e}^{-pu/2}$ and using that lemma, we obtain, with $Z = \mathrm{e}^{-u}$,

$$\|Z\|_{L^{p\beta}(\mu)} \le (Cp)^{1/p} \|Z\|_{L^p(\mu)} \quad (p \ge p_0).$$

Iterating with $p = p_0 \beta^j$, $j = 0, 1, 2, \ldots$, we obtain a bound for $\sup_X Z$; the product of the constants is finite because $\sum_j (1 + \log(p_0 \beta^j))/(p_0 \beta^j) < \infty$. Hence, for a uniform $C_1 \ge 1$ and $m = \inf_X u$,

$$\mathrm{e}^{-p_0 m} \le C_1 \int_X \mathrm{e}^{-p_0 u} \, \mathrm{d}\mu. \tag{9.5}$$

The right-hand side still involves the unknown potential. Divide by $\mathrm{e}^{-p_0 m}$ and set $A = p_0^{-1} \log(2C_1)$. The integrand $\mathrm{e}^{-p_0(u-m)}$ is at most one everywhere and at most $(2C_1)^{-1}$ outside $S = \{u \le m + A\}$. Therefore (9.5) implies

$$\mu(S) \ge \frac{1}{2C_1} =: \delta > 0.$$

Since $\sup_X u = 0$, Theorem 1.4.1 gives $\int_X (-u) \, \mathrm{d}\mu \le C_0$. On S we have $-u \ge -m - A$, so

$$C_0 \geq \int_X (-u)\,\mathrm{d}\mu \geq \delta(-m - A)$$

when $-m \geq A$; otherwise the desired bound is immediate. Thus $-m \leq A + C_0/\delta$, proving the theorem. □

9.3 The linearized equation and smooth dependence

Recall from (4.8) that the linearization of $u \mapsto \log(\omega_u^n/\mathrm{d}V)$ at u is $L_u v = n\,\mathrm{dd^c} v \wedge \omega_u^{n-1}/\omega_u^n$. This operator annihilates constants, and by Proposition 4.8.1 its range consists of the functions with zero mean under the adjoint probability measure μ_u. Including the scalar b as an unknown removes this obstruction. In dimension one, $\mu_u = \omega_u / \int_X \omega_u$, and the compatibility condition follows from Stokes' theorem.

The normalization $\sup_X u = 0$ is convenient for compactness, but it need not depend differentiably on the data. To differentiate solutions, we use instead the linear normalization

$$\int_X u\,\mathrm{d}V = 0.$$

Passing from one normalization to the other only adds a constant to u and leaves b unchanged.

Proposition 9.3.1 *With this linear normalization, the solution (u, b) of (9.1) depends smoothly on F in Hölder spaces, and hence smoothly on the parameters of every smooth finite-dimensional family of smooth data.*

Proof Fix an integer $k \geq 0$ and a real exponent $0 < \alpha < 1$. Consider the map

$$(u, b, F) \longmapsto \log \frac{(\omega + \mathrm{dd^c} u)^n}{\mathrm{d}V} - F - b$$

on the open set of potentials in $C^{k+2,\alpha}$ with $\omega_u > 0$, restricted to $\int_X u\,\mathrm{d}V = 0$. Its derivative in (u, b) is

$$(v, a) \longmapsto L_u v - a.$$

Given $h \in C^{k,\alpha}$, integrating $L_u v - a = h$ against μ_u forces $a = -\int_X h\,\mathrm{d}\mu_u$. For this value, the equation for v satisfies the compatibility condition of Proposition 4.8.1, and it has a unique solution with zero $\mathrm{d}V$-mean. Schauder estimates show that this inverse is bounded. The implicit function theorem in Banach spaces therefore gives a smooth local solution map around any given solution; this step does not use the global existence theorem. Uniqueness identifies the local maps wherever they overlap, and elliptic regularity allows arbitrary k for smooth data. □

9.4 Second derivatives and ellipticity

The equation controls the product of the eigenvalues of ω_u relative to ω, so an upper bound for their sum gives uniform ellipticity. We obtain this trace bound by completing a square in the differentiated equation. The remaining torsion term is of first order in the trace, and it can be absorbed at the maximum of a suitable function of the trace and the potential.

In holomorphic coordinates $(z^1, \dots, z^n)$, subscripts denote coordinate derivatives, inverse matrices carry upper indices, and repeated indices run from 1 to n. Write

$$\omega = \frac{\mathrm{i}}{2\pi} g_{i\bar{j}}\, \mathrm{d}z^i \wedge \mathrm{d}\bar{z}^j, \qquad \omega_u = \frac{\mathrm{i}}{2\pi} h_{i\bar{j}}\, \mathrm{d}z^i \wedge \mathrm{d}\bar{z}^j, \qquad h_{i\bar{j}} = g_{i\bar{j}} + u_{i\bar{j}}.$$

For a smooth real function v, set $\Delta_g v = g^{i\bar{j}} v_{i\bar{j}}$ and $\Delta_h v = h^{i\bar{j}} v_{i\bar{j}}$. Thus $\Delta_h = L_u$ and $\Delta_h u = n - \mathrm{tr}_h\, g$. Write also $|\partial v|_h^2 = h^{i\bar{j}} v_i v_{\bar{j}}$. Let ∇ be the Chern connection of the fixed metric g, with

$$\Gamma^p_{ik} = g^{p\bar{q}} \partial_i g_{k\bar{q}}, \qquad T^p_{ik} = \Gamma^p_{ik} - \Gamma^p_{ki}, \qquad \tau_k = \sum_i T^i_{ik}.$$

Here T is the torsion of ∇ and τ its trace; all bounds for this connection, its torsion and its curvature depend only on g.

Lemma 9.4.1 *Suppose $h = g + (u_{i\bar{j}}) > 0$, and put*

$$S = \mathrm{tr}_g\, h, \qquad B = \mathrm{tr}_h\, g, \qquad G = \log \frac{\det h}{\det g}.$$

There is C_g such that, at every point where $S \geq 1$,

$$\Delta_h \log S \geq \frac{2}{S^2} \mathrm{Re}\big(h^{k\bar{q}} \tau_k S_{\bar{q}}\big) + \frac{\Delta_g G}{S} - C_g B. \tag{9.6}$$

Proof The identity $\mathrm{d}\omega_u = \mathrm{d}\omega$ is equivalent to

$$\nabla_i h_{k\bar{j}} - \nabla_k h_{i\bar{j}} = T^p_{ik}(g_{p\bar{j}} - h_{p\bar{j}}), \tag{9.7}$$

together with its complex conjugate; this can also be checked directly, since the third derivatives of u cancel.

For tensors with two holomorphic and one antiholomorphic lower index, we use the norm

$$\|A\|^2 = g^{i\bar{\ell}} h^{k\bar{q}} h^{p\bar{j}} A_{ik\bar{j}} \overline{A_{\ell q\bar{p}}}.$$

Set $A_{ik\bar{j}} = \nabla_i h_{k\bar{j}}$ and $D_{ik\bar{j}} = T^p_{ik} h_{p\bar{j}}$. We first claim

$$\Delta_h S = \|A + D\|^2 + \Delta_g G + E, \qquad |E| \leq C_g(1 + S)B. \tag{9.8}$$

To prove this, start with $\Delta_h S = h^{i\bar{j}} g^{k\bar{\ell}} \nabla_i \nabla_{\bar{j}} h_{k\bar{\ell}}$. Switch $\bar{j}, \bar{\ell}$ by the conjugate of (9.7), commute $\nabla_i, \nabla_{\bar{\ell}}$, and then switch i, k by (9.7). The terms with a derivative of h are

$$h^{i\bar{j}} g^{k\bar{\ell}} \nabla_{\bar{\ell}} \nabla_k h_{i\bar{j}} - 2\,\mathrm{Re}\big(h^{i\bar{j}} g^{k\bar{\ell}} T^p_{ik} \nabla_{\bar{\ell}} h_{p\bar{j}}\big).$$

The first switch also produces the term $-h^{i\bar{j}} g^{k\bar{\ell}} \overline{T^q_{j\ell}} \nabla_i h_{k\bar{q}}$. Applying (9.7) to it gives one of the two conjugate derivative terms displayed above, together with

$$h^{i\bar{j}} g^{k\bar{\ell}} T^p_{ik} \overline{T^q_{j\ell}} (h_{p\bar{q}} - g_{p\bar{q}}).$$

The part of this expression containing $h_{p\bar{q}}$ is $\|D\|^2$. Differentiating the logarithmic determinant twice gives

$$\Delta_g G = h^{i\bar{j}} g^{k\bar{\ell}} \nabla_{\bar{\ell}} \nabla_k h_{i\bar{j}} - \|A\|^2.$$

By the antisymmetry of T, the two remaining derivative terms combine to $2\,\mathrm{Re}\langle A, D\rangle$, where $\langle \cdot, \cdot \rangle$ is the inner product of the norm above. These identities give (9.8).

To bound the remainder E explicitly, let

$$C_{i\bar{\ell}k\bar{j}} = (\nabla_i \nabla_{\bar{\ell}} - \nabla_{\bar{\ell}} \nabla_i) h_{k\bar{j}}.$$

The remainder is the contraction by $h^{i\bar{j}} g^{k\bar{\ell}}$ of

$$\begin{aligned}(\nabla_i \overline{T^q_{j\ell}})(g_{k\bar{q}} - h_{k\bar{q}}) + (\nabla_{\bar{\ell}} T^p_{ik})(g_{p\bar{j}} - h_{p\bar{j}}) \\ + C_{i\bar{\ell}k\bar{j}} - T^p_{ik} \overline{T^q_{j\ell}} g_{p\bar{q}}.\end{aligned}$$

The commutator C is the curvature of ∇ acting linearly on h, as one sees by inserting $\nabla = \partial + \Gamma$ and canceling the derivatives of h. In a g-unitary frame diagonalizing h, every coefficient in this remainder is bounded by $C_g(1 + S)$, so the contraction is bounded by $C_g(1 + S) \sum_i h^{i\bar{i}} = C_g(1 + S)B$, as asserted. In particular, no derivative of h remains in E.

It remains to control the gradient term introduced by the logarithm. Define

$$H_{ik\bar{j}} = h_{i\bar{j}} \frac{S_k}{S}, \qquad K = \|A + D - H\|^2 \geq 0.$$

By (9.7),

$$g^{i\bar{\ell}} (A + D)_{ik\bar{\ell}} = S_k + \tau_k.$$

Moreover $\|H\|^2 = |\partial S|^2_h / S$. Expanding the square therefore gives

$$K = \|A + D\|^2 - \frac{|\partial S|^2_h}{S} - \frac{2}{S} \mathrm{Re}(h^{k\bar{q}} \tau_k S_{\bar{q}}).$$

Combining this with (9.8) and with $\Delta_h \log S = \Delta_h S / S - |\partial S|^2_h / S^2$, we obtain the exact identity

$$\Delta_h \log S = \frac{K}{S} + \frac{2}{S^2}\operatorname{Re}(h^{k\bar{q}}\tau_k S_{\bar{q}}) + \frac{\Delta_g G}{S} + \frac{E}{S}.$$

Since $K \geq 0$ and $S \geq 1$, and since $E/S \geq -2C_g B$, enlarging the constant proves the lemma. □

Theorem 9.4.1 *Fix $D, K > 0$ and a smooth real function G on X. Suppose u is smooth, $\omega_u > 0$, and*

$$\operatorname{osc}_X u \leq D, \qquad \omega_u^n = e^G \omega^n, \qquad |G| \leq K, \qquad \Delta_g G \geq -K.$$

There is a constant $C = C(\omega, D, K)$ such that

$$C^{-1}\omega \leq \omega_u \leq C\omega.$$

Proof Use $h = g + (u_{i\bar{j}})$, $S = \operatorname{tr}_g h$, and $B = \operatorname{tr}_h g$ as in Lemma 9.4.1. Write $s = u - \inf_X u + 1$, so that $1 \leq s \leq D + 1$, and consider the maximum of

$$Q = \log S - Au + s^{-1}$$

on X, where $A \geq 1$ will be fixed below. Let x be a maximum point. If $S(x) < 1$, an upper bound for S on X already follows from the oscillation bound and the definition of Q, as at the end of the proof. We may therefore assume $S(x) \geq 1$ and use Lemma 9.4.1.

Since the eigenvalues of h relative to g are positive, $SB \geq n^2$, and hence $\Delta_g G/S \geq -KB/n^2$. Moreover, $\partial Q = 0$ at x gives

$$\frac{S_k}{S} = (A + s^{-2})u_k.$$

Because $|\tau|_h^2 \leq C_g B$, the absolute value of the torsion term is bounded by

$$\begin{aligned}\left|\frac{2}{S^2}\operatorname{Re}(h^{k\bar{q}}\tau_k S_{\bar{q}})\right| &\leq \frac{C_g(A+1)}{S}\sqrt{B}\,|\partial u|_h \\ &\leq \frac{|\partial u|_h^2}{s^3} + \frac{C_g(A+1)^2 s^3}{S^2}B.\end{aligned} \tag{9.9}$$

If $S(x)^2 \leq (A+1)^2(D+1)^3$, then $S(x)$ is bounded once A is fixed, and again so is S on X. In the remaining case the coefficient of B in the last term is at most C_g.

On the other hand, direct computation gives

$$\Delta_h Q = \Delta_h \log S + (A + s^{-2})(B - n) + 2s^{-3}|\partial u|_h^2.$$

The trace inequality and (9.9) imply at x

$$0 \geq \Delta_h Q \geq (A - C_g - K/n^2)B - n(A+1),$$

after a fixed enlargement of C_g. Choosing $A > C_g + K/n^2 + 1$, we conclude that $B(x)$ is bounded. If $\lambda_1, \dots, \lambda_n$ are the eigenvalues of h relative to g, then $\prod_i \lambda_i = \mathrm{e}^G$, and for $n \geq 2$

$$S = \sum_i \lambda_i = \mathrm{e}^G \sum_i \prod_{j \neq i} \lambda_j^{-1} \leq n \mathrm{e}^K B^{n-1}.$$

For $n = 1$, directly $S = \mathrm{e}^G$. Thus $S(x)$ is bounded in all cases. For every $y \in X$, the maximality of Q at x gives

$$\log S(y) \leq \log S(x) + A(u(y) - u(x)) + s(x)^{-1} - s(y)^{-1} \leq \log S(x) + AD + 1.$$

This proves $S \leq C$ on X. The lower bound for the determinant then gives $\lambda_i \geq \mathrm{e}^{-K} C^{-(n-1)}$, which proves the uniform equivalence. □

Some equations give a trace estimate that still depends on the gradient. A linear dependence suffices to close the estimate, because elliptic regularity for the fixed operator Δ_g bounds a Hölder norm of the gradient, and interpolation makes its contribution to the supremum norm arbitrarily small.

Lemma 9.4.2 *Let $A, M \geq 0$. There is $C = C(g, A, M)$ such that every smooth real function v on X satisfying*

$$\operatorname{osc}_X v \leq M, \qquad \|\Delta_g v\|_{L^\infty} \leq A\big(1 + \|\mathrm{d}v\|_{L^\infty(g)}\big)$$

also satisfies

$$\|\mathrm{d}v\|_{L^\infty(g)} + \|\Delta_g v\|_{L^\infty} \leq C.$$

Here all volume and function-space norms use the fixed smooth metric g.

Proof Subtract $\inf_X v$, so that $0 \leq v \leq M$, and put $K = \|\mathrm{d}v\|_{L^\infty(g)}$. Fix $p > 2n$ and $0 < \alpha < 1 - 2n/p$. The fixed operator Δ_g is uniformly elliptic on the underlying real manifold. The local $W^{2,p}$ estimates, patched by a finite atlas, and Morrey's inequality give

$$\|v\|_{C^{1,\alpha}} \leq C_g \|v\|_{W^{2,p}} \leq C_g\big(\|v\|_{L^p} + \|\Delta_g v\|_{L^p}\big) \leq C_g\big(M + A(1 + K)\big).$$

These are the standard linear elliptic estimates of [GT01, Chapter 9]; the constants depend on the fixed metric and on the chosen p, α.

For $0 < t \leq t_0$, with t_0 fixed by the atlas, integration along a coordinate segment of length t gives

$$K \leq C_g t^{-1} M + C_g t^\alpha \|v\|_{C^{1,\alpha}}.$$

Indeed, the difference quotient is bounded by $2M/t$, and its difference from the derivative at the initial point is bounded by $C_g t^\alpha \|v\|_{C^{1,\alpha}}$. A finite atlas with smaller charts controls every point and coordinate direction; equivalence with the g-norm gives the displayed estimate. Consequently,

$$K \leq C_g t^{-1} M + C_g^2 t^\alpha (M + A) + C_g^2 A t^\alpha K.$$

Choose $t \le t_0$ so small that $C_g^2 A t^\alpha \le 1/2$. This choice depends only on g, A, including when $A = 0$. Absorbing the last term bounds K in terms of g, A, M, and the assumed trace estimate then bounds $\|\Delta_g v\|_\infty$. □

Corollary 9.4.1 *Fix ω. For smooth solutions of*

$$(\omega + \mathrm{dd^c} u)^n = \mathrm{e}^G \omega^n, \qquad \omega + \mathrm{dd^c} u > 0,$$

a uniform C^0 bound for u and uniform bounds for the smooth real logarithmic density G in every C^k norm imply uniform bounds for u in every C^k norm.

Proof Theorem 9.4.1 gives uniform ellipticity and a bound for $\Delta_g u = S - n$. The linear elliptic $W^{2,p}$ estimates for the fixed operator Δ_g first bound u in $C^{1,\alpha}$ for every $0 < \alpha < 1$. The local Evans–Krylov estimate for the concave logarithmic determinant then gives a uniform $C^{2,\beta}$ bound for some $0 < \beta < 1$. To apply it in its real form, project real symmetric Hessians to their complex Hermitian part and extend the logarithmic determinant concavely from the compact set of positive matrices given by the preceding theorem. The extension is uniformly elliptic on real symmetric matrices because the projection preserves positivity and the trace, so the usual Evans–Krylov theorem applies. Finally, differentiating the equation gives linear uniformly elliptic equations with Hölder coefficients, and Schauder estimates and induction give all higher bounds. No regularity results beyond these standard local elliptic estimates are needed. □

The same conclusion holds for equations $\omega_u^n = \mathrm{e}^{au+F}\omega^n$ with a in a fixed bounded interval of nonnegative numbers, u uniformly bounded, and F uniformly bounded in every C^k norm. Indeed, with $G = au + F$,

$$\Delta_g(au + F) = a(S - n) + \Delta_g F \ge -an + \Delta_g F,$$

so Theorem 9.4.1 applies without any prior bound for derivatives of u. The estimate for the fixed operator Δ_g then gives a $C^{1,\alpha}$ bound, after which the same local regularity and bootstrapping apply.

9.5 The continuity method

We join the background density to the prescribed one by a path of equations. The local inverse of Proposition 9.3.1 shows that the set of solvable parameters is open. The extremum bound for the scalar, the potential estimate and the derivative estimates give compactness along the path, and uniform ellipticity preserves positivity at a limiting parameter.

Proof (of Theorem 9.1.1) The case $n = 1$ was treated after the statement of the theorem. For $n \ge 2$ put $G = F + \log(\mathrm{d}V/\omega^n)$ and consider

$$(\omega + \mathrm{dd^c} u_t)^n = \mathrm{e}^{tG+b_t}\omega^n, \qquad \sup_X u_t = 0, \qquad 0 \le t \le 1.$$

At $t = 0$, take $u_0 = 0$ and $b_0 = 0$. The local implicit-function argument in Proposition 9.3.1, with the additive constant temporarily fixed by a linear mean, shows that the set of solvable parameters is open.

At every solvable parameter, Proposition 9.1.1 gives

$$-\sup_X(tG) \le b_t \le -\inf_X(tG), \qquad \mathrm{e}^{tG+b_t} \le \mathrm{e}^{\operatorname{osc}_X G}.$$

The constants b_t are therefore uniformly bounded, and Theorem 9.2.1 bounds u_t in C^0. By Corollary 9.4.1, the solutions are bounded in every C^k norm. Along any sequence of solvable parameters converging in $[0,1]$, a subsequence of (u_t, b_t) therefore converges smoothly to a solution; uniform equivalence of the metrics preserves strict positivity, and the supremum normalization passes to the limit. Thus the solvable set is closed. Since it is nonempty, open and closed, connectedness of $[0,1]$ gives a solution at $t = 1$, and Proposition 9.1.2 gives uniqueness. □

9.6 The smooth exponential equation

When the logarithmic density contains a positive multiple of the potential, the extrema of the potential are bounded directly, and the linearization acquires a negative zeroth-order term. The continuity method then needs neither an additive normalization nor an extra scalar unknown.

Proposition 9.6.1 *Let $\lambda > 0$, let F be smooth, and let v, w be smooth strictly ω-plurisubharmonic functions. If*

$$\omega_v^n \ge \mathrm{e}^{\lambda v + F}\omega^n, \qquad \omega_w^n \le \mathrm{e}^{\lambda w + F}\omega^n,$$

then $v \le w$. In particular, two smooth solutions coincide.

Proof Suppose that $v - w$ has a positive maximum at a point x. Then $\omega_v(x) \le \omega_w(x)$, and taking determinants and applying the two assumptions gives $\mathrm{e}^{\lambda v(x)+F(x)} \le \mathrm{e}^{\lambda w(x)+F(x)}$, which contradicts $v(x) > w(x)$. For two solutions, apply the comparison in both orders. □

Theorem 9.6.1 *For every $\lambda > 0$ and every smooth real F, there is a unique smooth u with $\omega_u > 0$ such that*

$$\omega_u^n = \mathrm{e}^{\lambda u + F}\omega^n.$$

The solution satisfies

$$-\lambda^{-1}\sup_X F \le u \le -\lambda^{-1}\inf_X F.$$

Proof At a minimum of u, the equation gives $\lambda u + F \ge 0$; at a maximum it gives $\lambda u + F \le 0$. These inequalities prove the stated bounds.

Consider the equations

$$\omega_{u_t}^n = e^{\lambda u_t + tF}\omega^n, \qquad 0 \le t \le 1.$$

At $t = 0$, $u_0 = 0$ is a solution. The linearization in u is $L_u - \lambda$, whose kernel is zero by the maximum principle. Its Fredholm index is zero: deform its principal coefficients to those of a fixed Laplacian while keeping the negative zeroth-order term; the latter operator is invertible, and the index is constant along this deformation of elliptic operators. Thus $L_u - \lambda$ is an isomorphism between the usual Hölder spaces, with bounded inverse by Schauder theory, and the implicit function theorem proves that the set of solvable parameters is open.

The extremum bounds give $\|u_t\|_\infty \le \lambda^{-1}\|F\|_\infty$. The semilinear version of Theorem 9.4.1 and Corollary 9.4.1, stated in the remark following that corollary, then gives uniform ellipticity and bounds in every C^k norm. Along any convergent sequence of solvable parameters, a subsequence of the solutions therefore converges smoothly to a strictly positive solution at the limit parameter. This proves closedness, and hence existence at $t = 1$. Uniqueness is Proposition 9.6.1. □

For a fixed smooth real obstacle f on X and a parameter $\beta > 0$, the choice $\lambda = \beta$ and $F = -\beta f$ gives

$$\omega_{u_\beta}^n = e^{\beta(u_\beta - f)}\omega^n.$$

These equations penalize values above the obstacle. In Proposition 13.1.1 we use them to construct the envelope of f and to show that its Monge–Ampère measure is supported on the contact set. The convergence argument there uses only bounded regularization and the comparison just proved.

9.7 Variation of the normalization scalar

Integration against the adjoint probability measure eliminates the derivatives of the potential from the first variation of b. In the second variation, the second derivative of the logarithmic determinant contributes a nonnegative square with a minus sign. This gives concavity of b and identifies the equality case.

Write $b(F)$ for the scalar in (9.1), and use the linear normalization $\int_X u\,dV = 0$. For a smooth family F_t, with t in an open interval $I \subset \mathbb{R}$, write (u_t, b_t) for the corresponding solutions and put $\eta_t = \omega_{u_t}$. By Proposition 9.3.1 these depend smoothly on t; a dot denotes differentiation in t.

Theorem 9.7.1 *Let $A_t = \eta_t^{-1}\mathrm{dd^c}\dot{u}_t$ be the endomorphism of the tangent bundle that represents the real $(1,1)$-form $\mathrm{dd^c}\dot{u}_t$ with respect to η_t; it is Hermitian with respect to η_t. The normalization constant satisfies*

$$\dot{b}_t = -\int_X \dot{F}_t \,\mathrm{d}\mu_{u_t}, \tag{9.10}$$

$$\ddot{b}_t = -\int_X \ddot{F}_t \,\mathrm{d}\mu_{u_t} - \int_X \mathrm{tr}(A_t^2)\,\mathrm{d}\mu_{u_t}. \tag{9.11}$$

In particular, for smooth real functions F_0, G on X and the affine family $F_t = F_0 + tG$, the function b_t is concave. Its second derivative vanishes at a parameter value if and only if G is constant on X.

Proof Differentiating the logarithm of (9.1) gives

$$L_{u_t}\dot{u}_t = \dot{F}_t + \dot{b}_t.$$

Integration against μ_{u_t} proves (9.10).

For a smooth family of positive Hermitian matrices H_t, differentiation of the inverse matrix gives

$$\frac{\mathrm{d}^2}{\mathrm{d}t^2}\log\det H_t = \mathrm{tr}(H_t^{-1}\ddot{H}_t) - \mathrm{tr}\big((H_t^{-1}\dot{H}_t)^2\big).$$

Apply this pointwise to the matrices of η_t, using $\dot{\eta}_t = \mathrm{dd^c}\dot{u}_t$ and $\ddot{\eta}_t = \mathrm{dd^c}\ddot{u}_t$. The second derivative of the logarithmic equation is

$$L_{u_t}\ddot{u}_t - \mathrm{tr}(A_t^2) = \ddot{F}_t + \ddot{b}_t.$$

Integrating against μ_{u_t} at this fixed parameter proves (9.11); there is no need to differentiate the measure.

The eigenvalues of the Hermitian endomorphism A_t are real, so $\mathrm{tr}(A_t^2) \geq 0$. For affine F_t we have $\ddot{F}_t = 0$, so the second derivative of b_t is nonpositive. If it vanishes, strict positivity of the smooth density of μ_{u_t} implies $A_t = 0$ everywhere. Thus $\mathrm{dd^c}\dot{u}_t = 0$, and the maximum principle shows that $\dot{u}_t$ is constant. The first differentiated equation then gives $G = -\dot{b}_t$, a constant. Conversely, if G is constant, the solution metric is independent of t and $b_t = b_0 - tG$. □

Corollary 9.7.1 *For two smooth functions F, G, the normalization constants satisfy*

$$-\sup_X(G-F) \le b(G)-b(F) \le -\inf_X(G-F).$$

In particular, $|b(G)-b(F)| \le \|G-F\|_\infty$. If $G-F$ is nonconstant, both inequalities in the first display are strict.

Proof Apply (9.10) along $F_t = F + t(G-F)$ and integrate over $0 \le t \le 1$. Each μ_{u_t} is a probability measure with strictly positive smooth density, so the integral of a nonconstant continuous function against it lies strictly between the minimum and the maximum of that function. □

Thus b is a decreasing, concave, Lipschitz functional of the logarithmic density, with $b(F+a) = b(F) - a$ for every real constant a. By uniform approximation, it extends uniquely to a Lipschitz functional of continuous F. This extension concerns the scalar functional only; the existence and regularity of corresponding potentials require further estimates.

9.8 Normalization on the Hopf threefold

On the Hopf threefold of Chapter 8, the deviation of b from the closed-background formula (9.2) can be computed: it is the energy of the solution along the elliptic fibers. In this section, X is that threefold and ω its Gauduchon metric; we use the projection $\pi : X \to \mathbb{P}^2$, the probability measure $\nu = \omega^3/6$ and the averaging operator A of Proposition 8.7.1, and we write $\beta = \omega - \pi^*\omega_{\mathrm{FS}}$ for the rank-one form of that construction. As in Chapter 8, the fiber derivative u_w does not depend on the local trivialization of the elliptic bundle.

For $F \in C^\infty(X,\mathbb{R})$, let $(u_F, b(F))$ be the solution of

$$(\omega + \mathrm{dd^c} u_F)^3 = \mathrm{e}^{F+b(F)}\omega^3, \qquad \omega + \mathrm{dd^c} u_F > 0, \qquad \int_X u_F \,\mathrm{d}\nu = 0.$$

Define

$$D(F) = b(F) + \log \int_X \mathrm{e}^F \,\mathrm{d}\nu.$$

For a closed background, the corresponding quantity vanishes by (9.2).

Proposition 9.8.1 *For every smooth real F on this threefold,*

$$e^{D(F)} = 1 + \int_X |(u_F)_w|^2 \, d\nu, \tag{9.12}$$

$$\|u_F - Au_F\|^2_{L^2(X,\nu)} \le 4\big(e^{D(F)} - 1\big). \tag{9.13}$$

Thus $D(F) \ge 0$, with equality if and only if $F = \pi^* H$ for some $H \in C^\infty(\mathbb{P}^2, \mathbb{R})$.

Proof Integration of the equation and (8.2) give

$$e^{D(F)} = \frac{1}{6}\int_X (\omega + dd^c u_F)^3 = 1 + \int_X |(u_F)_w|^2 \, d\nu.$$

Substituting the first equality into (8.21) proves (9.13).

If $D(F) = 0$, then $(u_F)_w = 0$ everywhere, because u_F is smooth. Since u_F is real, it is constant on each connected fiber, so it descends to a smooth real function q on $\mathbb{P}^2$, and $\omega_{FS} + dd^c q > 0$ as in the proof of Proposition 8.7.1. Since $\beta^2 = 0$ and $\omega = \pi^*\omega_{FS} + \beta$, we have

$$(\omega + dd^c \pi^* q)^3 = 3\pi^*(\omega_{FS} + dd^c q)^2 \wedge \beta.$$

Dividing by $\omega^3 = 3\pi^*\omega_{FS}^2 \wedge \beta$ and taking logarithms proves that F is a smooth base pullback.

Conversely, suppose $F = \pi^* H$. Apply Theorem 9.1.1 on $(\mathbb{P}^2, \omega_{FS})$ to obtain a smooth real q and a scalar c with

$$\omega_{FS} + dd^c q > 0, \qquad (\omega_{FS} + dd^c q)^2 = e^{H+c}\omega_{FS}^2.$$

Since the base form is closed, Stokes' theorem gives $e^c \int_{\mathbb{P}^2} e^H \omega_{FS}^2 = 1$. The preceding cube identity shows that $\pi^* q$, after subtraction of its ν-mean, solves the equation on X with scalar c, and uniqueness gives $b(F) = c$. Since the base measure of ν is ω_{FS}^2, it follows that $D(F) = 0$. □

In particular, if a smooth positive density f satisfies $\int_X f \, d\nu = 1$, the equation $(\omega + dd^c u)^3 = e^b f \omega^3$ has $b \ge 0$, with equality if and only if f is the pullback of a function on the base. Fixing the total integral of the density therefore does not determine the scalar on this nonclosed background.

Corollary 9.8.1 *Let $G \in C^\infty(X, \mathbb{R})$, let $L_0 v = 3\, dd^c v \wedge \omega^2/\omega^3$ be the linearized operator at $u = 0$, and let v be the unique smooth real function satisfying*

$$L_0 v = G - \int_X G \, d\nu, \qquad \int_X v \, d\nu = 0.$$

Then

$$\frac{d}{dt} D(tG)\Big|_{t=0} = 0, \qquad \frac{d^2}{dt^2} D(tG)\Big|_{t=0} = 2\int_X |v_w|^2 \, d\nu.$$

The second derivative vanishes if and only if G is a smooth base pullback.

Proof For real t near zero put $u_t = u_{tG}$ and $b_t = b(tG)$. By Proposition 9.3.1, this is a smooth family, with $u_0 = b_0 = 0$. Differentiating the logarithmic equation at $t = 0$ gives $L_0\dot{u}_0 = G + \dot{b}_0$. Since ω is Gauduchon, ν is the adjoint probability measure of L_0, and integration gives $\dot{b}_0 = -\int_X G\,\mathrm{d}\nu$. Hence $\dot{u}_0 = \nu$; this also proves the existence and uniqueness of ν.

Smooth dependence gives $(u_t)_w = tv_w + O(t^2)$ uniformly on X, so (9.12) gives

$$\mathrm{e}^{D(tG)} = 1 + t^2 \int_X |v_w|^2\,\mathrm{d}\nu + O(t^3).$$

Taking logarithms proves the derivative formulas.

If the second derivative vanishes, then $v_w = 0$, so $v = \pi^* q$ for a smooth real function q on the base. Expanding $\omega^2 = \pi^*\omega_{\mathrm{FS}}^2 + 2\pi^*\omega_{\mathrm{FS}} \wedge \beta$ gives

$$L_0(\pi^* q) = \pi^*\left(\frac{2\mathrm{dd}^{\mathrm{c}} q \wedge \omega_{\mathrm{FS}}}{\omega_{\mathrm{FS}}^2}\right).$$

Hence $G = L_0 v + \int_X G\,\mathrm{d}\nu$ is a base pullback. Conversely, when G is a base pullback, Proposition 9.8.1 gives $D(tG) = 0$ for every real t. □

This is a second-variation formula at the background density only. It does not determine whether D is convex globally, because the second derivatives of b and of the logarithmic integral have opposite signs.

9.9 Prescribing a Gauduchon volume form

We now return to a general connected compact complex manifold X, of dimension $n \geq 2$. To stay in a fixed Aeppli class of Gauduchon metrics, we vary the $(n-1)$st power of the metric by a term of the form $\partial\xi + \bar{\partial}\bar{\xi}$. The resulting scalar ansatz contains first derivatives of the potential as well as its complex Hessian.

Theorem 9.9.1 (Székelyhidi–Tosatti–Weinkove) *Fix a Hermitian form γ_0, a Gauduchon form γ, and a smooth real function F. There is a unique pair $(u, b) \in C^\infty(X, \mathbb{R}) \times \mathbb{R}$ with $\sup_X u = 0$ such that the $(n-1, n-1)$-form*

$$\Gamma_u = \gamma_0^{n-1} + \mathrm{dd^c} u \wedge \gamma^{n-2} + \mathrm{Re}\left(\frac{\mathrm{i}}{2\pi} \partial u \wedge \bar\partial (\gamma^{n-2}) \right)$$

is strictly positive, and the Hermitian form η_u with $\eta_u^{n-1} = \Gamma_u$ satisfies

$$\eta_u^n = \mathrm{e}^{F+b} \gamma^n .$$

Here we use the linear-algebra fact that a real $(n-1, n-1)$-form is strictly positive if and only if it is the $(n-1)$st power of a Hermitian form, and that this Hermitian form is unique; the matrix form of this correspondence is described in Section 9.12. Keep γ_0 and γ fixed for the remainder of the chapter, and write $\mathcal{D}_\gamma u = \Gamma_u - \gamma_0^{n-1}$ for the part of the ansatz that is linear in u.

To see which geometry is preserved, set $\xi_u = \mathrm{i}\, \bar\partial u \wedge \gamma^{n-2}/(4\pi)$. The Leibniz rule gives $\Gamma_u - \gamma_0^{n-1} = \partial \xi_u + \overline{\partial \xi_u}$. Since $\mathrm{dd^c}(\partial \xi_u + \overline{\partial \xi_u}) = 0$, if γ_0 is Gauduchon then so is η_u, and the $(n-1)$st powers of γ_0 and η_u have the same Aeppli class. The uniqueness in Theorem 9.9.1 concerns this scalar ansatz; it does not assert uniqueness among all Gauduchon metrics in the Aeppli class.

9.10 Bounds for the Gauduchon potential

Taking the trace of the positive form Γ_u gives a lower bound for a fixed linear elliptic operator applied to the potential, and its Green kernel then gives an L^1 bound. Near a minimum, supporting affine functions select a contact set on which the gradient is small and the real Hessian is bounded below; the determinant equation forces this set to have uniformly positive volume. Combining the two estimates bounds the minimum. This is an Alexandrov–Bakelman–Pucci type argument.

Proposition 9.10.1 *Every smooth solution (u, b) of the equation in Theorem 9.9.1 with $\sup_X u = 0$ satisfies*

$$|b| + \|u\|_{L^\infty(X)} \le C .$$

The constant depends only on X, γ_0, γ and an upper bound for $\|F\|_\infty$; in particular, it does not depend on derivatives of F.

Proof We first bound the scalar. At a maximum of u, the first derivatives of u vanish and $\mathrm{dd^c} u \le 0$, so $\Gamma_u \le \gamma_0^{n-1}$; at a minimum the reverse inequality holds. The determinant is monotone with respect to the order of positive matrices, and $(\eta_u^n/\gamma^n)^{n-1}$ is the determinant of the coefficient matrix of Γ_u relative to γ (see (9.18) below). Evaluating the equation at these two points gives

$$\inf_X \left(\log \frac{\gamma_0^n}{\gamma^n} - F \right) \le b \le \sup_X \left(\log \frac{\gamma_0^n}{\gamma^n} - F \right) .$$

This proves the scalar bound.

Consider the fixed real linear elliptic operator

$$Lu = \frac{\gamma \wedge \mathcal{D}_\gamma u}{\gamma^n}.$$

Its principal part is $\mathrm{dd}^{\mathrm{c}} u \wedge \gamma^{n-1}/\gamma^n$, its remaining term is of first order, and it has no zeroth-order term. Since Γ_u is positive, $\gamma \wedge \Gamma_u \geq 0$, and therefore $Lu \geq -C_0$ for a fixed constant C_0.

By the Fredholm and maximum-principle argument in the proof of Theorem 4.1.1, the operator L has an adjoint probability measure ν with smooth strictly positive density, that is, $\int_X Lv \, \mathrm{d}\nu = 0$ for every smooth v. Since $Lv \leq 0$ at a maximum of v, its normalized Green kernel can be written

$$v(x) - \int_X v \, \mathrm{d}\nu = -\int_X K(x,y) Lv(y) \, \mathrm{d}\nu(y),$$
$$K \geq 0, \qquad \sup_x \int_X K(x,y) \, \mathrm{d}\nu(y) < +\infty.$$

Here the kernel is smooth off the diagonal and locally integrable. To obtain this representation, construct the inverse of L on functions of zero ν-mean by the Fredholm alternative. With the minus sign above, the local fundamental solution has a positive leading singularity, so compactness gives a lower bound for the kernel. Adding a constant to K makes it nonnegative and does not change the formula, since $\int_X Lv \, \mathrm{d}\nu = 0$. The local estimates for the Green kernel give the uniform integral bound.

Apply the formula to u and use $Lu \geq -C_0$. At a maximum point, where $u = 0$, we obtain

$$-\int_X u \, \mathrm{d}\nu \leq C_1.$$

Because $u \leq 0$ and ν has a fixed smooth positive density, this is a uniform L^1 bound for u with respect to any fixed smooth volume form.

Now let $M = \min_X u$, and choose holomorphic coordinates on a ball centered at a minimum point. By compactness, the coordinate radius can be fixed, with uniform bounds for the metric coefficients and their derivatives; rescale the ball to the unit ball $B \subset \mathbb{R}^{2n}$. Write x for the real coordinates, D and D^2 for the Euclidean gradient and Hessian, $\mathrm{d}x$ for Euclidean volume, and I for an identity matrix of the appropriate size. Fix a small number $\varepsilon > 0$, depending only on those bounds, and set

$$v(x) = u(x) + \varepsilon |x|^2.$$

For every real vector p with $|p| < \varepsilon/2$, the function $v(x) - p \cdot x$ attains its minimum at an interior point, because its boundary values are larger than $M + \varepsilon/2$, whereas its value at the center is M. At such a point,

$$Dv = p, \qquad D^2 v \geq 0, \qquad v \leq M + \varepsilon/2.$$

Let $A \subset B$ be the set of all points satisfying $|Dv| \le \varepsilon/2$, $D^2 v \ge 0$, and $v \le M + \varepsilon/2$. Since $u \ge M$, this set lies in $\{|x| \le 1/\sqrt{2}\}$. It is closed there, hence compact in B, and by the preceding paragraph its image under the gradient map Dv contains the ball $B_{\varepsilon/2}$ of radius $\varepsilon/2$. The area formula for the smooth gradient map therefore gives

$$|B_{\varepsilon/2}| \le \int_A \det D^2 v \, \mathrm{d}x. \tag{9.14}$$

The Hessian is nonnegative on A, so no absolute value is needed in the determinant.

We now bound this determinant pointwise on A. There,

$$|Du| \le \frac{5}{2}\varepsilon, \qquad D^2 u \ge -2\varepsilon I.$$

The complex Hessian of u has the corresponding lower bound. Wedging with the fixed positive form γ^{n-2} and bounding the first-order term of Γ_u by the gradient estimate, we find that $\Gamma_u \ge \gamma_0^{n-1} - C\varepsilon\gamma^{n-1}$. Let Q_u be the coefficient matrix of Γ_u in a fixed local frame of $(n-1,0)$-forms. Since γ_0^{n-1} is strictly positive, choosing ε small gives

$$Q_u \ge cI$$

with a uniform $c > 0$. The equation and the bounds for $F + b$ already proved bound $\det Q_u$ from above, because the determinant of this matrix is, up to a fixed positive factor depending on the frame, the $(n-1)$st power of the density of η_u^n. All eigenvalues of Q_u are therefore bounded above as well: their product is bounded, and each of them is at least c.

In particular, $\gamma \wedge \Gamma_u / \gamma^n$ is uniformly bounded on A. Subtracting its fixed background term and its bounded first-order term, we obtain an upper bound for

$$\frac{\mathrm{d}\mathrm{d}^{\mathrm{c}} u \wedge \gamma^{n-1}}{\gamma^n}.$$

This is a fixed positive multiple of the γ-trace of the complex Hessian of u, which differs from that of v by a bounded term. The complex Hessian of v is nonnegative on A, since the real Hessian is nonnegative there, so comparison of metrics bounds its Euclidean trace from above. The real trace of $D^2 v$ is four times this complex trace. It follows that

$$0 \le \det D^2 v \le \left(\frac{\mathrm{tr}_{\mathbb{R}} D^2 v}{2n} \right)^{2n} \le C_2 \quad \text{on } A.$$

Inequality (9.14) now gives $|A| \ge c_2 > 0$, where c_2 is independent of u. On A we also have $u \le v \le M + \varepsilon/2$. Consequently the uniform L^1 bound gives

$$C_3 \ge \int_A (-u) \, \mathrm{d}x \ge c_2(-M - \varepsilon/2).$$

This bounds $-M$ and completes the proof. □

9.11 The adjoint equation for Gauduchon volume

As for the Monge–Ampère equation, solving the linearized Gauduchon volume equation requires a compatibility condition, given by an adjoint probability measure. Taking the $(n-1)$st root multiplies the trace linearization by the factor $n/(n-1)$, and the first-order term of the ansatz introduces a drift term. We compute the linearized operator at any potential with $\Gamma_u > 0$, and then express its adjoint condition as an equation for a positive $(1,1)$-form. Throughout this section we put $K = \gamma^{n-2}$.

Proposition 9.11.1 *On the open set of smooth potentials u with $\Gamma_u > 0$, the derivative of*

$$\mathcal{G}(u) = \log \frac{\eta_u^n}{\gamma^n}$$

is the real elliptic operator

$$\mathcal{L}_u v = \frac{n}{n-1} \frac{\eta_u \wedge \mathcal{D}_\gamma v}{\eta_u^n}. \tag{9.15}$$

It has no zeroth-order term, and its kernel consists of the constants. There is a unique smooth positive function ρ_u, normalized by $\int_X \rho_u \eta_u^n = 1$, such that the probability measure

$$\mathrm{d}\mu_u^\gamma = \rho_u \eta_u^n$$

satisfies $\int_X \mathcal{L}_u v \, \mathrm{d}\mu_u^\gamma = 0$ for every smooth real v.

Proof For a smooth path of potentials $u(t)$, write $\eta = \eta_{u(t)}$ and $\Gamma = \Gamma_{u(t)}$. Differentiating $\eta^{n-1} = \Gamma$ gives $(n-1)\dot\eta \wedge \eta^{n-2} = \dot\Gamma$, where $\dot\Gamma = \mathcal{D}_\gamma \dot u$. Wedging with η and dividing by η^n, we obtain

$$\frac{\mathrm{d}}{\mathrm{d}t} \log \eta^n = \frac{n}{n-1} \frac{\eta \wedge \dot\Gamma}{\eta^n},$$

which proves (9.15).

Only the second-order term $\mathrm{dd}^{\mathrm{c}} v \wedge \gamma^{n-2}$ of $\mathcal{D}_\gamma v$ contributes to the principal symbol. For a nonzero complex covector ζ of type $(1,0)$, the form

$$\eta_u \wedge \mathrm{i}\zeta \wedge \overline{\zeta} \wedge \gamma^{n-2}$$

is a positive volume form. Hence the principal symbol is positive definite, and by compactness the operator is uniformly elliptic for each fixed u. The remaining term is of first order, and constants are annihilated, so the strong maximum principle gives $\ker \mathcal{L}_u = \mathbb{R}$.

The Fredholm and positivity arguments in the proof of Theorem 4.1.1 apply to this real elliptic operator with first-order terms and no zeroth-order term. Its index is zero by deformation to a Laplacian, so its formal adjoint with respect to η_u^n has a one-dimensional kernel spanned by a smooth strictly positive function. Normalizing its integral to one gives ρ_u and proves uniqueness. □

The adjoint condition can be expressed as an equation for the positive $(1,1)$-form $\rho_u \eta_u$. For a smooth real $(1,1)$-form A, set

$$\mathcal{A}_\gamma(A) = \mathrm{d}\mathrm{d}^{\mathrm{c}} A \wedge \gamma^{n-2} + \operatorname{Re}\left(\frac{\mathrm{i}}{2\pi} \partial A \wedge \bar\partial (\gamma^{n-2}) \right).$$

This is a real form of top degree, and $\mathcal{A}_\gamma$ is the formal adjoint of $\mathcal{D}_\gamma$ under the pairing of $(1,1)$-forms with $(n-1,n-1)$-forms, as the proof below shows.

Proposition 9.11.2 *The function ρ_u of Proposition 9.11.1 is characterized by*

$$\mathcal{A}_\gamma(\rho_u \eta_u) = 0, \qquad \int_X \rho_u \eta_u^n = 1. \tag{9.16}$$

When $n = 2$, its first equation is $\mathrm{d}\mathrm{d}^{\mathrm{c}}(\rho_u \eta_u) = 0$. When $\eta_u = \gamma$, the function ρ_u is constant and $\mathrm{d}\mu_u^\gamma = \gamma^n / \int_X \gamma^n$.

Proof We first prove that, for every smooth real $(1,1)$-form A and every smooth real function v on X,

$$\int_X A \wedge \mathcal{D}_\gamma v = \int_X v \, \mathcal{A}_\gamma(A). \tag{9.17}$$

Write $c = \mathrm{i}/(2\pi)$. Since A, K, v are real, expanding the real part gives

$$\mathcal{D}_\gamma v = c\, \partial\bar\partial v \wedge K + \frac{c}{2}\big(\partial v \wedge \bar\partial K - \bar\partial v \wedge \partial K \big).$$

Integrating the first term by parts twice gives $\int_X v\, c\partial\bar\partial (A \wedge K)$, and integrating each first-order term by parts once gives the correction

$$\int_X v \, \frac{c}{2}\big(-\partial A \wedge \bar\partial K + \bar\partial A \wedge \partial K - 2A \wedge \partial\bar\partial K \big).$$

Finally,

$$\partial\bar\partial (A \wedge K) = \partial\bar\partial A \wedge K - \bar\partial A \wedge \partial K + \partial A \wedge \bar\partial K + A \wedge \partial\bar\partial K.$$

Adding these contributions cancels the terms containing $A \wedge \partial\bar\partial K$ and leaves $\mathcal{A}_\gamma(A)$. This proves (9.17). Applied to $A = \rho_u \eta_u$, it shows by (9.15) that $\int_X \mathcal{L}_u v \, \mathrm{d}\mu_u^\gamma$ is a fixed positive multiple of $\int_X v\, \mathcal{A}_\gamma(\rho_u \eta_u)$, so the adjoint condition is equivalent to (9.16).

For $n = 2$, we have $K = 1$, which gives the first special case. For the second, the product rule gives

$$\mathcal{A}_\gamma(\gamma) = \frac{1}{n-1} \mathrm{d}\mathrm{d}^{\mathrm{c}}(\gamma^{n-1}) = 0.$$

By uniqueness, ρ_u is consequently the constant $(\int_X \gamma^n)^{-1}$. □

For $n > 2$ the equation for $\rho_u \eta_u$ involves the first derivatives of γ^{n-2}, so the fixed auxiliary metric γ remains part of the adjoint equation; it is not simply the Gauduchon condition for η_u.

9.12 The matrix structure of the Gauduchon equation

The Hodge star converts the positive $(n-1,n-1)$-form Γ_u into a Hermitian matrix whose logarithmic determinant is a concave function of the complex Hessian. Two features will control the largest eigenvalue in the second-order estimate: the positive background gives coercivity, and the torsion coefficients omit exactly those gradient indices that would otherwise carry the largest inverse weight. We derive both properties before differentiating the equation.

For the matrix and derivative calculations, set $v = u/(2\pi)$, so that $\mathrm{dd}^{\mathrm{c}}u = \mathrm{i}\partial\bar\partial v$. All covariant derivatives are taken with respect to the Chern connection ∇ of γ. In holomorphic coordinates $z^1,\dots,z^n$, write $v_i = \partial_i v$ and $v_{\bar\jmath} = \partial_{\bar\jmath} v$; indices range from 1 to n, and δ_{ij} is the Kronecker symbol. Write $\gamma = \mathrm{i}\gamma_{a\bar b}\,\mathrm{d}z^a \wedge \mathrm{d}\bar z^b$, with repeated indices summed. We denote by $\star_\gamma$ the Hodge star of γ, and by $\det_\gamma$ the determinant of the Hermitian matrix of a real $(1,1)$-form relative to γ. Write the torsion of ∇ as T^c_{ab} and lower the last index with γ. Thus

$$T_{ab\bar c} = \partial_a \gamma_{b\bar c} - \partial_b \gamma_{a\bar c}, \qquad T_{ab\bar c} = -T_{ba\bar c}.$$

Let $Q_0 = \star_\gamma \gamma_0^{n-1}/(n-1)!$ and

$$Z = \frac{1}{(n-1)!}\,\star_\gamma \operatorname{Re}\bigl(\mathrm{i}\partial v \wedge \bar\partial \gamma^{n-2}\bigr).$$

Here the real $(1,1)$-forms on the right are identified with their Hermitian coefficient matrices relative to γ. Set

$$\chi = (\operatorname{tr}_\gamma Q_0)\gamma - (n-1)Q_0, \quad W = (\operatorname{tr}_\gamma Z)\gamma - (n-1)Z, \quad g = \chi + \mathrm{i}\partial\bar\partial v + W.$$

The linear map $P_\gamma(A) = ((\operatorname{tr}_\gamma A)\gamma - A)/(n-1)$ on real $(1,1)$-forms, or Hermitian matrices, is invertible, and the equation of Theorem 9.9.1 becomes

$$\begin{aligned} Q_u &:= P_\gamma(g) = Q_0 + P_\gamma(\mathrm{i}\partial\bar\partial v) + Z > 0, \\ \log\det_\gamma Q_u &= h = (n-1)(F+b). \end{aligned} \tag{9.18}$$

Here $Q_u = \star_\gamma \Gamma_u/(n-1)!$ is the coefficient matrix of Γ_u. The tensor g need not be positive. To check the Hessian term, diagonalize $\mathrm{i}\partial\bar\partial v$ in a unitary frame: the coefficient of $\star_\gamma(\mathrm{i}\partial\bar\partial v \wedge \gamma^{n-2})/(n-1)!$ in each diagonal position is the sum of the other diagonal entries divided by $n-1$. If η_u has eigenvalues a_i relative to γ, then Q_u has eigenvalues $\prod_{j\neq i} a_j$, whose product is $(\prod_i a_i)^{n-1}$. This proves the determinant identity.

Lemma 9.12.1 *At a point in a unitary frame,*

$$2(n-1)Z_{i\bar{j}} = \delta_{ij}\sum_{p,k} v_p\overline{T_{pk\bar{k}}} - v_i\sum_k \overline{T_{jk\bar{k}}} - \sum_k v_k\overline{T_{kj\bar{i}}} + \delta_{ij}\sum_{p,k} v_{\bar{p}}T_{pk\bar{k}} - v_{\bar{j}}\sum_k T_{ik\bar{k}} - \sum_k v_{\bar{k}}T_{ki\bar{j}}. \tag{9.19}$$

In particular $Z_{i\bar{j}}$ contains no v_j or $v_{\bar{i}}$. Moreover

$$2(n-1)Z_{i\bar{i}} = \sum_{p\neq i,\ k\neq i} \bigl(v_p\overline{T_{pk\bar{k}}} + v_{\bar{p}}T_{pk\bar{k}}\bigr). \tag{9.20}$$

Covariant differentiation preserves these coefficient identities. For example $\nabla_1 Z_{1\bar{1}}$ contains no pure Hessian v_{11} or its conjugate, and $\nabla_{\bar{1}}\nabla_1 Z_{1\bar{1}}$ contains no $v_{11\bar{1}}$ or its conjugate, nor a pure v_{11} or its conjugate.

Proof For $n = 2$, the defining expression of Z is zero, and so are the formulas below, because the generalized Kronecker symbol with three indices vanishes in two dimensions. Suppose $n \geq 3$ and use coordinates that are unitary at the point. Direct antisymmetrization gives

$$\bar{\partial}\gamma = -\frac{\mathrm{i}}{2}\sum_{a,b,c} \overline{T_{bc\bar{a}}}\,\mathrm{d}z^a \wedge \mathrm{d}\bar{z}^b \wedge \mathrm{d}\bar{z}^c.$$

We use $\bar{\partial}\gamma^{n-2} = (n-2)\bar{\partial}\gamma \wedge \gamma^{n-3}$. To write the contraction explicitly, put

$$\delta^{paj}_{bci} = \det\begin{pmatrix} \delta_{pb} & \delta_{pc} & \delta_{pi} \\ \delta_{ab} & \delta_{ac} & \delta_{ai} \\ \delta_{jb} & \delta_{jc} & \delta_{ji} \end{pmatrix}.$$

Let $A = \star_\gamma(\mathrm{i}\partial v \wedge \bar{\partial}\gamma^{n-2})/(n-1)!$. Expanding the $n-3$ remaining copies of γ leaves the three complementary indices and gives

$$A_{i\bar{j}} = \frac{1}{2(n-1)}\sum_{p,a,b,c} v_p\overline{T_{bc\bar{a}}}\,\delta^{paj}_{bci}.$$

Indeed, the factor is $(n-2)(n-3)!/[2(n-1)!]$, and the determinant records the signs of the remaining holomorphic and antiholomorphic indices. Expanding its six terms and using $T_{bc\bar{a}} = -T_{cb\bar{a}}$, we obtain

$$A_{i\bar{j}} = \frac{1}{n-1}\left(\delta_{ij}\sum_{p,k} v_p\overline{T_{pk\bar{k}}} - v_i\sum_k \overline{T_{jk\bar{k}}} - \sum_k v_k\overline{T_{kj\bar{i}}}\right).$$

Since $Z = (A + A^*)/2$, where A^* denotes the Hermitian adjoint matrix, this gives (9.19).

For $i \neq j$, the coefficient of v_j in this expression vanishes because $T_{jj\bar{i}} = 0$, and the coefficient of $v_{\bar{i}}$ vanishes in the conjugate expression. For $i = j$, canceling the terms with $p = i$ and $k = i$ gives (9.20). These are tensor identities valid in every unitary frame. Since the Chern connection preserves the metric, they can be differentiated in a unitary frame that is parallel at the point. For instance, the first derivative of a summand in (9.20) is

$$(\nabla_1 v_p)\overline{T_{pk\bar{k}}} + v_p \nabla_1 \overline{T_{pk\bar{k}}}, \qquad p, k \neq 1,$$

together with its conjugate counterpart. A further derivative in the direction $\bar{1}$ still has $p \neq 1$. This gives the stated exclusions, including the terms in which a derivative falls on a coefficient. □

The second-order estimate uses these exclusions; an arbitrary first-order perturbation could not be substituted for Z.

Lemma 9.12.2 *Diagonalize g at a point and order its eigenvalues as $\lambda_1 \geq \cdots \geq \lambda_n$. Put*

$$\mu_i = \frac{\sum_{j \neq i} \lambda_j}{n-1} > 0, \quad t_i = \mu_i^{-1}, \quad f_i = \frac{1}{n-1} \sum_{j \neq i} t_j, \quad \mathcal{F} = \sum_i f_i = \sum_i t_i.$$

Then $\mu_1 \leq \cdots \leq \mu_n$, $f_1 \leq \cdots \leq f_n$, and

$$\sum_i f_i \lambda_i = n, \qquad \frac{\mathcal{F}}{n(n-1)} \leq f_k \leq \frac{\mathcal{F}}{n-1} \quad (k > 1), \qquad t_i \leq (n-1) f_1 \quad (i > 1), \tag{9.21}$$

$$f_n \geq \mathcal{F}/n.$$

Fix $\tau, D > 0$ and assume $Q_0 \geq \tau\gamma$ and $\det P_\gamma(g) \leq D$. For λ_1 larger than a constant depending only on n, τ, D,

$$\sum_i f_i (\chi_{i\bar{i}} - \lambda_i) \geq \frac{\tau}{2} \mathcal{F}. \tag{9.22}$$

There is also a uniform positive lower bound for $\mathcal{F}$ depending only on n, D.

Proof The ordering follows from the formula for μ_i, and then from that for f_i. The identity $\sum_i f_i \lambda_i = n$, which reflects the relation $\log \det P_\gamma(sg) = \log \det P_\gamma(g) + n \log s$, can be checked directly:

$$\sum_i f_i \lambda_i = \sum_j \frac{t_j}{n-1} \sum_{i \neq j} \lambda_i = \sum_j t_j \mu_j = n.$$

For $k > 1$, the sum defining f_k contains the largest weight $t_1 \geq \mathcal{F}/n$. The upper bound for f_k and the estimate for t_i are immediate, and the largest weight f_n is at least the average $\mathcal{F}/n$.

The map P_γ is self-adjoint for the matrix trace pairing. Consequently

$$\sum_i f_i \chi_{i\bar{\imath}} = \sum_i t_i (Q_0)_{i\bar{\imath}} \geq \tau \mathcal{F}.$$

Moreover $\sum_i \lambda_i = \sum_i \mu_i > \lambda_1 > 0$, where the strict inequality follows from $\mu_1 > 0$. Hence $\mu_n > \lambda_1/n$. Since the other $n-1$ numbers μ_i are at least μ_1,

$$\mu_1^{n-1} \mu_n \leq \prod_i \mu_i \leq D, \qquad \mathcal{F} \geq \mu_1^{-1} \geq \left(\frac{\lambda_1}{nD} \right)^{1/(n-1)}.$$

For λ_1 sufficiently large this is at least $2n/\tau$, so $n \leq \tau \mathcal{F}/2$. Subtracting $\sum_i f_i \lambda_i = n$ therefore proves (9.22). Finally, the arithmetic–geometric mean inequality applied to the t_i gives $\mathcal{F} \geq n D^{-1/n}$. □

The concavity of the logarithmic determinant will supply a positive term with an explicit formula. For the matrix function $\Phi(g) = \log \det P_\gamma(g)$, the negative second differential in a complex matrix direction B and its adjoint is

$$-D^2 \Phi_g(B, B^*) = \operatorname{tr}\bigl(P_\gamma(g)^{-1} P_\gamma(B) P_\gamma(g)^{-1} P_\gamma(B)^* \bigr) \geq 0. \tag{9.23}$$

This follows by differentiating the inverse matrix. In a unitary frame diagonalizing g, the off-diagonal terms of this expression include

$$\frac{|B_{k\bar{1}}|^2}{(n-1)^2 \mu_k \mu_1}.$$

When $\lambda_k < \lambda_1$, that coefficient is exactly

$$\frac{f_k - f_1}{\lambda_1 - \lambda_k} = \frac{1}{(n-1)^2 \mu_k \mu_1}.$$

The expression on the right also makes sense when the two eigenvalues coincide. This positive square and the weights f_i enter the largest-eigenvalue estimate in the next section.

9.13 The largest-eigenvalue estimate

The matrix structure now gives a bound for the complex Hessian in terms of the squared gradient. We apply the maximum principle to the largest eigenvalue of g, corrected by functions of the gradient and of the potential. The missing torsion indices allow the concavity square to absorb the third derivatives. If the smallest eigenvalue is not too negative, the positive background closes the estimate; otherwise that eigenvalue produces a large positive Hessian square.

We keep the notation of Section 9.12. Plain subscripts on scalar functions and subscripts after a comma on matrix coefficients denote coordinate derivatives, and the coefficients of the Chern connection of γ are written Γ^q_{ik}. Choose $\tau > 0$ with $Q_0 \geq \tau\gamma$.

Theorem 9.13.1 *Fix smooth Hermitian forms γ_0, γ on a compact complex manifold X of dimension $n \geq 2$. For a smooth real function h on X, suppose that v is a smooth solution of*

$$Q = Q_0 + P_\gamma(\mathrm{i}\partial\bar\partial v) + Z(\partial v) > 0, \qquad \log \det_\gamma Q = h,$$

with the tensors of Section 9.12. If $\|v\|_{C^0}$ and $\|h\|_{C^2}$ are bounded, then

$$\sup_X |\mathrm{i}\partial\bar\partial v|_\gamma \leq C\bigl(1 + \sup_X |\partial v|^2_\gamma\bigr),$$

where C depends only on these bounds and the fixed smooth data.

Proof Adding a constant, we may assume $\sup_X v = 0$, and we write $-M \leq v \leq 0$. Set

$$K = 1 + \sup_X |\partial v|^2_\gamma, \qquad \phi(s) = -\tfrac{1}{2}\log(1 - s/(2K)), \qquad \psi(t) = D_1 \mathrm{e}^{-D_2 t}.$$

The positive constants D_1, D_2 will be chosen below using only the fixed data. On $0 \leq s \leq K$,

$$\frac{1}{4K} \leq \phi' \leq \frac{1}{2K}, \qquad \phi'' = 2(\phi')^2, \qquad 0 \leq \phi \leq \tfrac{1}{2}\log 2.$$

Let λ_1 be the largest eigenvalue of $g = \chi + \mathrm{i}\partial\bar\partial v + W$ relative to γ. It is positive, because $\mathrm{tr}_\gamma\, g = \mathrm{tr}_\gamma\, Q > 0$. Consider a maximum point of

$$H = \log\lambda_1 + \phi(|\partial v|^2_\gamma) + \psi(v).$$

It suffices to bound λ_1/K at this point, because the other two terms of H are uniformly bounded once D_1, D_2 are fixed. We may assume that this ratio exceeds any fixed constant specified in the course of the argument.

Choose holomorphic coordinates that are unitary at the maximum point, with g diagonal there and eigenvalues ordered as $\lambda_1 \geq \cdots \geq \lambda_n$. All estimates below are at this point, and repeated indices are summed only when a sum is written. Put $\lambda = \lambda_1$ and use the weights t_i, f_k and their sum $\mathcal{F}$ from Lemma 9.12.2. Since $\sum_i \lambda_i > 0$ and the eigenvalues are ordered,

$$|\lambda_i| \leq (n-1)\lambda, \qquad |v_{i\bar j}| \leq C\lambda \quad \text{if } \lambda \geq K.$$

The constant C may change from line to line; it is independent of K and, until D_1, D_2 are fixed below, also of D_1, D_2. The pure second derivatives v_{ij} are not covered by this bound.

Differentiating the largest eigenvalue.

Since λ_1 need not be smooth where it is a multiple eigenvalue, we first perturb g. Choose a smooth local unitary frame that is parallel for the Chern connection at the point, with first vector an eigenvector for λ. Let B be the tensor that is diagonal in this frame, with eigenvalues $0, \epsilon_0, \ldots, \epsilon_0$, where $\epsilon_0 > 0$ is fixed and small. Then $B \geq 0$, $\nabla B = 0$ at the point, and its second derivatives are bounded by fixed constants. The largest eigenvalue $\widetilde{\lambda}$ of $g - B$ is simple near the point, is at most $\lambda_1(g)$, and equals λ at the point. Hence the smooth function $\widetilde{H}$, defined like H with $\widetilde{\lambda}$ in place of λ_1, also has a local maximum there. Only the largest eigenvalue needs to be simple.

For a family of self-adjoint matrices with a simple largest eigenvalue, differentiate the equation for the normalized eigenvector. Its component in the pth eigenspace is the corresponding derivative of the matrix divided by the eigenvalue gap. Differentiating the eigenvalue once more therefore gives

$$\begin{aligned} a_k &:= \widetilde{\lambda}_k = \nabla_k g_{1\bar{1}}, \\ \widetilde{\lambda}_{k\bar{k}} &= \nabla_{\bar{k}} \nabla_k g_{1\bar{1}} + O(1) + \sum_{p>1} \frac{|\nabla_k g_{1\bar{p}}|^2 + |\nabla_k g_{p\bar{1}}|^2}{\lambda - \lambda_p + \epsilon_0}. \end{aligned}$$

This formula remains valid if some of the lower eigenvalues coincide, with the sum taken over any orthonormal basis of their eigenspaces. The gaps are positive and at most $n\lambda + \epsilon_0$. In holomorphic coordinates, $a_k = g_{1\bar{1},k} + O(\lambda)$, while converting the second covariant derivative to partial derivatives introduces an error of at most $C \sum_p |g_{1\bar{p},k}| + C\lambda$. We also convert the off-diagonal covariant derivatives in the positive squares, with errors $O(\lambda)$, and absorb the linear off-diagonal terms by Young's inequality. Thus, after decreasing a fixed positive coefficient,

$$\widetilde{\lambda}_{k\bar{k}} \geq g_{1\bar{1},k\bar{k}} + \frac{1}{8n\lambda} \sum_{p>1} (|g_{1\bar{p},k}|^2 + |g_{p\bar{1},k}|^2) - C(|g_{1\bar{1},k}| + \lambda). \tag{9.24}$$

The precise positive constant will not be used.

Write $V_k = \partial_k(|\partial v|^2_\gamma)$. The first derivative of $\widetilde{H}$ gives

$$\frac{a_k}{\lambda} = -\phi' V_k - \psi' v_k, \qquad |V_k| \leq C\sqrt{K} \sum_p (|v_{pk}| + |v_{p\bar{k}}|) + CK. \tag{9.25}$$

In the second derivative, the derivatives of the fixed metric in $|\partial v|^2_\gamma$ cost only a small fraction of the positive Hessian squares and a constant. Therefore

$$\begin{aligned} \widetilde{H}_{k\bar{k}} \geq \frac{\widetilde{\lambda}_{k\bar{k}}}{\lambda} - \frac{|a_k|^2}{\lambda^2} + \phi' \sum_p (v_p v_{\bar{p}k\bar{k}} + v_{\bar{p}} v_{pk\bar{k}}) + \frac{1}{5K} \sum_p (|v_{pk}|^2 + |v_{p\bar{k}}|^2) \\ + \phi'' |V_k|^2 + \psi'' |v_k|^2 + \psi' v_{k\bar{k}} - C. \end{aligned} \tag{9.26}$$

The third and fourth terms are obtained by differentiating $\sum \gamma^{p\bar{q}} v_p v_{\bar{q}}$ twice and applying $ab \le \varepsilon a^2 + C_\varepsilon b^2$ to each term containing a derivative of the metric.

The third derivatives and the torsion term.

We now estimate the third derivatives in this inequality. Define

$$E = \sum_{k,p} f_k (|v_{pk}|^2 + |v_{p\bar{k}}|^2), \qquad S = \sum_{k,p} f_k (|v_{pk}| + |v_{p\bar{k}}|),$$
$$C = -D^2 \Phi_g (\nabla_1 g, (\nabla_1 g)^*) \ge 0.$$

The first differentiated equation is

$$\sum_k f_k \nabla_p g_{k\bar{k}} = h_p. \tag{9.27}$$

Since $P_\gamma(W) = Z$ and the connection preserves γ, one has the exact contractions

$$\sum_k f_k \nabla_p W_{k\bar{k}} = \sum_i t_i \nabla_p Z_{i\bar{i}}, \qquad \sum_k f_k \nabla_{\bar{1}} \nabla_1 W_{k\bar{k}} = \sum_i t_i \nabla_{\bar{1}} \nabla_1 Z_{i\bar{i}}. \tag{9.28}$$

The weights in these identities are evaluated at the point; they are not differentiated.

The large weights are controlled as follows. By (9.21), the only weight t_i not bounded by $(n-1) f_1$ is t_1. In $Z_{1\bar{1}}$, every gradient index differs from 1, by (9.20). Thus a pure second derivative in $\nabla_p Z_{1\bar{1}}$ has an index $q > 1$, and it can be weighted by f_q, which is comparable to $\mathcal{F}$; here we use that pure derivatives commute in these coordinates. A mixed second derivative can similarly be placed in column q by conjugate symmetry. All other t_i are bounded by a constant times every f_k, and derivatives of coefficients cost $C\sqrt{K}\mathcal{F}$. Applying these observations to the first identity in (9.28), and then to (9.27), we obtain, for each p,

$$\left| \sum_k f_k v_{k\bar{k}p} \right| + \left| \sum_k f_k v_{k\bar{k}\bar{p}} \right| \le C(S + \sqrt{K}\mathcal{F}). \tag{9.29}$$

The connection terms in the differentiated equation contribute weighted mixed second derivatives and terms bounded by $C\sqrt{K}\mathcal{F}$, which are already on the right. The bounded derivatives of h are absorbed using the positive lower bound for $\mathcal{F}$ in Lemma 9.12.2.

Next we insert the second derivative of the equation into the eigenvalue estimate. Since partial derivatives of v commute,

$$g_{1\bar{1},k\bar{k}} = g_{k\bar{k},1\bar{1}} + W_{1\bar{1},k\bar{k}} - W_{k\bar{k},1\bar{1}} + O(1).$$

Differentiating the equation twice covariantly gives

$$\sum_k f_k \nabla_{\bar 1} \nabla_1 g_{k\bar k} = h_{1\bar 1} + C.$$

The conversion to partial derivatives uses

$$\nabla_{\bar 1} \nabla_1 g_{k\bar k} = g_{k\bar k, 1\bar 1} - 2 \operatorname{Re} \sum_q \overline{\Gamma^q_{1k}} g_{k\bar q, 1} + O(\lambda).$$

We rewrite the derivative of g in this term using $g_{k\bar q,1} = g_{1\bar q,k} + W_{k\bar q,1} - W_{1\bar q,k} + O(1)$ and its conjugate. The first part is absorbed by the off-diagonal squares in (9.24), at the cost of $C\lambda\mathcal{F} + C\sum_k f_k |g_{1\bar 1,k}|$. The part involving $W_{1\bar q,k}$ is bounded by $C\lambda\mathcal{F} + C\sum_{k,p} f_k |v_{pk}|$. For the remaining part we use

$$2 \operatorname{Re} \sum_q \overline{\Gamma^q_{1k}} W_{k\bar q,1} = W_{k\bar k, 1\bar 1} - \nabla_{\bar 1} \nabla_1 W_{k\bar k} + O(\sqrt{K}).$$

This cancels the partial second derivative $-W_{k\bar k,1\bar 1}$ above, and we obtain

$$\begin{aligned} \sum_k f_k \widetilde{\lambda}_{k\bar k} \geq C + \sum_k f_k (W_{1\bar 1, k\bar k} - \nabla_{\bar 1} \nabla_1 W_{k\bar k}) \\ - C \left(\sum_k f_k |g_{1\bar 1,k}| + \sum_{k,p} f_k |v_{pk}| + \lambda \mathcal{F} \right). \end{aligned} \tag{9.30}$$

The second contraction in (9.28) bounds the negative torsion term here. In the part with weight t_1, the possible third derivatives are $v_{q1\bar 1}$ and their conjugates with $q > 1$; all other parts have weights bounded by Cf_1. We commute partial derivatives and use

$$v_{1\bar 1,k} = g_{1\bar 1,k} - \chi_{1\bar 1,k} - W_{1\bar 1,k}.$$

The exclusions in Lemma 9.12.1 ensure that any remaining pure derivative v_{11} carries only the small weight Cf_1, and derivatives of the connection contribute second derivatives with the same weighted bounds. It follows that

$$\left| \sum_k f_k \nabla_{\bar 1} \nabla_1 W_{k\bar k} \right| \leq C \left(\sum_k f_k |g_{1\bar 1,k}| + \sum_{k,p} f_k |v_{pk}| + \lambda \mathcal{F} \right).$$

For the positive torsion term, write $W_{1\bar 1} = \sum_p (c^p v_p + \overline{c^p} v_{\bar p})$ with fixed smooth coefficients c^p. Two derivatives give $c^p \sum_k f_k v_{pk\bar k}$ and its conjugate, plus terms bounded by $C(S + \sqrt{K}\mathcal{F})$. The former are bounded by (9.29), and in S the mixed second derivatives can be bounded by $C\lambda$, giving

$$\left| \sum_k f_k W_{1\bar 1, k\bar k} \right| \leq C \left(\sum_{k,p} f_k |v_{pk}| + \lambda \mathcal{F} \right).$$

Substitute these estimates in (9.30), multiply (9.26) by f_k and sum over k. The third derivatives in the latter are bounded by (9.29) and $\phi'|\partial v| \le C/\sqrt{K}$, and the resulting linear terms in the second derivatives are absorbed by a small part of E/K, at the cost of $C\mathcal{F}$. Since $\widetilde{H}$ has a local maximum, $\sum_k f_k \widetilde{H}_{k\bar{k}} \le 0$, and thus

$$0 \ge \frac{C}{\lambda} - \sum_k f_k \frac{|a_k|^2}{\lambda^2} + \frac{E}{6K} + \phi'' \sum_k f_k |V_k|^2 + \psi'' \sum_k f_k |v_k|^2 + \psi' \sum_k f_k v_{k\bar{k}} - C\left(\sum_k f_k \frac{|g_{1\bar{1},k}|}{\lambda} + \mathcal{F} \right). \tag{9.31}$$

Cancellation when the smallest eigenvalue is controlled.

Fix $0 < \delta < 1/2$, to be chosen after D_1, D_2. First suppose that $\lambda_n \ge -\delta\lambda$. Put $I = \{k : f_k > \delta^{-1} f_1\}$, so that $1 \notin I$. Equation (9.25) and $\phi'' = 2(\phi')^2$ give

$$-\sum_{k\notin I} f_k |a_k|^2/\lambda^2 \ge -\phi'' \sum_{k\notin I} f_k |V_k|^2 - 2(\psi')^2 \delta^{-1} f_1 K,$$
$$-2\delta \sum_{k\in I} f_k |a_k|^2/\lambda^2 \ge -2\delta\phi'' \sum_{k\in I} f_k |V_k|^2 - 4\delta(\psi')^2 \sum_{k\in I} f_k |v_k|^2.$$

Choose δ small enough that $4\delta(\psi')^2 \le \psi''/2$ throughout $[-M, 0]$. By (9.23),

$$\frac{C}{\lambda} \ge \sum_{k\in I} \frac{f_k - f_1}{\lambda(\lambda - \lambda_k)} |\nabla_1 g_{k\bar{1}}|^2 \ge (1 - 2\delta) \sum_{k\in I} \frac{f_k |\nabla_1 g_{k\bar{1}}|^2}{\lambda^2}.$$

Here we used $(1-\delta)/(1+\delta) \ge 1 - 2\delta$.

We need the following comparison of the two derivatives $\nabla_1 g_{k\bar{1}}$ and $a_k = \nabla_k g_{1\bar{1}}$. For every $\varepsilon > 0$, provided λ/K is sufficiently large depending on the fixed function ψ,

$$\sum_{k\in I} f_k \frac{|\nabla_1 g_{k\bar{1}}|^2 - |a_k|^2}{\lambda^2} \ge -\frac{E}{12K} - C\mathcal{F} - \varepsilon C|\psi'|\mathcal{F} - C_\varepsilon |\psi'| \sum_k f_k |v_k|^2. \tag{9.32}$$

To prove this, let $U = \sum_{p>1,q} |v_{pq}|$. Commuting partial derivatives in g gives, for $k > 1$,

$$\nabla_1 g_{k\bar{1}} - a_k = W_{k\bar{1},1} - W_{1\bar{1},k} + O(\lambda), \qquad |W_{k\bar{1},1}| + |W_{1\bar{1},k}| \le C(\lambda + U).$$

The second inequality uses the absence of v_1 in $Z_{k\bar{1}}$, so that differentiation in the direction 1 introduces no pure derivative v_{11}. All mixed second derivatives are bounded by $C\lambda$, and every other pure second derivative occurs in U.

Use $|a+e|^2 - |a|^2 \geq -2|a||e|$, and then (9.25). For $k > 1$, the pure second derivatives in V_k all occur in U. With $H_k = \sum_p |v_{p\bar{k}}|$, the resulting negative terms, divided by λ^2, are bounded by a constant times

$$K^{-1/2} H_k + K^{-1/2} U + \frac{U^2}{\lambda\sqrt{K}} + 1 + |\psi'||v_k| + \frac{|\psi'|}{\lambda}|v_k|U.$$

Here we used $H_k \leq C\lambda$ and $\lambda \geq K$ to simplify the cross terms. The weight comparison (9.21), the symmetry of pure derivatives and the Cauchy–Schwarz inequality give $\mathcal{F}U^2 \leq CE$. Consequently, after multiplication by f_k and summation, the first two terms are bounded by any fixed small fraction of E/K plus $C\mathcal{F}$. The third is at most $CE/(\lambda\sqrt{K})$, which is absorbed by another such fraction when λ/K is large. For the last two terms we use

$$|v_k| \leq \varepsilon + C_\varepsilon |v_k|^2, \qquad |v_k|U \leq |v_k|^2 + U^2.$$

The contribution of U^2 is at most $C|\psi'|E/\lambda$, which can again be absorbed when λ/K is large. Choosing the fractions with sum $1/12$ proves (9.32).

Insert this cancellation and the preceding inequalities into (9.31). The remaining derivative error satisfies, by (9.25),

$$C\sum_k f_k |g_{1\bar{1},k}|/\lambda \leq \frac{E}{60K} + C\mathcal{F} + \varepsilon C|\psi'|\mathcal{F} + C_\varepsilon |\psi'| \sum_k f_k |v_k|^2,$$

after Young's inequality and an adjustment of constants. The torsion contraction also satisfies

$$\left|\sum_k f_k W_{k\bar{k}}\right| = \left|\sum_i t_i Z_{i\bar{i}}\right| \leq C\sum_k f_k |v_k| \leq \varepsilon C\mathcal{F} + C_\varepsilon \sum_k f_k |v_k|^2.$$

The first inequality uses again the missing gradient index in $Z_{1\bar{1}}$. Since $\psi' < 0$ and $v_{k\bar{k}} = \lambda_k - \chi_{k\bar{k}} - W_{k\bar{k}}$, we conclude, after decreasing the remaining coefficient of E if necessary, that

$$\begin{aligned} 0 \geq f_1 \left(\frac{\lambda^2}{40K} - 2(\psi')^2 \delta^{-1} K\right) + \left(\frac{\psi''}{2} - C_\varepsilon |\psi'|\right) \sum_k f_k |v_k|^2 \\ - C_0\mathcal{F} - \varepsilon C_0 |\psi'|\mathcal{F} + |\psi'| \sum_k f_k (\chi_{k\bar{k}} - \lambda_k). \end{aligned} \tag{9.33}$$

For the first term we used $|v_{1\bar{1}}|^2 \geq \lambda^2/2 - CK$, which follows from $\chi + W = O(\sqrt{K})$, and $E \geq f_1 |v_{1\bar{1}}|^2$.

For large λ, Lemma 9.12.2 bounds the last sum below by $\tau\mathcal{F}/2$. Choose first ε with $\varepsilon C_0 < \tau/4$. Next choose D_2 so that $\psi''/2 > C_\varepsilon |\psi'|$, and then choose D_1 so that $|\psi'|\tau/4 > C_0$ on $[-M, 0]$. Finally choose δ as above. All these choices depend only

on the fixed data. Inequality (9.33) then forces $\lambda^2 \le 80\,\delta^{-1} \sup_{[-M,0]} |\psi'|^2 K^2$, which proves the desired bound in the first case.

The remaining eigenvalue configuration.

Suppose now that $\lambda_n < -\delta\lambda$, keeping the same constants. Since $f_n \ge \mathcal{F}/n$ and $|\chi + W| \le C\sqrt{K}$,

$$\frac{E}{6K} \ge \frac{f_n}{6K}|v_{n\bar{n}}|^2 \ge \frac{\delta^2\lambda^2}{12nK}\mathcal{F} - C\mathcal{F}.$$

In (9.31), discard C and the term with ψ''. Since ψ is now fixed, $|\psi' \sum_k f_k v_{k\bar{k}}| \le C\lambda\mathcal{F}$. Using $g_{1\bar{1},k} = a_k + O(\lambda)$ and Young's inequality, we bound the last error term by $\frac{1}{2}\sum_k f_k|a_k|^2/\lambda^2 + C\mathcal{F}$. This leaves

$$0 \ge -\tfrac{3}{2}\sum_k f_k|a_k|^2/\lambda^2 + \frac{\delta^2\lambda^2}{12nK}\mathcal{F} + \phi''\sum_k f_k|V_k|^2 - C\lambda\mathcal{F}.$$

By (9.25) and the scalar inequality $\frac{3}{2}|a+b|^2 \le 2|a|^2 + 6|b|^2$,

$$\tfrac{3}{2}\sum_k f_k|a_k|^2/\lambda^2 \le \phi''\sum_k f_k|V_k|^2 + CK\mathcal{F}.$$

Since $\lambda \ge K$, combining the last two inequalities and dividing by $\lambda\mathcal{F} > 0$ gives $\lambda/K \le C$. This finishes both cases. Since H attains its maximum at the chosen point, the bound for λ_1/K there gives a bound at all points, and $|\lambda_i| \le (n-1)\lambda_1$ then bounds every entry of the complex Hessian, as asserted. □

9.14 A Liouville theorem for the limiting cone

Rescaling at a point of large gradient removes the background and first-order terms of the Gauduchon equation and leaves a degenerate equation on $\mathbb{C}^n$, whose solutions are maximal for a cone of matrices. We show that its bounded Lipschitz solutions are constant. The proof argues by induction on the dimension: if the energy of a solution in some complex direction becomes small on large balls, a limit is independent of one variable; if all directional energies stay positive, they give a strictly admissible comparison function.

On $\mathbb{C}^n$ we use Euclidean coordinates $z = (z_1, \dots, z_n)$, the identity matrix I, the Euclidean balls $B(x, r)$ and Euclidean volume $\mathrm{d}y$. In this section ∇ and Δ denote the Euclidean real gradient and Laplacian, and ∂_ξ denotes differentiation in a complex direction ξ.

For $n \geq 2$ and a Hermitian matrix H, set

$$P_n(H) = \frac{(\operatorname{tr} H)I - H}{n-1}.$$

This is the map P_γ of Section 9.12 for the Euclidean metric. It preserves nonnegativity and satisfies $P_n(I) = I$ and $\operatorname{tr} P_n(H) = \operatorname{tr} H$. For a real function v write $H(v) = (v_{i\bar{j}})$ in Euclidean coordinates. A continuous function v on an open set of $\mathbb{C}^n$ is *admissible* if $P_n(H(v)) \geq 0$ in the sense of matrix-valued distributions. It is *maximal for this cone* if it is admissible and every smooth function h touching v from below at a point satisfies

$$P_n(H(h)) \not> 0$$

at that point. Here touching means that $v - h$ has a local minimum with value zero, which need not be a strict minimum. Maximality is thus the viscosity supersolution condition for the degenerate equation $\det P_n(H(v)) = 0$ on the boundary of the cone, together with distributional admissibility.

Taking the trace shows that admissible functions are subharmonic. Since P_n is linear, convolution preserves admissibility, and so do nonnegative linear combinations and integrals of admissible smooth functions. Translations and unitary changes of coordinates preserve both conditions, as do multiplication by a positive constant and addition of a constant.

Lemma 9.14.1 *Local uniform limits of admissible maximal functions are admissible and maximal. If v is maximal on a bounded open set $D \subset \mathbb{C}^n$, h is smooth and admissible on D, both functions are continuous on $\overline{D}$, and $h \leq v$ on ∂D, then $h \leq v$ on D.*

Proof Let v_j be admissible maximal functions converging locally uniformly to v. Distributional positivity is preserved under this convergence. For maximality, suppose that a smooth function h touches v from below at z_0 and $P_n(H(h)(z_0)) > 0$. Choose a small ball on which $v - h \geq 0$. Replacing h by $h - \delta|z - z_0|^2$, with $\delta > 0$ sufficiently small, keeps its matrix strictly positive near z_0 and makes the minimum strict. Uniform convergence then produces interior minimum points of $v_j - h + \delta|z - z_0|^2$ tending to z_0. Adding the minimum value to the test function gives a function touching v_j from below with strictly positive matrix, a contradiction.

For comparison, choose R with $\overline{D} \subset \{|z| \leq R\}$. If $h > v$ somewhere, then for small $\delta > 0$ the smooth function

$$h_\delta = h + \delta(|z|^2 - R^2)$$

still exceeds v at some interior point and is at most v on the boundary. Hence the negative minimum of $v - h_\delta$ is attained in the interior. But $P_n(H(h_\delta)) = P_n(H(h)) + \delta I > 0$ there, which contradicts maximality after the minimum value is added to h_δ. No boundary regularity of D is needed for this argument. □

Theorem 9.14.1 *A bounded globally Lipschitz function on $\mathbb{C}^n$, $n \geq 2$, that is maximal for this cone is constant.*

Proof Let v be a bounded globally Lipschitz maximal function on $\mathbb{C}^n$. We argue by induction on n. For $n = 2$, $P_2(H) \geq 0$ is equivalent to $H \geq 0$, so v is plurisubharmonic, and Lemma 1.3.5 shows that it is constant.

We first explain the reduction in dimension for $n \geq 3$. If a function is independent of z_n, its complex Hessian has the block form $H \oplus 0$. The first block of $P_n(H \oplus 0)$ is

$$\frac{n-2}{n-1} P_{n-1}(H),$$

and the last entry is $\operatorname{tr} H/(n-1)$. Nonnegativity of $P_{n-1}(H)$ implies $\operatorname{tr} H \geq 0$, and positive definiteness implies $\operatorname{tr} H > 0$. Thus $P_n(H \oplus 0)$ is nonnegative, respectively positive definite, exactly when $P_{n-1}(H)$ is. The distributional version follows from the same linear identities. A test function in $n-1$ variables extends to $\mathbb{C}^n$ independently of z_n, so maximality also passes to $n-1$ variables. Consequently the induction hypothesis applies to bounded Lipschitz maximal functions that are independent of one complex variable.

Suppose now that v is nonconstant. Adding a constant and multiplying by a positive constant, we may assume that $\inf v = 0$ and $\sup v = 1$. Let L be the Lipschitz constant of v. Choose a smooth radial nonnegative probability kernel η, supported in the closed unit ball and strictly positive in its interior. For a bounded measurable function f and $r > 0$, write

$$[f]_r(x) = \int_{\mathbb{C}^n} f(x+y)\eta_r(y)\,\mathrm{d}y, \qquad \eta_r(y) = r^{-2n}\eta(y/r), \qquad v_\epsilon = [v]_\epsilon.$$

Both v and v^2 are subharmonic. For v^2, use $v_\epsilon \geq 0$ and $\Delta(v_\epsilon^2) = 2v_\epsilon \Delta v_\epsilon + 2|\nabla v_\epsilon|^2 \geq 0$, and pass to the uniform limit as $\epsilon \to 0$.

For $f = v$ and for $f = v^2$, the averages $[f]_r(x)$ increase with r, by the monotonicity of spherical means of subharmonic functions. Their limit as $r \to \infty$ is independent of x, since

$$|[f]_r(x) - [f]_r(y)| \leq \|f\|_\infty \|\eta_r(\cdot - x) - \eta_r(\cdot - y)\|_{L^1} \leq C\frac{|x-y|}{r}.$$

By the submean inequality this limit is at least $f(x)$ for every x, while it is at most $\sup f = 1$. Therefore

$$[v]_r(x) \longrightarrow 1, \qquad [v^2]_r(x) \longrightarrow 1. \tag{9.34}$$

We distinguish two cases. First suppose that there exist $\rho > 0$, sequences $\epsilon_k \downarrow 0$ and $r_k \to \infty$, points x_k and unit complex directions ξ_k such that

$$[v^2]_{r_k}(x_k) + [v]_\rho(x_k) - 2v(x_k) \geq \frac{4}{3}, \qquad \int_{B(x_k, r_k)} |\partial_{\xi_k} v_{\epsilon_k}|^2\,\mathrm{d}y \longrightarrow 0. \tag{9.35}$$

Translate x_k to the origin and make ξ_k the last complex direction by a unitary change of coordinates. The resulting functions have the same bounds and Lipschitz constant, so by the Arzelà–Ascoli theorem and Lemma 9.14.1 a subsequence converges locally

uniformly to a maximal function a. The corresponding mollifications at scale ϵ_k have the same local uniform limit, and by the integral condition their derivatives in the last complex direction tend to zero in L^2 on every fixed ball. Hence $\partial a/\partial z_n = 0$ in the sense of distributions. Since a is real and continuous, it is independent of z_n.

The dimension reduction and the induction hypothesis show that a is a constant $c \in [0,1]$. In the first inequality of (9.35), the first term is at most one, while the average at the fixed radius ρ and the value at the origin both tend to c. It would follow that $4/3 \le 1 - c \le 1$, a contradiction.

In the remaining case, for every fixed $\rho > 0$ there is $C_\rho \ge 1$ such that, whenever $0 < \epsilon < C_\rho^{-1}$, $r > C_\rho$, and

$$[v^2]_r(x) + [v]_\rho(x) - 2v(x) \ge \frac{4}{3},$$

one has

$$\int_{B(x,r)} |\partial_\xi v_\epsilon|^2 \, dy \ge C_\rho^{-1} \quad \text{for every unit complex direction } \xi. \tag{9.36}$$

Indeed, if this failed for $C_\rho = k$ for every integer k, a diagonal choice would give sequences as in (9.35).

After a translation we may assume that $v(0) < 1/12$. By (9.34), choose ρ with $[v]_\rho(0) > 3/4$, and then $r > C_\rho$ with $[v^2]_r(0) > 3/4$. The open set

$$D = \{x : 2v(x) < [v^2]_r(x) + [v]_\rho(x) - 4/3\}$$

contains the origin. We claim that, for some $c > 0$,

$$[v^2]_r - c|z|^2$$

is smooth and admissible on D.

To prove the claim, differentiate the square of the smooth mollification:

$$H(v_\epsilon^2) = 2v_\epsilon H(v_\epsilon) + 2(\partial_i v_\epsilon \, \overline{\partial_j v_\epsilon})_{ij}.$$

Denote by A_ϵ and B_ϵ the convolutions at the fixed radius r of these two terms. The first satisfies $P_n(A_\epsilon) \ge 0$, because $v_\epsilon \ge 0$, v_ϵ is admissible, and P_n is linear.

The second satisfies $B_\epsilon \ge c_0 I$ on D for small ϵ, with a constant $c_0 > 0$. Here the passage from the unweighted integral in (9.36) to the convolution needs care. The bound $|\nabla v_\epsilon| \le L$ makes the energy of a sufficiently thin boundary annulus of $B(x,r)$ at most $C_\rho^{-1}/2$, uniformly in x, ϵ, ξ. On the remaining smaller closed ball, the fixed kernel η_r has a positive minimum. For points $x \in D$, (9.36) then gives a uniform positive lower bound for the weighted integral in every direction, which is the asserted matrix inequality for B_ϵ.

Choose $0 < c \le c_0$. Since P_n preserves nonnegative matrices,

$$P_n\big(H([v_\epsilon^2]_r) - cI\big) \ge 0 \quad \text{on } D.$$

As $\epsilon \downarrow 0$, $v_\epsilon^2 \to v^2$ uniformly, and convolution at the fixed positive radius r gives convergence of all derivatives. This proves the claim.

The smooth function

$$h = \tfrac{1}{2}\big([v^2]_r - c|z|^2 + [v]_\rho - 4/3\big)$$

is therefore admissible on D. The set $D' = \{v < h\}$ contains the origin, it is bounded because v and its averages are bounded, and it lies in D. Moreover $v = h$ on $\partial D'$. Lemma 9.14.1, applied on D', gives $h \le v$ there, which contradicts the definition of D'. This excludes the second case and proves the theorem. □

The Lipschitz bound is used both for the compactness of translates and for the annulus estimate. For $n > 1$, the conclusion would not follow from boundedness and subharmonicity alone, since $\mathbb{C}^n = \mathbb{R}^{2n}$ carries nonconstant bounded subharmonic functions.

9.15 The gradient bound by rescaling

If the gradients of a family of solutions were unbounded, rescaling at points of maximal gradient would produce functions on growing Euclidean balls with gradient one at the origin. The Hessian estimate makes these functions compact in C^1 on every fixed ball, so a limit is a bounded Lipschitz function on $\mathbb{C}^n$ with nonzero gradient at the origin. The rescaled determinant tends to zero, so the limit is maximal for the cone of Section 9.14, which contradicts Theorem 9.14.1.

Consider a family of smooth solutions (u, b) of the equation in Theorem 9.9.1, normalized by $\sup_X u = 0$, with $\|F\|_{C^0} \le M$ for a fixed $M > 0$. By Proposition 9.10.1, $\|u\|_{C^0}$ and $|b|$ are uniformly bounded. The following proposition shows that a Hessian estimate in terms of the squared gradient implies bounds for both.

Proposition 9.15.1 *Suppose there is a constant K such that every solution in this family satisfies*

$$\sup_X |\mathrm{dd^c} u|_\gamma \le K\big(1 + \sup_X |\partial u|_\gamma^2\big). \tag{9.37}$$

Then $\sup_X |\partial u|_\gamma$ and $\sup_X |\mathrm{dd^c} u|_\gamma$ are bounded by a constant depending only on X, γ_0, γ, M and K.

Proof We use the matrices Q_u of (9.18). Their background term Q_0 is fixed, and Z is linear in the first derivatives of $u/(2\pi)$.

Suppose that the gradient bound fails. Then there are solutions (u_j, b_j) with prescribed functions F_j such that

$$A_j = \sup_X |\partial u_j|_\gamma = |\partial u_j(x_j)|_\gamma \longrightarrow \infty.$$

After passing to a subsequence, the points x_j lie in one fixed coordinate neighborhood. Translate the coordinates so that x_j becomes the origin, and apply a uniformly

controlled complex linear change of coordinates so that the matrix of γ at x_j is the identity; a coordinate ball of fixed radius remains available around every x_j. On balls whose radii tend to infinity define

$$v_j(z) = u_j(x_j + z/A_j),$$

in these coordinates. The coefficient matrices $g_j(z)$ of γ at the points $x_j + z/A_j$ converge smoothly to the identity on every fixed ball. In this notation

$$|v_j| \le C, \qquad |\partial v_j|_{g_j} \le 1, \qquad |\partial v_j(0)| = 1.$$

The assumed estimate (9.37) gives a uniform bound for all complex Hessian entries of v_j on every fixed ball, since two derivatives contribute the factor A_j^{-2}. Hence the Euclidean Laplacians of the v_j are uniformly bounded, and the interior estimates for the Laplacian give local $W^{2,p}$ bounds for every finite p. Choosing $p > 2n$ and using Sobolev embedding and compactness, we extract a diagonal subsequence converging in C^1 on compact subsets to a function v on $\mathbb{C}^n$. This function is bounded and globally Lipschitz, and

$$|\partial v(0)| = 1.$$

Now divide the matrix in (9.18) by A_j^2 and evaluate it at the scaled points. The background term becomes $O(A_j^{-2})$, and the first-order term becomes $O(A_j^{-1})$, since one derivative of u_j is A_j times a derivative of v_j. Since the complex Hessians of v_j are uniformly bounded and $g_j \to I$, we obtain on any fixed ball

$$A_j^{-2} Q_{u_j} = P_n\left(\frac{H(v_j)}{2\pi}\right) + o(1), \qquad \det(A_j^{-2} Q_{u_j}) = A_j^{-2n} \mathrm{e}^{(n-1)(F_j + b_j)} \longrightarrow 0. \tag{9.38}$$

To be precise, we compute in the unitary frames obtained from the positive square roots $S_j = g_j^{-1/2}$. In these frames the principal matrix is $P_n(S_j H(v_j) S_j/(2\pi))$, which differs from $P_n(H(v_j)/(2\pi))$ by an error tending to zero uniformly; no derivatives of the frames are taken, and the determinant identity is exact in unitary frames. Since the matrices on the left of (9.38) are positive and the positive factor $1/(2\pi)$ does not change the cone, passing to the limit in the sense of distributions gives $P_n(H(v)) \ge 0$.

It remains to check maximality. Suppose that a smooth function h touches v from below at z_0 and $P_n(H(h)(z_0)) > 0$. Subtract $\delta|z - z_0|^2$ with $\delta > 0$ small; on a small ball this makes the contact strict and preserves strict positivity of the matrix. Local uniform convergence gives points $z_j \to z_0$ at which v_j minus this perturbed test function has an interior local minimum. At such a minimum,

$$H(v_j)(z_j) \ge H(h)(z_j) - \delta I.$$

Because P_n preserves nonnegative matrices, (9.38) now implies $A_j^{-2} Q_{u_j}(z_j) \ge cI$ for a fixed $c > 0$ and all sufficiently large j. The determinant of this matrix is then at least c^n, which contradicts the limit zero in (9.38). Thus v is maximal for the cone of Section 9.14.

By Theorem 9.14.1, v is constant, which contradicts $|\partial v(0)| = 1$. This proves the uniform gradient bound, and substitution in (9.37) gives the uniform complex Hessian bound. □

For prescribed functions F bounded in C^2, Proposition 9.10.1 bounds u and b, and Theorem 9.13.1, applied to $v = u/(2\pi)$ and $h = (n-1)(F+b)$, proves (9.37). Thus both the gradient and the complex Hessian are uniformly bounded.

9.16 Existence for the Gauduchon ansatz

The potential, gradient and Hessian bounds put the matrices Q_u in a compact set of positive matrices. This yields uniform ellipticity after the real Hessian is projected to its complex part and transformed by P_n, so local elliptic regularity gives the compactness needed for closedness in the continuity method; the adjoint probability measure gives openness. The maximum principle then proves uniqueness within the scalar ansatz.

Lemma 9.16.1 *Let γ_0, γ be as in Theorem 9.9.1. If the prescribed functions F range over a set of smooth functions bounded in every C^k norm, then the smooth solutions (u, b) with $\sup_X u = 0$ are bounded in every C^k norm.*

Proof Work with $v = u/(2\pi)$ and write $Q = Q_u$ for the matrix in (9.18). By Propositions 9.10.1 and 9.15.1 and Theorem 9.13.1, the function v, its gradient and its complex Hessian are uniformly bounded, and so are the constants b. Hence the eigenvalues of Q are uniformly bounded above, and by the equation its determinant is uniformly bounded below. Every eigenvalue is therefore also bounded below by a positive constant. Choose fixed numbers $0 < a < b_0$ such that $aI \le Q \le b_0 I$ in unitary frames for every solution.

The function $\Delta_\gamma v = \mathrm{tr}_\gamma(\mathrm{i}\partial\bar\partial v)$ is uniformly bounded, and Δ_γ is a fixed uniformly elliptic operator. Its interior $W^{2,p}$ estimates, applied on a finite cover, bound v in $W^{2,p}$ for every finite p. Choose $p > 2n$ and $0 < \alpha < 1 - 2n/p$; Sobolev embedding gives a uniform $C^{1,\alpha}$ bound. Thus the matrix $R(x) = Q_0(x) + Z_x(\partial v(x))$ is uniformly bounded in C^α.

On a coordinate ball, let $\mathcal{H}_x(A)$ denote the Hermitian matrix of $\mathrm{i}\partial\bar\partial v$ at x in a fixed smooth unitary frame, expressed as a function of the real Hessian $A = D^2_{\mathbb{R}} v(x)$. It is a real linear function of A depending smoothly on x. If a real symmetric matrix N is nonnegative, then $\mathcal{H}_x(N) \ge 0$, and its trace is comparable to $\mathrm{tr}_{\mathbb{R}}\, N$ with uniform positive constants on the ball. This follows by evaluating on a vector and its rotation by i, or from the coordinate formula for $v_{i\bar j}$.

Freeze the function $\partial v(x)$ already obtained in $R(x)$, and define for all real symmetric matrices A

$$\widetilde{\Phi}(A, x) = \inf_{aI \le B \le b_0 I} \left\{ \log\det B + \mathrm{tr}\left[B^{-1}\left(R(x) + P_n(\mathcal{H}_x(A)) - B \right) \right] \right\}.$$

The infimum is over a fixed compact set of positive Hermitian matrices, and each expression in braces is an affine function of A, so $\widetilde{\Phi}$ is concave in A. If $R(x) + P_n(\mathcal{H}_x(A))$ lies in that compact set, then $\widetilde{\Phi}(A, x)$ equals its logarithmic determinant: each expression in braces is a tangent affine function of the concave logarithmic determinant, and the tangent at that matrix itself attains equality.

For $N \geq 0$, each of these affine functions increases by

$$\operatorname{tr}\bigl(B^{-1} P_n(\mathcal{H}_x(N))\bigr)$$

when A is replaced by $A + N$. Since P_n preserves positivity and trace, this increment lies between fixed positive multiples of $\operatorname{tr}_{\mathbb{R}} N$, uniformly in B and x. Taking infima preserves both inequalities, so $\widetilde{\Phi}$ is uniformly elliptic on all real symmetric matrices.

Smoothness of $\mathcal{H}_x$ and the uniform C^α bound for R also give

$$|\widetilde{\Phi}(A, x) - \widetilde{\Phi}(A, y)| \leq C|x - y|^\alpha (1 + \|A\|).$$

These are the hypotheses of the local Evans–Krylov estimate for concave uniformly elliptic equations with Hölder dependence on x, in the formulation given in Section 34.6. The value $\widetilde{\Phi}(0, x)$ is uniformly bounded, by the compactness of the set of matrices B and the bound for R. By the choice of a and b_0, the given smooth function solves

$$\widetilde{\Phi}(D^2_{\mathbb{R}} v, x) = (n - 1)(F + b)$$

on the ball. The Evans–Krylov estimate, applied on smaller balls of a finite cover, yields a uniform $C^{2,\beta}$ bound for some $\beta > 0$.

Differentiating the original matrix equation gives linear uniformly elliptic equations for the first derivatives of v, whose coefficients, including the first-order coefficients coming from Z, are now Hölder continuous. Local Schauder estimates give $C^{3,\beta}$ bounds, and differentiation and induction give all higher bounds. The finite coordinate cover makes the bounds global. The only regularity results used here are the standard $W^{2,p}$ estimates for the Laplacian, the Evans–Krylov estimate for concave equations, and the Schauder estimates. □

Proof (of Theorem 9.9.1) Let

$$F_0 = \log \frac{\gamma_0^n}{\gamma^n}, \qquad F_t = (1 - t)F_0 + tF, \quad 0 \leq t \leq 1.$$

We use the continuity method along the path F_t. At $t = 0$, the pair $u = 0$, $b = 0$ solves the equation, since $\eta_0 = \gamma_0$. During the continuity argument we normalize potentials by $\int_X u\, \gamma^n = 0$; adding a constant does not affect the equation, and at the end we impose $\sup_X u = 0$ instead.

For openness, the derivative of the equation with respect to the mean-zero potential and the scalar is $(w, a) \mapsto \mathcal{L}_u w - a$. Given a right-hand side q, integration against the adjoint probability measure of Proposition 9.11.1 forces $a = -\int_X q \, \mathrm{d}\mu_u^\gamma$. The Fredholm alternative then gives a unique mean-zero solution w, and Schauder

estimates bound this inverse between Hölder spaces. Since positivity of Γ_u is an open condition, the implicit function theorem gives solutions for all nearby parameters.

For closedness, note that the functions F_t are uniformly bounded in every C^k norm. After supremum normalization, Proposition 9.10.1 bounds u and b, the second-order and rescaling estimates bound the gradient and the complex Hessian, and Lemma 9.16.1 gives all higher bounds. Subtracting the mean preserves all derivative bounds and changes the potentials by uniformly bounded constants. A subsequence of mean-zero solutions along a convergent sequence of parameters therefore converges smoothly to a solution at the limiting parameter, and the bounds $aI \le Q \le b_0 I$ preserve strict positivity in the limit. Thus the set of solvable parameters is nonempty, open and closed, hence equal to $[0, 1]$.

Finally, consider two solutions (u, b) and (w, c) for the same F. At a maximum of $u - w$ their gradients agree and their complex Hessians are ordered, so the first-order terms are equal there and, since P_n preserves the order, $Q_u \le Q_w$. The equation then gives $b \le c$, and at a minimum the reverse inequality gives $b \ge c$. Hence $b = c$. Along the segment between u and w, the matrices Q remain positive because the ansatz is affine in the potential. Integrating the derivative of the logarithmic determinant along that segment produces a uniformly elliptic scalar operator with first-order terms and no zeroth-order term that annihilates $u - w$. The maximum principle shows that $u - w$ is constant, and the supremum normalization makes the constant zero. □

9.17 Normalization for the Gauduchon equation

By Theorem 9.9.1, every smooth real function F determines a scalar $b_\gamma(F)$, the constant b of that theorem. As for the Monge–Ampère equation, its variation is governed by the adjoint probability measure μ_u^γ of Proposition 9.11.1 and by the concavity of the logarithmic determinant. To differentiate solutions, we fix a smooth positive volume form $\mathrm{d}V_0$ and use the normalization $\int_X u \, \mathrm{d}V_0 = 0$ in place of $\sup_X u = 0$.

Lemma 9.17.1 *The solution $(u, b_\gamma(F))$, normalized by $\int_X u \, \mathrm{d}V_0 = 0$, depends smoothly on the parameters of every smooth finite-dimensional family of functions F.*

Proof The map $\Gamma \mapsto \eta$ with $\eta^{n-1} = \Gamma$ is smooth on positive forms, since in a frame it is the inverse of the smooth map $\eta \mapsto \eta^{n-1}$, whose differential is invertible. The openness argument in the proof of Theorem 9.9.1, with the $\mathrm{d}V_0$-mean in place of the γ^n-mean, gives a bounded inverse for the derivative with respect to the potential and the scalar between the relevant Hölder spaces. The implicit function theorem gives local smooth solution maps, and uniqueness shows that they agree on overlaps. Applying this for every order of Hölder regularity gives the assertion for smooth data. □

For a smooth family of prescribed functions $F_t \in C^\infty(X,\mathbb{R})$, with t in an open interval of $\mathbb{R}$, let u_t be the corresponding solutions with $\int_X u_t \, dV_0 = 0$, and set $Q_t = Q_{u_t}$ as in (9.18). The expression

$$\operatorname{tr}\big((Q_t^{-1}\dot{Q}_t)^2\big)$$

is independent of the chosen frame and nonnegative, because $Q_t^{-1}\dot{Q}_t$ is similar to the Hermitian matrix $Q_t^{-1/2}\dot{Q}_t Q_t^{-1/2}$.

Theorem 9.17.1 *For a smooth family F_t and its solutions,*

$$\dot{b}_\gamma(F_t) = -\int_X \dot{F}_t \, d\mu_{u_t}^\gamma,$$
$$\ddot{b}_\gamma(F_t) = -\int_X \ddot{F}_t \, d\mu_{u_t}^\gamma - \frac{1}{n-1}\int_X \operatorname{tr}\big((Q_t^{-1}\dot{Q}_t)^2\big)\, d\mu_{u_t}^\gamma.$$

In particular, b_γ is concave, and along $F_t = F_0 + tG$ its second derivative is strictly negative unless G is constant. Moreover, for smooth real functions F, G on X and every real constant a,

$$b_\gamma(F + a) = b_\gamma(F) - a, \qquad |b_\gamma(G) - b_\gamma(F)| \le \|G - F\|_\infty.$$

Proof By (9.18),

$$\mathcal{G}(u) = \frac{1}{n-1}\log \det_\gamma Q_u.$$

Differentiating $\mathcal{G}(u_t) = F_t + b_\gamma(F_t)$ once gives $\mathcal{L}_{u_t}\dot{u}_t = \dot{F}_t + \dot{b}_\gamma(F_t)$, and integration against the adjoint probability measure gives the first formula.

Because Γ_u is affine in u, its second derivative along the family is $\mathcal{D}_\gamma \ddot{u}_t$. The formula for the second derivative of $\log\det$ used in the proof of Theorem 9.7.1 therefore gives

$$\mathcal{L}_{u_t}\ddot{u}_t - \frac{1}{n-1}\operatorname{tr}\big((Q_t^{-1}\dot{Q}_t)^2\big) = \ddot{F}_t + \ddot{b}_\gamma(F_t).$$

Integrating against $\mu_{u_t}^\gamma$ at this fixed parameter gives the second formula; no derivative of the measure is needed.

For affine F_t, we have $\ddot{F}_t = 0$, and positivity of the density of $\mu_{u_t}^\gamma$ proves concavity. If the second derivative vanishes, then $\dot{Q}_t = 0$, so $\dot{\Gamma}_{u_t} = 0$ and $\mathcal{L}_{u_t}\dot{u}_t = 0$. By Proposition 9.11.1, $\dot{u}_t$ is constant, and the first differentiated equation forces G to be constant. Conversely, adding a constant to F changes only b, by the opposite constant. Finally, integrate the first derivative along the segment from F to G: since $\mu_{u_t}^\gamma$ is a probability measure, the derivative lies between $-\sup_X(G-F)$ and $-\inf_X(G-F)$, which proves the Lipschitz bound. □

The Lipschitz bound extends b_γ uniquely to continuous functions F. Constructing corresponding weak solutions would require, in addition, a volume measure for the $(n-1)$st roots of singular forms in the Aeppli ansatz, compactness of their potentials, and stability of the adjoint equation.

On a surface with Gauduchon background form γ_0, conservation of the total mass makes the scalar and the adjoint probability measure explicit.

Example 9.17.1 If $n = 2$ and γ_0 is Gauduchon, then $\Gamma_u = \gamma_0 + \mathrm{dd}^c u = \eta_u$, and η_u is also Gauduchon. The mass identity of Theorem 2.2.2 gives $\int_X \eta_u^2 = \int_X \gamma_0^2$. Therefore

$$b_\gamma(F) = \log \int_X \gamma_0^2 - \log \int_X \mathrm{e}^F \gamma^2, \qquad \mathrm{d}\mu_u^\gamma = \frac{\mathrm{e}^F \gamma^2}{\int_X \mathrm{e}^F \gamma^2}.$$

The adjoint equation of Proposition 9.11.2 gives the same measure, because $\mathrm{dd}^c \eta_u = 0$ and hence ρ_u is constant. Along $F + tG$, the second derivative of b_γ is minus the variance of G with respect to this probability measure.

In Chapter 10 we return to the potential equation for $\omega + \mathrm{dd}^c u$. Smooth approximation will extend its solvability to nonnegative, nonzero L^p densities, $p > 1$; control of the normalization constant and uniform convergence of the potentials will replace the derivative estimates used here.

Chapter 10
Continuous solutions and normalization

Throughout this chapter, X is a connected compact complex manifold of dimension $n \geq 1$, ω is a Hermitian form and $\mathrm{d}V$ is a smooth positive volume form on X. As in Chapter 9, we write $\omega_u = \omega + \mathrm{dd}^{\mathrm{c}} u$; for a bounded ω-plurisubharmonic function u, the power ω_u^n is the Bedford–Taylor product of Proposition 1.7.1. We fix $p > 1$ and a nonnegative $f \in L^p(X, \mathrm{d}V)$ with $\int_X f \, \mathrm{d}V > 0$. Norms and almost-everywhere statements refer to $\mathrm{d}V$ unless another measure is specified.

We seek continuous ω-plurisubharmonic solutions of $\omega_u^n = c f \, \mathrm{d}V$, with an unknown constant $c > 0$, and of $\omega_u^n = \mathrm{e}^{\lambda u} f \, \mathrm{d}V$, with $\lambda > 0$. Smooth positive approximations of f give solutions by Chapter 9. To pass to a limit, we need uniform control of both their constants and their potentials. Integration against a Gauduchon metric bounds the constants and hence the L^p norms of the resulting densities. Modified comparison then turns normalized L^1 compactness into uniform compactness, which identifies the limiting Monge–Ampère measure.

For the exponential equation, a weighted Gauduchon mean also controls the additive constants. Letting λ decrease to zero determines the normalization constant c from f, even when the normalized potential is not unique. When a bounded solution has a smooth positive density depending on the point and the potential, proper exponential equations with a frozen smooth approximation of that potential give a trace estimate and prove that the solution is smooth.

On the Hopf threefold, the constant has a sharp lower bound, with equality exactly for densities pulled back from the projective plane. For densities of unit integral with a common L^p bound, $1 < p < \infty$, near equality forces normalized potentials to approach their fiber averages uniformly and gives weak convergence in L^p for the density differences. Smooth oscillating examples show why strong L^1 convergence of the densities need not follow.

For $n \geq 2$, the final two sections fix a smooth real $(1,1)$-form χ and study concave functions of the eigenvalues of $\omega^{-1}(\chi + \mathrm{dd}^{\mathrm{c}} u)$. An admissible reference with a strict asymptotic gap controls an auxiliary Monge–Ampère comparison, giving stability as positive right-hand sides tend to zero. Equicontinuous data then give uniform compactness. Nearby smooth admissible functions yield a gradient bound if the first derivatives of the data are uniformly bounded.

10.1 Continuous solvability

There are two natural ways to normalize the prescribed density: by an unknown positive constant, or by an exponential of the potential.

Theorem 10.1.1 (Kołodziej–Nguyen) *There are $c > 0$ and $u \in \mathrm{PSH}(X, \omega) \cap C(X)$ such that*

$$(\omega + \mathrm{dd^c} u)^n = c f \, \mathrm{d}V.$$

The potential can be normalized by $\sup_X u = 0$.

The constant c is uniquely determined by f, by Proposition 10.6.1. The normalized potential, however, need not be unique, even for a smooth density; see Theorem 11.6.1.

Theorem 10.1.2 (Nguyen) *For every $\lambda > 0$, there is a unique continuous ω-plurisubharmonic function u_λ satisfying*

$$(\omega + \mathrm{dd^c} u_\lambda)^n = \mathrm{e}^{\lambda u_\lambda} f \, \mathrm{d}V. \tag{10.1}$$

10.2 The modified comparison principle

For a Hermitian background, the total Monge–Ampère mass varies with the potential, and the ordinary comparison principle fails in general (see Theorem 11.5.2). A weaker form survives. Replacing the comparison potential v by $(1 - \varepsilon)v$ leaves the strictly positive form $\varepsilon\omega$ in reserve, and this reserve absorbs the torsion terms. On a sublevel set of height s, integration by parts makes the error proportional to s, and a finite induction controls the intermediate mixed products. The resulting multiplicative correction tends to one as s tends to zero with ε fixed.

Since X is compact and ω is positive, we can choose $B_0 \geq 1$ such that

$$-B_0\omega^2 \leq \mathrm{dd^c}\omega \leq B_0\omega^2, \qquad -B_0\omega^3 \leq \mathrm{d}\omega \wedge \mathrm{d^c}\omega \leq B_0\omega^3.$$

These inequalities are understood after wedging with positive forms of complementary degree; forms of degree larger than $2n$ vanish, and the corresponding terms below are omitted.

Theorem 10.2.1 *Let $u, v \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$ and $0 < \varepsilon < 1$. For $s > 0$, put*

$$m_\varepsilon = \inf_X \big(u - (1-\varepsilon)v\big), \qquad U_{\varepsilon,s} = \{u < (1-\varepsilon)v + m_\varepsilon + s\}.$$

If $0 < s < \varepsilon^3/(32B_0n^2)$, then, with $a = B_0n^2s\varepsilon^{-3}$,

$$(1-4a)^n \int_{U_{\varepsilon,s}} \omega^n_{(1-\varepsilon)v} \le \int_{U_{\varepsilon,s}} \omega^n_u. \tag{10.2}$$

In particular, the reverse factor $(1-4a)^{-n}$ tends to one as $s \downarrow 0$ for fixed ε.

Proof Write $v_\varepsilon = (1-\varepsilon)v$, $U = U_{\varepsilon,s}$ and

$$\phi = \max(u, v_\varepsilon + m_\varepsilon + s), \qquad T_k = \omega_u^k \wedge \omega_\phi^{n-k}, \qquad I_k = \int_U T_k \quad (0 \le k \le n).$$

Set $I_{-1} = I_{-2} = 0$. Then $0 \le \phi - u \le s$, this difference vanishes outside U, and on U plurifine locality gives $\omega_\phi = \omega_{v_\varepsilon} \ge \varepsilon\omega$ in all bounded products.

By Lemma 1.7.1, for every fixed positive mixed product W of $n-1$ bounded-potential factors,

$$\mathbf{1}_{\{u=\phi\}}\omega_u \wedge W \le \mathbf{1}_{\{u=\phi\}}\omega_\phi \wedge W.$$

For $0 \le k \le n-1$, apply this with $W = \omega_u^k \wedge \omega_\phi^{n-k-1}$. Since $u = \phi$ on $X \setminus U$, the difference $T_k - T_{k+1} = (\omega_\phi - \omega_u) \wedge W$ is nonnegative there. Consequently

$$I_k - I_{k+1} \le \int_X \mathrm{dd^c}(\phi - u) \wedge W = \int_X (\phi - u)\mathrm{dd^c}W. \tag{10.3}$$

This integration by parts is valid for bounded potentials. To see this, approximate u and ϕ by decreasing sequences of smooth, uniformly bounded ω-plurisubharmonic functions, using Theorem 1.11.1. For smooth functions the identity is ordinary integration by parts. The form $\mathrm{dd^c}W$ expands as below into bounded Hessian products and smooth forms, and bounded Bedford–Taylor convergence, also against bounded quasi-continuous coefficients converging in capacity, passes each term to the limit.

Set $r = n-k-1$. Since $\mathrm{d}\omega_u = \mathrm{d}\omega_\phi = \mathrm{d}\omega$, expansion gives

$$\begin{aligned}\mathrm{dd^c}W = {}& k\mathrm{dd^c}\omega \wedge \omega_u^{k-1} \wedge \omega_\phi^r + r\mathrm{dd^c}\omega \wedge \omega_u^k \wedge \omega_\phi^{r-1} \\ & + k(k-1)\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge \omega_u^{k-2} \wedge \omega_\phi^r \\ & + 2kr\,\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge \omega_u^{k-1} \wedge \omega_\phi^{r-1} \\ & + r(r-1)\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge \omega_u^k \wedge \omega_\phi^{r-2}.\end{aligned}$$

Terms containing a negative power have coefficient zero and are omitted. On U we may replace each ω^j in an upper bound by $\varepsilon^{-j}\omega_\phi^j$, since $\omega_\phi \ge \varepsilon\omega$ there. Using $\phi - u \le s$ and $\varepsilon^{-2} \le \varepsilon^{-3}$ in (10.3), we obtain

$$I_k - I_{k+1} \le B_0 s\varepsilon^{-3}\big(k(k-1)I_{k-2} + k(1+2r)I_{k-1} + r^2 I_k\big).$$

Each coefficient is at most n^2, and $a = B_0 n^2 s\varepsilon^{-3}$. Hence

$$I_k - I_{k+1} \le a(I_{k-2} + I_{k-1} + I_k). \tag{10.4}$$

Put $q = 1 - 4a$; the assumption on s gives $a < 1/32$, so $q > 7/8$. Suppose inductively that $qI_j \le I_{j+1}$ for $j < k$. Then $I_{k-1} \le q^{-1} I_k$ and $I_{k-2} \le q^{-2} I_k$ whenever the indices exist. Since

$$1 + q^{-1} + q^{-2} \le 1 + 8/7 + 64/49 < 4,$$

(10.4) gives $qI_k \le I_{k+1}$. The case $k = 0$ follows from the same formula with the two absent terms set to zero. By induction, $q^n I_0 \le I_n$. Since $T_0 = \omega_{v_\varepsilon}^n$ on U and $T_n = \omega_u^n$, this is the theorem. In dimension one all torsion terms vanish and the same argument applies. □

A strict multiplicative inequality between the Monge–Ampère measures on $\{u < v\}$ absorbs the error in modified comparison. One first chooses the positivity reserve ε, and then a sublevel set thin enough to preserve the strict inequality.

Theorem 10.2.2 *Let $u, v \in \mathrm{PSH}(X, \omega) \cap L^\infty(X)$, and let $0 \le c < 1$. If*

$$\mathbf{1}_{\{u<v\}} \omega_u^n \le c\, \mathbf{1}_{\{u<v\}} \omega_v^n,$$

then $u \ge v$. In particular, $\omega_u^n(\{u < v\}) = 0$ implies $u \ge v$.

Proof Suppose $m = \inf_X(u - v) < 0$. Choose $\varepsilon > 0$ so small that

$$(1 - \varepsilon)^n > c, \qquad 2\varepsilon \|v\|_\infty < -m/4,$$

omitting the second restriction if $v = 0$. Let m_ε and $U_{\varepsilon,s}$ be defined as in Theorem 10.2.1 for this pair u, v. Since $|m_\varepsilon - m| \le \varepsilon \|v\|_\infty$, for all sufficiently small $s > 0$ the set $U = U_{\varepsilon,s}$ is contained in $\{u < v\}$: there

$$u - v < m_\varepsilon + s - \varepsilon v \le m + 2\varepsilon \|v\|_\infty + s < 0.$$

The set U is nonempty by the definition of the infimum and has positive volume by Lemma 1.3.4.

Decrease s further so that Theorem 10.2.1 applies and $(1 - 4B_0 n^2 s\varepsilon^{-3})^n (1-\varepsilon)^n > c$. Write the first factor as q^n. Positivity of every mixed term gives

$$\omega_{(1-\varepsilon)v}^n \ge (1 - \varepsilon)^n \omega_v^n + \varepsilon^n \omega^n.$$

Modified comparison and the assumption would therefore imply

$$q^n (1 - \varepsilon)^n \int_U \omega_v^n + q^n \varepsilon^n \int_U \omega^n \le \int_U \omega_u^n \le c \int_U \omega_v^n.$$

All integrals are finite, so the choice $q^n(1 - \varepsilon)^n > c$ and the positive volume of U make this impossible. Hence $m \ge 0$. □

Corollary 10.2.1 *Every bounded ω-plurisubharmonic function has strictly positive Monge–Ampère mass.*

Proof Let u be a bounded ω-plurisubharmonic function. If $\omega_u^n = 0$, then Theorem 10.2.2, applied with $c = 0$ and the constant potential $v = \sup_X u + 1$, would give $u \geq v$, a contradiction. □

The positive lower bound in Corollary 10.2.1 depends on the potential. A bound that is uniform over all bounded potentials is the condition $v_-(\omega) > 0$ of Definition 6.5.1.

Corollary 10.2.2 *If $u, v \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$ and $\lambda > 0$, then*

$$\mathrm{e}^{-\lambda v}\omega_v^n \geq \mathrm{e}^{-\lambda u}\omega_u^n \quad \Longrightarrow \quad v \leq u.$$

Proof For every $t > 0$, the assumption gives $\omega_u^n \leq \mathrm{e}^{-\lambda t}\omega_v^n$ on $\{u < v - t\}$. Since $\omega_{v-t} = \omega_v$, Theorem 10.2.2, applied to u and $v - t$, gives $u \geq v - t$. Letting $t \downarrow 0$ proves $v \leq u$. □

10.3 Capacity estimates and uniform compactness

Let $\mathrm{Cap} = \mathrm{Cap}_\omega$ denote the capacity of Section 1.8. Modified comparison bounds the capacity of a thin sublevel set by the Monge–Ampère mass of a slightly larger one. A bound by a power $1 + \alpha$ of capacity, $\alpha > 0$, makes the resulting iteration converge. For an L^p density, Corollary 1.8.1 supplies the case $\alpha = 1$. Iterating the two inequalities gives a lower bound for the capacity of every sublevel set of fixed height above the minimum. Since the capacity of deep sublevel sets of normalized potentials is small by the tail estimate (1.15), this bounds the depth of a normalized solution.

Lemma 10.3.1 *Let $u, v \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$, with $-H \leq v \leq 0$ and $H \geq 1$. Fix $0 < \varepsilon < 1$, and put*

$$m = \inf_X (u - (1-\varepsilon)v), \qquad U_s = \{u < (1-\varepsilon)v + m + s\}.$$

There are $\delta_\varepsilon > 0$, depending only on (X, ω, ε), and $C_H > 0$, depending only on (n, H), such that

$$t^n \,\mathrm{Cap}(U_s) \leq C_H \int_{U_{s+t}} \omega_u^n \qquad (0 < s, t,\ s + t < \delta_\varepsilon). \tag{10.5}$$

Every U_s, $s > 0$, has positive capacity.

Proof Let B_0 be the constant of Theorem 10.2.1, and set

$$\delta_\varepsilon = \min\{1 - \varepsilon, \varepsilon^3/(128 B_0 n^2)\}.$$

For a capacity test $0 \le \rho \le 1$, put

$$\tau = \frac{t}{2(1-\varepsilon)(H+1)}, \quad w = (1-\tau)v + \tau\rho, \quad m' = \inf_X (u - (1-\varepsilon)w).$$

Then $0 < \tau < 1$ and $0 \le (1-\varepsilon)(w-v) \le t/2$, so $m - t/2 \le m' \le m$. Consequently

$$U_s \subset V := \{u < (1-\varepsilon)w + m' + s + t/2\} \subset U_{s+t}.$$

We apply modified comparison to u, w at height $s + t/2 < \delta_\varepsilon$; by the choice of δ_ε, its inverse factor is at most $(8/7)^n$. Moreover,

$$\omega_{(1-\varepsilon)w} \ge (1-\varepsilon)\tau\omega_\rho = \frac{t}{2(H+1)}\omega_\rho.$$

Integrating over $U_s \subset V$, applying modified comparison on V, and taking the supremum over ρ, we obtain (10.5) with $C_H = [2(H+1)]^n(8/7)^n$. Finally, each U_s is nonempty by the definition of the infimum, so it has positive smooth volume by Lemma 1.3.4, and hence positive capacity, as the constant test function shows. □

Lemma 10.3.2 *In the setting of Lemma 10.3.1, suppose that $A, \alpha > 0$ and*

$$\omega_u^n(E) \le A \operatorname{Cap}_\omega(E)^{1+\alpha} \qquad (E \subset X \text{ Borel}).$$

For every $0 < D < \delta_\varepsilon$,

$$D \le C_\alpha (C_H A)^{1/n} \operatorname{Cap}_\omega(U_D)^{\alpha/n}, \qquad C_\alpha = \frac{2}{1-2^{-\alpha}}. \tag{10.6}$$

In particular, when $\alpha = 1$,

$$\operatorname{Cap}(U_D) \ge \frac{D^n}{4^n C_H A}. \tag{10.7}$$

Proof Put $a(s) = \operatorname{Cap}_\omega(U_s)^{1/n} > 0$ and $K = (C_H A)^{1/n}$. The thin-sublevel estimate gives

$$t\, a(s) \le K a(s+t)^{1+\alpha} \qquad (0 < s, t,\ s + t < \delta_\varepsilon).$$

Suppose $C_\alpha K a(D)^\alpha < D$. Starting with $s_0 = D$, set

$$t_j = 2K a(s_j)^\alpha, \qquad s_{j+1} = s_j - t_j.$$

If $a(s_i) \le 2^{-i} a(D)$ for $0 \le i \le j$, then

$$\sum_{i=0}^{j} t_i \le 2K a(D)^\alpha \sum_{i=0}^{j} 2^{-i\alpha} < C_\alpha K a(D)^\alpha < D.$$

Thus $s_{j+1} > 0$, and the sublevel estimate, applied with $s = s_{j+1}$ and $t = t_j$, gives $a(s_{j+1}) \le a(s_j)/2$. Induction justifies every step. The decreasing sequence s_j has a

limit

$$s_\infty \geq D - C_\alpha K a(D)^\alpha > 0.$$

Monotonicity now gives $0 < a(s_\infty) \leq 2^{-j} a(D)$ for every j, a contradiction. This proves (10.6), including the case in which $U_D = X$. □

Theorem 10.3.1 *There are constants $C_p, c_p > 0$, depending only on $(X, \omega, \mathrm{d}V, p)$, such that, whenever $u \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$, $\sup_X u = 0$, and*

$$\omega_u^n = F\,\mathrm{d}V, \qquad F \in L^p(X, \mathrm{d}V), \quad F \geq 0,$$

we have

$$\|u\|_\infty \leq C_p(1 + \|F\|_p), \qquad \|F\|_p \geq c_p. \tag{10.8}$$

Proof By Corollary 10.2.1, F is not almost everywhere zero. Apply Lemma 10.3.2 with $v = 0$, $H = 1$, $\varepsilon = 1/2$, and $A = C\|F\|_p > 0$, where C is the constant of Corollary 1.8.1. Fix $D = \delta_{1/2}/2$, and put $M = -\inf_X u$. Since $U_D = \{u < -M + D\}$, the resulting inequality reads

$$\mathrm{Cap}(\{u < -M + D\}) \geq c/\|F\|_p.$$

If $M > D + 1$, (1.15) bounds this capacity above by $C/(M - D)$, and the first assertion follows; the case $M \leq D + 1$ is immediate. Bounding the same capacity above by $\mathrm{Cap}(X)$ gives the second assertion. □

Suppose that two uniformly bounded solutions are far apart at some point. The preceding estimates give a fixed positive lower bound for the capacity of a sublevel set of their difference. If their L^1 distance is small, this set has small volume, and the uniform L^p bound for the densities then makes its Monge–Ampère mass small. This contradicts the sublevel estimate (10.5), and so upgrades L^1 compactness to uniform compactness. Put $p' = p/(p-1)$.

Theorem 10.3.2 *Suppose $u_j \in \mathrm{PSH}(X,\omega) \cap C(X)$, $\sup_X u_j = 0$, and*

$$\omega_{u_j}^n = F_j\,\mathrm{d}V, \qquad F_j \geq 0, \qquad \sup_j \|F_j\|_p < \infty$$

for the fixed $p > 1$. If (u_j) is Cauchy in $L^1(X, \mathrm{d}V)$, then it is Cauchy uniformly. In particular, every such family has a subsequence converging uniformly to a continuous ω-plurisubharmonic function.

Proof By Theorem 10.3.1, there is a common $H \geq 1$ with $-H \leq u_j \leq 0$. Suppose that the sequence is not uniformly Cauchy. After exchanging indices if necessary, we find $a > 0$ and arbitrarily large j, k with

$$S := \inf_X (u_k - u_j) \leq -a.$$

Choose $0 < \varepsilon < 1$ such that $\varepsilon H < a/4$, and choose a fixed $D > 0$ with $2D < \delta_\varepsilon$ and $2D < a/4$. Apply the preceding sublevel lemmas with $u = u_k$ and $v = u_j$. Since $v \le 0$, $m = \inf(u - (1-\varepsilon)v) \le S$. Thus

$$U_{2D} \subset \{u - v < S + 2D + \varepsilon H\} \subset \{|u - v| > a/2\}.$$

The capacity lower bound (10.7), with a constant A independent of j, k given by Corollary 1.8.1, yields $\operatorname{Cap}(U_D) \ge c > 0$. On the other hand, (10.5) and the inequalities of Hölder and Chebyshev give

$$\begin{aligned} D^n \operatorname{Cap}(U_D) &\le C_H \int_{U_{2D}} F_k \, dV \\ &\le C_H \|F_k\|_p \left(\frac{2\|u_k - u_j\|_1}{a} \right)^{1/p'} \longrightarrow 0. \end{aligned}$$

This contradiction proves that the sequence is uniformly Cauchy. For the last assertion, the normalized compactness theorem, Theorem 1.4.1, gives an L^1-Cauchy subsequence of any such family. Its uniform limit is continuous, and distributional convergence preserves ω-plurisubharmonicity. □

10.3.1 Stability under a power capacity bound

The capacity lower bound of Lemma 10.3.2 turns an integral error against the solution measure into a uniform error. The argument uses only the power capacity bound on this measure and therefore applies to singular measures as well.

Proposition 10.3.1 *Fix $A, \alpha > 0$ and $H \ge 1$. Let $u, v \in \operatorname{PSH}(X, \omega) \cap C(X)$ satisfy $\sup_X u = 0$ and $-H \le v \le 0$, and suppose*

$$\mu(E) \le A \operatorname{Cap}_\omega(E)^{1+\alpha}, \qquad \mu = \omega_u^n, \qquad E \subset X \text{ Borel}.$$

There is a constant C, depending only on $(X, \omega), A, \alpha, H$, such that

$$\sup_X (v - u)_+ \le C \left(\int_X (v - u)_+ \, d\mu \right)^{\sigma_\alpha}, \qquad \sigma_\alpha = \frac{\alpha}{3n(1+\alpha) + \alpha}. \tag{10.9}$$

For the square-capacity bound, $\alpha = 1$, the exponent is $1/(6n+1)$.

Proof Write $L = \int_X (v-u)_+ \, d\mu$ and $S = \sup_X (v-u)_+$. Apply Lemma 10.3.2 with competitor zero, $\varepsilon = 1/2$ and one fixed $0 < D < \delta_{1/2}$. It bounds $\operatorname{Cap}_\omega\{u < \inf_X u + D\}$ below by a positive constant. The tail estimate (1.15) therefore bounds $-\inf_X u$ in terms of $(X, \omega), A, \alpha$. Consequently S has a fixed upper bound.

For $0 < \varepsilon \le 1/2$, choose a fixed small $c > 0$ and put $D = c\varepsilon^3$. The formula for δ_ε in Lemma 10.3.1 allows c to be chosen so that $2D < \delta_\varepsilon$ and $4D \le \varepsilon$. With

$$m = \inf_X (u - (1-\varepsilon)v), \qquad U_s = \{u < (1-\varepsilon)v + m + s\},$$

we have $m \le -S$ when $S > 0$, since $v \le 0$. On U_{2D},

$$v - u > S - \varepsilon H - 2D.$$

If $S > 2\varepsilon H + 4D$, this is greater than $S/2$. The backwards and thin-sublevel estimates give

$$c_0 D^{n(1+1/\alpha)} \le D^n \operatorname{Cap}_\omega(U_D) \le C_H \mu(U_{2D}) \le \frac{2C_H L}{S},$$

where $c_0 > 0$ depends only on the stated data. Hence $S \le CL\varepsilon^{-3n(1+1/\alpha)}$ in this case. In the other case, $S \le (2H+1)\varepsilon$.

For sufficiently small $L > 0$, choose $\varepsilon = L^{\sigma_\alpha}$. The two alternatives give (10.9). The remaining positive values of L are covered by the fixed upper bound for S. If $L = 0$, the first alternative is impossible for every small ε, and the second gives $S = 0$ on letting $\varepsilon \downarrow 0$. □

10.4 Construction of continuous solutions

Smooth approximation gives solutions with unknown normalization constants. A Gauduchon trace bounds these constants above, and the lower bound for the density norm in Theorem 10.3.1 bounds them away from zero. The resulting uniform L^p bound puts the potentials in the compact family of Theorem 10.3.2, so their limit solves the prescribed equation.

Proof (of Theorem 10.1.1) Choose smooth strictly positive functions $f_j \to f$ in $L^p(X, \mathrm{d}V)$. By Theorem 9.1.1, there are smooth u_j with $\omega_{u_j} > 0$ and constants c_j such that

$$\omega_{u_j}^n = c_j f_j \,\mathrm{d}V, \qquad \sup_X u_j = 0, \qquad c_j > 0.$$

We first bound the constants. For $n \ge 2$, fix a Gauduchon metric γ. By Proposition 4.2.2,

$$c_j^{1/n} A_j \le \int_X \omega \wedge \gamma^{n-1}, \qquad A_j = \int_X (f_j \mathrm{d}V/\gamma^n)^{1/n} \gamma^n.$$

Since $|x^{1/n} - y^{1/n}| \le |x-y|^{1/n}$ for $x, y \ge 0$, Hölder's inequality gives $A_j \to A > 0$, where $A = \int_X (f \mathrm{d}V/\gamma^n)^{1/n} \gamma^n$. Thus c_j is bounded above. In dimension one, Stokes' theorem gives the same estimate, with $A_j = \int_X f_j \,\mathrm{d}V$.

The lower bound for the density norm in Theorem 10.3.1 gives $c_j \|f_j\|_p \ge c_p$, so the constants are bounded away from zero. The densities $c_j f_j$ are therefore uniformly bounded in L^p, and the same theorem gives a common bound for the u_j. By Theorem 1.4.1, we may pass to a subsequence with $c_j \to c > 0$ and u_j Cauchy in L^1. By Theorem 10.3.2, $u_j \to u$ uniformly, with u continuous and $\sup_X u = 0$.

Bounded Bedford–Taylor continuity gives $\omega_{u_j}^n \rightharpoonup \omega_u^n$, while $c_j f_j \to cf$ in L^p. Hence $\omega_u^n = cf\,\mathrm{d}V$, as required. □

For the exponential equation, the role of the normalization constant is played by $\mathrm{e}^{\lambda \sup_X u}$. Its upper bound comes from Jensen's inequality: weighting the Gauduchon volume by the nth root of the density relates $\sup_X u$ to the Gauduchon trace of ω_u, which does not depend on u. The lower bound for the density norm again gives the reverse bound.

Lemma 10.4.1 *Fix $\lambda > 0$. Suppose that smooth functions u_j with $\omega_{u_j} > 0$ solve*

$$\omega_{u_j}^n = \mathrm{e}^{\lambda u_j} f_j\,\mathrm{d}V,$$

where the smooth strictly positive functions f_j converge in L^p to a nonnegative nonzero f. Then $M_j = \sup_X u_j$ is bounded above and below, uniformly in j.

Proof Absorbing the fixed smooth positive ratio $\mathrm{d}V/\omega^n$ into f_j and f preserves their L^p convergence, so we may assume $\mathrm{d}V = \omega^n$. Choose $\rho > 0$ smooth with $\mathrm{dd}^{\mathrm{c}}(\rho\omega^{n-1}) = 0$, using Theorem 4.1.1; for $n = 1$, take $\rho = 1$. Put

$$\alpha = \int_X \rho\omega^n, \quad A_j = \int_X f_j^{1/n}\rho\omega^n, \quad \psi_j = u_j - M_j \le 0.$$

Set $A = \int_X f^{1/n}\rho\omega^n$. The inequality for nth roots used in the preceding existence proof gives $A_j \to A > 0$. Since $\mathrm{dd}^{\mathrm{c}}(\rho\omega^{n-1}) = 0$, the trace $\int_X \omega_{u_j} \wedge \rho\omega^{n-1}$ equals α; the arithmetic–geometric mean inequality therefore implies

$$\alpha = \int_X \omega_{u_j} \wedge \rho\omega^{n-1} \ge \mathrm{e}^{\lambda M_j/n} \int_X \mathrm{e}^{\lambda\psi_j/n} f_j^{1/n}\rho\omega^n.$$

Applying Jensen's inequality to the probability measure $A_j^{-1} f_j^{1/n}\rho\omega^n$ and taking logarithms, we obtain

$$\lambda M_j \le n\log(\alpha/A_j) + \frac{\lambda}{A_j}\int_X (-\psi_j) f_j^{1/n}\rho\omega^n. \tag{10.10}$$

By Lemma 1.5.1, the normalized potentials ψ_j have uniform L^q bounds for every finite q. With $q = np/(np-1)$, Hölder's inequality gives a uniform bound for the last integral, since $\|f_j^{1/n}\|_{np} = \|f_j\|_p^{1/n}$. This proves the upper bound for M_j.

Finally, the density $F_j = \mathrm{e}^{\lambda u_j} f_j$ satisfies $\|F_j\|_p \le \mathrm{e}^{\lambda M_j}\|f_j\|_p$. The lower-density bound of Theorem 10.3.1, applied to ψ_j, gives $c_p \le \mathrm{e}^{\lambda M_j}\|f_j\|_p$, which bounds M_j below. □

Proof (of Theorem 10.1.2) Choose smooth strictly positive functions $f_j \to f$ in L^p. By Theorem 9.6.1, there are smooth u_j with $\omega_{u_j} > 0$ and $\omega_{u_j}^n = \mathrm{e}^{\lambda u_j} f_j \, \mathrm{d}V$. The preceding lemma bounds $M_j = \sup_X u_j$, and consequently bounds $F_j = \mathrm{e}^{\lambda u_j} f_j$ in L^p. The normalized potentials $\psi_j = u_j - M_j$ are uniformly bounded by Theorem 10.3.1. We may pass to a subsequence with $M_j \to M$ and ψ_j Cauchy in L^1. Theorem 10.3.2 gives uniform convergence $u_j \to u \in \mathrm{PSH}(X, \omega) \cap C(X)$.

Uniform convergence and $f_j \to f$ in L^p give $\mathrm{e}^{\lambda u_j} f_j \to \mathrm{e}^{\lambda u} f$ in L^p, and continuity of bounded products therefore gives $\omega_u^n = \mathrm{e}^{\lambda u} f \, \mathrm{d}V$. Uniqueness, even among all bounded solutions, follows from bounded exponential comparison, Corollary 10.2.2. □

For the exponential equation, a larger density gives a smaller solution, since the factor $\mathrm{e}^{\lambda u}$ has to compensate for the increase. Bounded exponential comparison gives this monotonicity even where the densities vanish.

Lemma 10.4.2 *Let $\lambda > 0$, and let f_a, f_b be nonnegative nonzero L^p densities. Suppose that $a, b \in \mathrm{PSH}(X, \omega) \cap L^\infty(X)$ solve*

$$\omega_a^n = \mathrm{e}^{\lambda a} f_a \, \mathrm{d}V, \qquad \omega_b^n = \mathrm{e}^{\lambda b} f_b \, \mathrm{d}V.$$

If $f_a \le f_b$ almost everywhere, then $b \le a$ on X.

Proof Since $f_a \le f_b$, the two equations give $\mathrm{e}^{-\lambda b} \omega_b^n \ge \mathrm{e}^{-\lambda a} \omega_a^n$. Hence $b \le a$ by Corollary 10.2.2, applied with $u = a$ and $v = b$. □

Corollary 10.4.1 *Every bounded ω-plurisubharmonic solution of $\omega_u^n = f \, \mathrm{d}V$ is continuous.*

Proof Since u is bounded, the density $\mathrm{e}^{-u} f$ is nonnegative, nonzero and belongs to L^p. By Theorem 10.1.2, applied with $\lambda = 1$ to this density, there is a continuous solution r of

$$\omega_r^n = \mathrm{e}^{r-u} f \, \mathrm{d}V.$$

The bounded potential u solves the same exponential equation. Applying Lemma 10.4.2 with $f_a = f_b = \mathrm{e}^{-u} f$ in both orders gives $u = r$, so u is continuous. □

10.5 Smoothness of bounded solutions

The continuous solutions constructed above have low regularity when the density is merely integrable. If the density is a smooth positive function of the point and the potential, every bounded solution is smooth. Differentiating that density directly would require derivatives of the solution. We instead freeze its occurrence in a smooth approximation and solve a proper exponential equation. A square of the prescribed potential in the maximum-principle function gives a trace estimate independent of its derivatives.

We first prove this estimate, retaining the matrix notation g, h, the traces S, B and the torsion trace τ of Lemma 9.4.1.

Lemma 10.5.1 *Fix $M \geq 0$ and a smooth real function G on $X \times [-M, M]$. There is C, depending only on ω, M and $\|G\|_{C^2}$, with the following property. If v, u are smooth, $\omega_v, \omega_u > 0$, $|v| \leq M$, and*

$$\omega_u^n = \mathrm{e}^{u+G(x,v)}\omega^n,$$

then

$$|u| \leq \|G\|_{C^0}, \qquad C^{-1}\omega \leq \omega_u \leq C\omega.$$

Proof The extrema of u give the first bound, as in Theorem 9.6.1. Put $k = g + (v_{i\bar{j}})$, $S_v = \operatorname{tr}_g k$, and $D = 2\|G\|_{C^0}$. The chain rule and Cauchy–Schwarz give, for $H = u + G(x, v)$,

$$\Delta_g H \geq -C_0\bigl(1 + S_v + |\partial v|_g^2\bigr).$$

Indeed $\Delta_g u = S - n \geq -n$, $\Delta_g v = S_v - n$, and the mixed derivatives of $G(x, v)$ are bounded below by $-C_0(1 + |\partial v|_g^2)$. Here and below constants depend only on the declared data.

Set $r = v + M + 1$, $R = 2M + 1$ and $s = u - \inf_X u + 1$, so $1 \leq r \leq R$ and $1 \leq s \leq D + 1$. For constants $A, L > 0$ to be chosen, maximize

$$Q = \log S + Ar^2 - Lu + s^{-1}$$

on X. If $S < 1$ at the maximum, the bounded ranges of r, u, s already bound S everywhere. Otherwise Lemma 9.4.1 applies there. Positivity gives

$$SB \geq n^2, \qquad S_v \leq S \operatorname{tr}_h k, \qquad |\partial v|_g^2 \leq S|\partial v|_h^2.$$

The middle inequality follows by diagonalizing h relative to g: every eigenvalue of h is at most S, and the diagonal entries of k are positive. Consequently,

$$\frac{\Delta_g H}{S} \geq -C_1 B - C_0 \operatorname{tr}_h k - C_0|\partial v|_h^2.$$

At the maximum,

$$\frac{\partial S}{S} = (L + s^{-2})\partial u - 2Ar\partial v.$$

Since $|\tau|_h^2 \leq C_g B$, Young's inequality bounds the torsion term by

$$\left|\frac{2}{S^2}\operatorname{Re}(h^{i\bar{j}}\tau_i S_{\bar{j}})\right| \leq s^{-3}|\partial u|_h^2 + A|\partial v|_h^2 + \frac{C_g\bigl((L+1)^2(D+1)^3 + AR^2\bigr)}{S^2}B.$$

Also

$$\Delta_h(Ar^2) \geq 2A \operatorname{tr}_h k - 2ARB + 2A|\partial v|_h^2,$$
$$\Delta_h(-Lu + s^{-1}) = (L + s^{-2})(B - n) + 2s^{-3}|\partial u|_h^2.$$

Combining these inequalities with (9.6) yields

$$0 \geq \Delta_h Q \geq \left(L - 2AR - C_2 - \frac{C_g((L+1)^2(D+1)^3 + AR^2)}{S^2} \right) B - n(L+1)$$
$$+ (2A - C_0)\operatorname{tr}_h k + (A - C_0)|\partial v|_h^2 + s^{-3}|\partial u|_h^2.$$

Choose $A > C_0 + 1$ and then $L > 2AR + C_2 + 2$. If the fraction in the coefficient of B is at least one, S^2 at the maximum is bounded by its numerator. Otherwise the displayed inequality gives $B \leq n(L+1)$ there. For $n \geq 2$, the bounded determinant gives

$$S \leq n\mathrm{e}^{2\|G\|_{C^0}} B^{n-1}.$$

For $n = 1$, $S = \mathrm{e}^{u+G(x,v)}$ directly. Thus S is bounded at the maximum in every case. Maximality of Q and the bounded ranges of r, u, s give the same bound globally. The positive lower determinant bound then bounds every eigenvalue of h away from zero. □

Theorem 10.5.1 *Let $F \in C^\infty(X \times \mathbb{R}, \mathbb{R})$. Every bounded $u \in \mathrm{PSH}(X, \omega)$ satisfying*

$$(\omega + \mathrm{d}\mathrm{d}^{\mathrm{c}} u)^n = \mathrm{e}^{F(x,u)}\,\mathrm{d}V$$

is smooth on X, and $\omega + \mathrm{d}\mathrm{d}^{\mathrm{c}} u > 0$.

Proof The density $\mathrm{e}^{F(x,u)}$ is bounded and strictly positive, so Corollary 10.4.1 makes u continuous. Choose smooth strictly ω-plurisubharmonic $v_j \downarrow u$ by Theorem 1.11.1. They have a common bound M and converge uniformly by Dini's theorem. Define

$$G(x,t) = F(x,t) - t + \log \frac{\mathrm{d}V}{\omega^n}.$$

By Theorem 9.6.1, there is a smooth strictly ω-plurisubharmonic a_j with

$$\omega_{a_j}^n = \mathrm{e}^{a_j + G(x, v_j)} \omega^n.$$

Put $\delta_j = \|G(x, v_j) - G(x, u)\|_{C^0} \to 0$. The given u solves the proper equation with coefficient $G(x, u)$. The weighted measures of $a_j - \delta_j$ and $a_j + \delta_j$ bracket its coefficient, so Corollary 10.2.2 gives

$$a_j - \delta_j \leq u \leq a_j + \delta_j.$$

Hence $a_j \to u$ uniformly. By Lemma 10.5.1, $C^{-1}\omega \leq \omega_{a_j} \leq C\omega$ uniformly. In particular $\Delta_g a_j$ is uniformly bounded. Fixed-operator elliptic estimates give uniform $W^{2,q}$ bounds for every finite q, so $u \in C^{1,\alpha}(X)$ for every $0 < \alpha < 1$.

We explain the uniformly elliptic passage to higher regularity, using the concave extension from Corollary 9.4.1. On a relatively compact coordinate chart, let P send a real Hessian to its complex Hermitian part, with the coordinate normalization of $\mathrm{d}\mathrm{d}^{\mathrm{c}}$. All matrices $g(x) + P(D^2 a_j)$ lie in a fixed compact interval $\mathcal{K} = \{\lambda I \leq A \leq \Lambda I\}$ of positive matrices. Define

$$\mathcal{F}(x, N) = \inf_{A \in \mathcal{K}} \left\{ \log\det A + \operatorname{tr}\left[A^{-1}(g(x) + P(N) - A) \right] \right\} - \log\det g(x).$$

The tangent inequality for the concave logarithmic determinant shows that this is the original operator whenever $g(x) + P(N) \in \mathcal{K}$. It is concave and uniformly elliptic on real symmetric matrices: for $N' \geq 0$, $P(N') \geq 0$ and its trace is a fixed positive multiple of $\operatorname{tr} N'$, while $A^{\pm 1}$ have uniform bounds. Its dependence on x is uniformly Lipschitz on this chart. Thus the a_j are classical, and hence viscosity, solutions of

$$\mathcal{F}(x, D^2 a_j) = a_j + G(x, v_j).$$

Both sides converge uniformly except for the Hessian variable. Stability of viscosity solutions gives $\mathcal{F}(x, D^2 u) = u + G(x, u)$ in the viscosity sense. The right-hand side is Hölder because $u \in C^{1,\alpha}$. The local Evans–Krylov estimate therefore gives $u \in C^{2,\beta}$ for some $\beta > 0$. The metric bounds pass to the limit, so the original equation is now uniformly elliptic with $\omega + \mathrm{dd}^{\mathrm{c}} u > 0$. Differentiating it and applying Schauder estimates repeatedly proves $u \in C^\infty(X)$. □

10.6 The vanishing exponent and scalar uniqueness

To show that the constant in Theorem 10.1.1 is unique, we compare the solution u_λ of (10.1) with constant translates of a solution u of the normalized equation. Translating u by its maximum and by its minimum gives two barriers for the exponential equation, whose separation is the oscillation of u. After multiplication by λ, both barriers converge to the logarithm of the constant as $\lambda \downarrow 0$. Since u_λ depends only on f and λ, the constant is determined by f.

Proposition 10.6.1 *Suppose $u \in \mathrm{PSH}(X, \omega) \cap C(X)$ and $c > 0$ satisfy $\omega_u^n = c f \, \mathrm{d}V$. Set $m = \inf_X u$ and $M = \sup_X u$. Then, for every $\lambda > 0$, the solution of (10.1) satisfies*

$$u + \frac{\log c}{\lambda} - M \leq u_\lambda \leq u + \frac{\log c}{\lambda} - m. \tag{10.11}$$

In particular,

$$\|\lambda u_\lambda - \log c\|_\infty \leq \lambda (M - m), \qquad \mathrm{e}^{\lambda u_\lambda} \longrightarrow c \quad \text{uniformly on } X \text{ as } \lambda \downarrow 0.$$

Consequently, c is the only constant for which the equation $\omega_v^n = c f \, \mathrm{d}V$ has a solution $v \in \mathrm{PSH}(X, \omega) \cap C(X)$.

Proof Set $a = u + \lambda^{-1} \log c - M$ and $b = u + \lambda^{-1} \log c - m$. These translates of u have the same Monge–Ampère measure as u, and since $m \leq u \leq M$,

$$\mathrm{e}^{\lambda a} f \, \mathrm{d}V \leq c f \, \mathrm{d}V = \omega_a^n = \omega_b^n \leq \mathrm{e}^{\lambda b} f \, \mathrm{d}V.$$

Thus $\mathrm{e}^{-\lambda a} \omega_a^n \geq f \, \mathrm{d}V = \mathrm{e}^{-\lambda u_\lambda} \omega_{u_\lambda}^n \geq \mathrm{e}^{-\lambda b} \omega_b^n$. Applying Corollary 10.2.2 first to the pair (u_λ, a) and then to the pair (b, u_λ) gives $a \leq u_\lambda \leq b$, which is (10.11). Multiplying these inequalities by λ and using $m \leq u \leq M$ gives the norm bound, and the uniform convergence follows.

If (v, c') is another such pair, the same argument applied to v gives $\lambda u_\lambda \to \log c'$, because u_λ depends only on f and λ. Hence $c' = c$. □

The barriers also give $\operatorname{osc}_X u_\lambda \le 2(M - m)$, and the densities $e^{\lambda u_\lambda} f$ converge to cf in L^p. By Theorem 10.3.2, the normalized potentials $u_\lambda - \sup_X u_\lambda$ are therefore precompact in $C^0(X)$ as $\lambda \downarrow 0$, and every cluster point solves the equation with constant c. Uniqueness of the constant does not, however, single out one cluster point; Proposition 14.19.1 describes the symmetries that these limits inherit.

For C^2 potentials, uniqueness of the constant also follows directly from the maximum principle: replacing one potential v by $(1 + \varepsilon)v$ leaves a strictly positive multiple of ω in reserve at an extremum.

Proposition 10.6.2 *Let $u, v \in C^2(X, \mathbb{R})$, and set $A = \omega + \mathrm{dd}^{\mathrm{c}} u$ and $B = \omega + \mathrm{dd}^{\mathrm{c}} v$. If $A, B \ge 0$ and $A^n = cB^n$ for a constant $c > 0$, then $c = 1$.*

Proof Fix $\varepsilon > 0$. At a maximum point of $u - (1 + \varepsilon)v$, the complex Hessian of this function is nonpositive, so that

$$A + \varepsilon\omega \le (1 + \varepsilon)B.$$

At this point $B > 0$, because $A + \varepsilon\omega > 0$. Monotonicity of the determinant and $A^n = cB^n$ give $c \le (1 + \varepsilon)^n$. Letting $\varepsilon \downarrow 0$ gives $c \le 1$, and interchanging the two potentials gives $c^{-1} \le 1$. □

10.7 Normalization on the Hopf threefold

In this section, X is the Hopf threefold of Chapter 8, with its Hermitian form ω and projection $\pi : X \to \mathbb{P}^2$. Recall that $\alpha = \pi^* \omega_{\mathrm{FS}}$ and $\beta = \omega - \alpha$, and that $\nu = \omega^3/6$ is a probability measure. We write E for the elliptic fiber, τ_a for the translation by $a \in E$, $\mathrm{d}A_E$ for the probability Haar measure of E, and A for the fiber-averaging operator of Proposition 8.7.1.

The minimum-mass characterization in that proposition gives a lower bound for the normalization constant, and equality forces every solution to descend to the projective base. The uniform L^p control of this chapter makes the equality case stable under limits of the data, although the densities themselves need only converge weakly.

Here we take $dV = \omega^3$; the density f is still a nonnegative nonzero function in L^p. By Theorem 10.1.1 and Proposition 10.6.1, there is a unique positive constant c_f for which the equation

$$(\omega + dd^c u)^3 = c_f f \omega^3$$

has a continuous ω-plurisubharmonic solution. Put $I_f = \int_X f \, d\nu$.

Proposition 10.7.1 *One has $c_f I_f \geq 1$, and every continuous solution u satisfies*

$$\|u - Au\|^2_{L^2(X,\nu)} \leq 4(c_f I_f - 1). \tag{10.12}$$

Moreover, $c_f I_f = 1$ if and only if $f = \pi^* g$ almost everywhere with respect to ν, for some nonnegative $g \in L^p(\mathbb{P}^2, \omega^2_{FS})$. In this case every continuous solution is the pullback of a continuous ω_{FS}-plurisubharmonic function.

Proof Integrating the equation gives $\int_X \omega_u^3 = 6 c_f I_f$. Both the inequality $c_f I_f \geq 1$ and (10.12) therefore follow from (8.21), whose left-hand side is nonnegative.

Suppose $c_f I_f = 1$. By Proposition 8.7.1, $u = \pi^* q$ for a bounded ω_{FS}-plurisubharmonic function q; local holomorphic sections of π show that q is continuous. Thus $u \circ \tau_a = u$ for every $a \in E$. Since bounded products are natural under biholomorphisms and ω is invariant under the translations, it follows that

$$\tau_a^*(f\nu) = f\nu \qquad (a \in E).$$

As f is defined only almost everywhere, we use this invariance as an identity of measures.

By Fubini's theorem, the fiber average Af is defined almost everywhere. It equals $\pi^* g$ for a measurable function g on the base, because local trivializations differ by translations of the Haar variable. Jensen's inequality gives

$$\int_{\mathbb{P}^2} |g|^p \omega^2_{FS} \leq \int_X |f|^p \, d\nu.$$

For every continuous real test function χ on X, the invariance of the measure gives $\int_X \chi f \, d\nu = \int_X (\chi \circ \tau_a) f \, d\nu$. Integrating in a, and using Fubini's theorem together with the invariance of Haar measure under $a \mapsto -a$, we obtain $\int_X \chi f \, d\nu = \int_X \chi Af \, d\nu$. Hence $f = Af = \pi^* g$ almost everywhere, with $g \geq 0$.

Conversely, suppose $f = \pi^* g$ almost everywhere. Disintegration gives $I_f = \int_{\mathbb{P}^2} g \omega^2_{FS}$. Applying Theorem 10.1.1 on the base, we find a continuous ω_{FS}-plurisubharmonic function q and a constant $k > 0$ with $(\omega_{FS} + dd^c q)^2 = k g \, \omega^2_{FS}$. Bounded decreasing regularization and Stokes' theorem give $\int_{\mathbb{P}^2} (\omega_{FS} + dd^c q)^2 = 1$, so $k = I_f^{-1}$.

Put $u = \pi^* q$. To compute its bounded product, take smooth strictly ω_{FS}-plurisubharmonic functions $q_j \downarrow q$ by Theorem 1.11.1. Their pullbacks decrease to u and are strictly ω-plurisubharmonic. Since $\alpha^3 = \beta^2 = 0$, the smooth cube identity gives, for each j,

$$(\omega + \mathrm{dd}^{\mathrm{c}}\pi^{*}q_j)^3 = 3\pi^{*}(\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}}q_j)^2 \wedge \beta.$$

In a local trivialization, the right-hand side is $6\mathrm{d}A_E$ times the base measure $(\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}}q_j)^2$: the horizontal components of β vanish against the base top-degree form, and its vertical restriction is $2\mathrm{d}A_E$. Continuity of bounded products on the base and on X, tested in these trivializations and patched by a partition of unity, therefore gives

$$(\omega + \mathrm{dd}^{\mathrm{c}}u)^3 = \frac{f}{I_f}\,\omega^3.$$

Uniqueness of the constant implies $c_f = I_f^{-1}$. Every continuous solution then has mass 6, so the mass characterization in Proposition 8.7.1 makes it a pullback from the base, and the descended potential is continuous by local sections, as above. □

When $c_f I_f$ is close to one, compactness gives uniform convergence of subsequences of potentials and weak convergence of their densities, and the equality case identifies the limits.

Proposition 10.7.2 *Fix $1 < p < \infty$ and $M \geq 1$. Suppose $f_j \geq 0$ satisfy*

$$\int_X f_j \,\mathrm{d}\nu = 1, \qquad \|f_j\|_{L^p(X,\nu)} \leq M, \qquad c_{f_j} \longrightarrow 1.$$

For each j, let u_j be any continuous solution of $\omega_{u_j}^3 = c_{f_j} f_j \omega^3$ normalized by $\sup_X u_j = 0$. Then

$$\|u_j - Au_j\|_{C^0(X)} \longrightarrow 0, \qquad f_j - Af_j \rightharpoonup 0 \quad \textit{weakly in } L^p(X,\nu).$$

Every subsequence has a further subsequence with $u_j \to \pi^{*}q$ uniformly and $f_j \rightharpoonup \pi^{*}g$ weakly in L^p, where q is a continuous ω_{FS}-plurisubharmonic function, $g \geq 0$, $\int_{\mathbb{P}^2} g\omega_{\mathrm{FS}}^2 = 1$, and

$$(\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}}q)^2 = g\omega_{\mathrm{FS}}^2.$$

Proof Since the constants c_{f_j} converge, the densities $c_{f_j} f_j$ have a common L^p bound. By Theorem 10.3.2, every subsequence has a further subsequence on which $u_j \to u$ uniformly. Since L^p is reflexive, a further extraction gives $f_j \rightharpoonup f$ weakly in L^p. Positivity, the unit integral and the bound $\|f\|_p \leq M$ pass to the limit, and continuity of bounded products under uniform convergence gives

$$(\omega + \mathrm{dd}^{\mathrm{c}}u)^3 = f\omega^3.$$

Thus $c_f = 1$. Since also $I_f = 1$, Proposition 10.7.1 gives $u = \pi^{*}q$ and $f = \pi^{*}g$. The bounded cube identity proved there, tested against pullbacks of continuous functions on the base, gives the asserted base equation. In particular, both limits are fixed by A.

Haar averaging is a contraction on $C^0(X)$ and on $L^p(X,\nu)$. It is also self-adjoint with respect to ν: Fubini's theorem and the invariance of ν under the fiber translations give $\int \chi A f \,\mathrm{d}\nu = \int A\chi f \,\mathrm{d}\nu$ for $\chi \in L^{p'}$. Along the extracted subsequence, therefore, $u_j - Au_j \to 0$ uniformly and $f_j - Af_j \rightharpoonup 0$ in L^p. If either convergence failed for

the original sequence, some subsequence would stay away from the limit (for the weak convergence, when tested against one fixed function in $L^{p'}$), and a further subsequence of the kind just constructed would give a contradiction. This proves both conclusions for the whole sequence. □

Example 10.7.1 Choose $0 < a < 1/2$, and use the function $s = \log|z|^2$ on the covering space $\mathbb{C}^3 \setminus \{0\}$ from Chapter 8. Since s changes by -2 under the defining contraction, every 2-periodic function of s descends to X. For an integer $m \geq 1$, define the smooth normalized potential

$$u_m = \frac{a}{\pi^2 m^2}\big(\cos(\pi m s) - 1\big), \qquad \|u_m - Au_m\|_{C^0} = \frac{a}{\pi^2 m^2} \longrightarrow 0.$$

Primes below denote derivatives with respect to s. Since $\mathrm{dd^c} s = \alpha$ and $\mathrm{d}s \wedge \mathrm{d^c} s = \beta$, the chain rule gives

$$\omega + \mathrm{dd^c} u_m = (1+u_m')\alpha + (1+u_m'')\beta, \quad u_m' = -\frac{a}{\pi m}\sin(\pi m s), \quad u_m'' = -a\cos(\pi m s).$$

Both coefficients are bounded below by positive constants independent of m. The rank identities $\alpha^3 = \beta^2 = 0$ imply

$$(\omega + \mathrm{dd^c} u_m)^3 = H_m \omega^3, \qquad H_m = \Big(1 - \frac{a}{\pi m}\sin(\pi m s)\Big)^2 \big(1 - a\cos(\pi m s)\big).$$

On each fiber, s is twice the real Haar coordinate plus a constant depending on the base point, so its distribution modulo 2 is uniform. When the periodic expression $H_m = (1+u_m')^2(1+u_m'')$ is averaged, the terms u_m', u_m'', $u_m' u_m''$ and $(u_m')^2 u_m''$ contribute zero, since they are derivatives of periodic functions. Hence

$$I_m := \int_X H_m \, \mathrm{d}\nu = AH_m = 1 + \frac{a^2}{2\pi^2 m^2}.$$

Set $f_m = H_m / I_m$. These smooth densities have unit integral and common strictly positive lower and finite upper bounds. Uniqueness of the constant gives $c_{f_m} = I_m \to 1$, and $Af_m = 1$. Nevertheless,

$$\|f_m - 1 + a\cos(\pi m s)\|_{C^0(X)} = O(m^{-1}), \qquad \lim_{m\to\infty} \|f_m - Af_m\|_{L^1(X,\nu)} = \frac{2a}{\pi} > 0.$$

Here the constant in $O(m^{-1})$ depends only on a, and the last identity uses the fact that the average of $|\cos|$ over a period is $2/\pi$. Thus near equality does not imply strong L^1 convergence to the fiber average, even for uniformly positive bounded smooth densities. For any pullback g of a function on the base, the contraction property gives $\|f_m - Af_m\|_1 \leq 2\|f_m - g\|_1$, so approximation by such pullbacks also fails in L^1.

10.8 Stability for concave equations

We now consider fully nonlinear equations defined by a concave symmetric function of the eigenvalues of $\omega^{-1}(\chi + \mathrm{dd^c}u)$. For such equations, a fixed admissible reference with a strict asymptotic gap replaces the determinant bounds used above: it bounds the positive matrix perturbations of the reference along which the operator stays below a given level. An auxiliary Monge–Ampère equation, whose density is concentrated where the difference of two solutions is nearly maximal, then shows that this set cannot be small. The resulting stability estimate remains uniform when the positive right-hand sides tend to zero.

Throughout this section and the next, $n \geq 2$, and χ is a fixed smooth real $(1,1)$-form on X. In these two sections the letter f denotes the function of eigenvalues introduced below, not the density fixed at the beginning of the chapter. For a smooth real function w and an endomorphism A of $T^{1,0}X$ that is Hermitian with respect to ω, put

$$A_w = \omega^{-1}(\chi + \mathrm{dd^c}w), \qquad F(A) = f(\lambda(A)),$$

where $\lambda(A) \in \mathbb{R}^n$ is the vector of eigenvalues of A. Let Γ be an open convex symmetric cone with $\Gamma_n \subseteq \Gamma \subseteq \Gamma_1$, where Γ_n is the positive orthant and $\Gamma_1 = \{\sum_i \lambda_i > 0\}$. Assume that $f \in C^\infty(\Gamma) \cap C^0(\overline{\Gamma})$ is symmetric, concave, positive on Γ, zero on $\partial\Gamma$, and satisfies

$$f_i > 0, \qquad \lim_{t\to\infty} f(t\lambda) = +\infty \quad (\lambda \in \Gamma),$$

where $f_i = \partial f/\partial\lambda_i$. We call w *admissible* if $\lambda(A_w) \in \Gamma$ everywhere. Write $e_1, \dots, e_n$ for the standard basis of $\mathbb{R}^n$ and $\mathbf{1} = (1, \dots, 1)$. For $\mu \in \Gamma$, define

$$f_{\infty,i}(\mu) = \lim_{t\to\infty} f(\mu + te_i), \qquad f_\infty(\mu) = \min_i f_{\infty,i}(\mu),$$

allowing the value $+\infty$. Fix a smooth admissible function $\underline{u}$ and positive constants H_0, δ_0. We consider smooth admissible solutions u of

$$F(A_u) = h, \qquad 0 < h \leq H_0, \qquad f_\infty(\lambda(A_{\underline{u}}(x))) \geq h(x) + \delta_0,$$

where the right-hand side h is a positive function on X; the last condition is the strict asymptotic gap at the reference $\underline{u}$. The right-hand sides satisfying these two conditions form the *family* of right-hand sides, and the solutions are normalized by $\inf_X u = 0$. We call $X, \omega, \chi, f, \Gamma, \underline{u}, H_0, \delta_0$ the *fixed data*; all constants in this section depend only on them. Norms are taken with respect to ω^n, and $\langle a\rangle_\omega = (\int_X \omega^n)^{-1} \int_X a\omega^n$ denotes the average of a function a.

Lemma 10.8.1 *There are a positive continuous function H on X and constants $r, R, \delta > 0$ with the following properties. Every right-hand side in the family satisfies $h \le H$; on X,*

$$\mu - 2r\mathbf{1} \in \Gamma, \qquad f_\infty(\mu - 2r\mathbf{1}) \ge H + 3\delta, \qquad \mu = \lambda(A_{\underline{u}});$$

and at every point of X, every positive semidefinite Hermitian endomorphism P satisfies

$$F(A_{\underline{u}} - r\,\mathrm{Id} + P) \le H + 2\delta \quad \Longrightarrow \quad P \le R\,\mathrm{Id}\,.$$

Proof Each $f_{\infty,i}$ is an increasing limit of positive concave functions, hence concave with values in $(0, +\infty]$. Suppose it is infinite at one point and finite at another point of Γ. Extend the segment joining them slightly beyond the second point, inside the open cone. The second point is then an interior point of the longer segment, so concavity forces the value there to be infinite, a contradiction. Thus $f_{\infty,i}$ is either finite everywhere, and then continuous, or infinite everywhere. By symmetry, the same alternative holds for every i.

Take $\delta = \frac{1}{8}\min\{\delta_0, \min_X f(\mu)\} > 0$. In the finite case set $H = \min\{H_0, f_\infty(\mu) - 4\delta\}$; otherwise set $H = H_0$. Since $f_\infty(\mu) \ge f(\mu) \ge 8\delta$, this function is positive. The conditions on the family give $h \le H$ and $f_\infty(\mu) \ge H + 4\delta$. Since $\mu(X)$ is a compact subset of Γ and the functions $f_{\infty,i}$ are continuous (or identically infinite), a sufficiently small $r > 0$ gives $\mu - 2r\mathbf{1} \in \Gamma$ and $f_\infty(\mu - 2r\mathbf{1}) \ge H + 3\delta$ on X.

If the matrix bound failed, there would be points $x_j \to x_*$ and $P_j \ge 0$ with unbounded norms and $F(A_{\underline{u}}(x_j) - r\,\mathrm{Id} + P_j) \le H(x_j) + 2\delta$. By monotonicity of eigenvalues, the ordered eigenvalues $\lambda^{(j)}$ of $A_{\underline{u}}(x_j) - r\,\mathrm{Id} + P_j$ satisfy $\lambda_i^{(j)} \ge \mu_i(x_j) - r$. Their sum tends to infinity, so some component k tends to infinity along a subsequence. For every fixed $t > 0$, eventually

$$\lambda^{(j)} \ge \mu(x_*) - 2r\mathbf{1} + te_k.$$

Since f is increasing in each variable, letting $t \to \infty$ shows that the lower limit of $F(A_{\underline{u}}(x_j) - r\,\mathrm{Id} + P_j)$ is at least $f_\infty(\mu(x_*) - 2r\mathbf{1}) \ge H(x_*) + 3\delta$, which contradicts the upper bound $H(x_j) + 2\delta$. Adding positive semidefinite matrices preserves the cone, so all these comparisons take place in Γ. □

Proposition 10.8.1 *Every solution satisfies $0 \le u \le C$.*

Proof Put $\theta = \chi + \mathrm{dd^c}\underline{u}$ and $w = u - \underline{u} - \sup_X(u - \underline{u}) \le 0$. Since $\Gamma \subseteq \Gamma_1$, we have $\mathrm{tr}_\omega\,\mathrm{dd^c} w \ge -\mathrm{tr}_\omega\,\theta \ge -C$. The Green-kernel argument in the proof of Proposition 9.10.1, applied to the operator $\mathrm{tr}_\omega\,\mathrm{dd^c}$, therefore bounds $\|w\|_{L^1}$ uniformly.

Center a holomorphic coordinate ball of fixed size at a minimum point of w, and rescale it to the real unit ball. For a fixed sufficiently small $\varepsilon > 0$, set $q = w + \varepsilon|x|^2$ and $m = \min_X w$. The real contact-set construction of (9.14) gives a compact set E on which

$$D^2 q \ge 0, \qquad q \le m + \varepsilon/2, \qquad |B_{\varepsilon/2}| \le \int_E \det D^2 q\,\mathrm{d}x.$$

On E, $\mathrm{dd^c} w \geq -C\varepsilon\omega$. Choose ε so that $C\varepsilon < r$. Then $P = \omega^{-1}(\mathrm{dd^c} w + r\omega) \geq 0$ and

$$F(A_{\underline{u}} - r\,\mathrm{Id} + P) = F(A_u) = h \leq H.$$

Lemma 10.8.1 bounds P, and hence the complex trace of the Hessian of q. The nonnegative real Hessian of q on E therefore has bounded trace, and hence bounded determinant, so the contact inequality implies $|E| \geq c > 0$. Since $w \leq m + \varepsilon/2$ on E, the L^1 bound gives $c(-m - \varepsilon/2) \leq C$. This bounds the oscillation of w, hence that of u; with the normalization $\inf_X u = 0$, this is the assertion. □

Theorem 10.8.1 *There is a constant C, depending only on the fixed data, such that any two normalized solutions u_1, u_2 with right-hand sides h_1, h_2 in the family satisfy*

$$\|u_1 - u_2\|_\infty \leq C\big(\|h_1 - h_2\|_\infty + \|u_1 - u_2\|_{L^1}\big).$$

In particular, C does not depend on a positive lower bound for the h_i or on bounds for their derivatives.

Proof Set $a = u_1 - \underline{u}$, $b = u_2 - \underline{u}$ and $\theta = \chi + \mathrm{dd^c}\underline{u}$. By Proposition 10.8.1, $|a|, |b| \leq C_0$ for a fixed $C_0 \geq 1$. It suffices to bound $s = \max_X(b - a)$ when it is positive; the opposite difference is handled by interchanging the solutions.

Fix r, R, δ from Lemma 10.8.1 and put $\alpha = r\omega$. For every smooth positive ρ with

$$\rho \geq \tfrac{1}{2}, \qquad \langle\rho\rangle_\alpha = 1, \qquad \langle\rho^2\rangle_\alpha \leq 4,$$

Theorem 9.1.1 gives a smooth solution

$$(\alpha + \mathrm{dd^c}\psi)^n = c\rho\alpha^n, \qquad \alpha + \mathrm{dd^c}\psi > 0, \qquad \sup_X \psi = 0.$$

At a maximum of ψ, $c\rho \leq 1$, so $c \leq 2$. Apply Theorem 10.3.1 with $p = 2$ and background α. Its potential and lower-density bounds give fixed $c_0, C_\psi > 0$ with

$$c \geq c_0, \qquad -C_\psi \leq \psi \leq 0.$$

These constants depend only on the three bounds for ρ, and not on the cutoff function chosen below.

Choose $\kappa > 0$ so that $2C_0\kappa \leq 1/4$, $\kappa C_0 \leq 1/16$ and $\kappa C_\psi/2 \leq 1/16$. Next choose $M \geq 1$ with $2^{-n}c_0 M r^n > R^n$, and then $\varepsilon_0 > 0$ with

$$\tfrac{16}{7}\varepsilon_0 \leq \min\{(2M)^{-1}, M^{-2}\}.$$

If one of the inequalities

$$\|h_1 - h_2\|_\infty \leq \kappa\delta s, \qquad \langle(b - a)_+\rangle_\omega \leq \varepsilon_0 s.$$

fails, then $s \leq C(\|h_1 - h_2\|_\infty + \|u_1 - u_2\|_{L^1})$, with C depending only on $\kappa, \delta, \varepsilon_0$ and the volume of X. We assume both and derive a contradiction. Put $t = \kappa s$; since

$s \le 2C_0$, we have $t \le 1/4$. On $\Omega = \{(1-t)b - a > s/2\}$, we have $b - a > 7s/16$, so by Chebyshev's inequality the relative volume of Ω is at most $16\varepsilon_0/7$.

Take a smooth $\zeta : \mathbb{R} \to [0,1]$, zero on $(-\infty, 1/2]$ and one on $[3/4, \infty)$, and set

$$\rho = b_0 + M\zeta\big(((1-t)b - a)/s\big), \qquad b_0 = 1 - M\big\langle \zeta\big(((1-t)b - a)/s\big)\big\rangle_\omega .$$

The second term is supported in Ω, so $1/2 \le b_0 \le 1$ and $\langle \rho^2 \rangle_\alpha \le 2 + 2M^2(16\varepsilon_0/7) \le 4$; here we use that averages with respect to $\alpha = r\omega$ and ω agree. Thus the auxiliary solution for this ρ satisfies the bounds with the same constants c_0, C_ψ.

At a point where $b - a = s$, the function $\Phi = (1-t)b - a + t\psi/2$ is at least $7s/8$, by the choice of κ. At a maximum point x_0 of Φ, therefore, $(1-t)b - a \ge 7s/8$ because $\psi \le 0$, and so $\rho(x_0) \ge M$. The second derivative test gives, at x_0,

$$P = \alpha + \mathrm{dd^c}\big((a - (1-t)b)/t\big) \ge \tfrac{1}{2}(\alpha + \mathrm{dd^c}\psi) + \tfrac{1}{2}\alpha > 0.$$

The identity

$$\theta + \mathrm{dd^c} a = t\big((\theta - \alpha) + P\big) + (1-t)(\theta + \mathrm{dd^c} b)$$

and concavity imply

$$F\big(\omega^{-1}((\theta - \alpha) + P)\big) \le h_2 + (h_1 - h_2)/t \le H + \delta.$$

Both forms in the convex combination are admissible, since $\mu - r\mathbf{1} \in \Gamma$ and $P > 0$. By Lemma 10.8.1, $P \le R\omega$. On the other hand, $P \ge \frac{1}{2}(\alpha + \mathrm{dd^c}\psi)$, so the auxiliary equation gives

$$R^n \ge P^n/\omega^n \ge 2^{-n} c\rho r^n \ge 2^{-n} c_0 M r^n > R^n,$$

a contradiction. Hence one of the two smallness inequalities fails, which gives the required bound for s. Interchanging the solutions proves the theorem. □

Corollary 10.8.1 *Let $\mathcal{H}$ be a set of right-hand sides in the family that is equicontinuous. Then the normalized solutions with right-hand sides in $\mathcal{H}$ form a precompact subset of $C^0(X)$ and have a common modulus of continuity.*

Proof Admissibility and $\Gamma \subseteq \Gamma_1$ give $\mathrm{tr}_\omega \mathrm{dd^c} u \ge -C$. By Theorem 4.1.1, there is a smooth function $\rho_0 > 0$ with $\mathrm{dd^c}(\rho_0 \omega^{n-1}) = 0$, so that $\int_X \mathrm{dd^c}\varphi \wedge \rho_0\omega^{n-1} = 0$ for every smooth φ. Integrating the product rule $\mathrm{dd^c}(u^2) = 2u\mathrm{dd^c}u + 2\mathrm{d}u \wedge \mathrm{d^c}u$ against $\rho_0\omega^{n-1}$, and using $0 \le u \le C$ from Proposition 10.8.1, we obtain a uniform bound for $\int_X |\mathrm{d}u|^2_\omega \omega^n$, because ρ_0 is bounded above and below. Rellich's theorem therefore gives precompactness in L^1.

Given a sequence of such solutions, the Arzelà–Ascoli theorem gives a subsequence whose right-hand sides converge uniformly, since they are equicontinuous and bounded by H_0. A further subsequence of the solutions is Cauchy in L^1, and Theorem 10.8.1 makes it uniformly Cauchy. This proves precompactness in $C^0(X)$. A common modulus of continuity follows from a finite uniform $\varepsilon/3$-net, since each of its finitely many members is uniformly continuous. □

10.9 Gradient bounds for concave equations

We keep the fixed data, the family of right-hand sides and the normalization of Section 10.8, and assume in addition that $\|\partial h\|_{L^\infty(\omega)} \le H_1$; throughout the section, u denotes a solution with such a right-hand side h. The gradient bound is obtained by comparison with a nearby smooth admissible function V. A maximum principle for a weighted gradient quantity bounds the gradient of u in terms of that of V, provided $\|u - V\|_\infty$ is below a threshold that does not depend on the derivatives of V. The C^0 compactness of Corollary 10.8.1 then shows that finitely many such comparison functions suffice for all solutions.

For the derivative calculation, write $U = u/(2\pi)$ and $\underline{U} = \underline{u}/(2\pi)$. Thus $\mathrm{dd^c} u = \mathrm{i}\partial\bar\partial U$. For any smooth real V, put $\mathcal{A}_V = \omega^{-1}(\chi + \mathrm{i}\partial\bar\partial V)$ and call V admissible if $\lambda(\mathcal{A}_V) \in \Gamma$. We use the Chern connection of ω, and define the endomorphism $B = DF(\mathcal{A}_U)$ by $\frac{\mathrm{d}}{\mathrm{d}t} F(\mathcal{A}_U + tM)|_{t=0} = \operatorname{tr}(BM)$. Write $\lambda = (\lambda_1, \dots, \lambda_n) = \lambda(\mathcal{A}_U)$. At a point where $\mathcal{A}_U$ is diagonal in a unitary frame, set

$$B_i = f_i(\lambda), \qquad \mathcal{L}q = \sum_i B_i q_{i\bar i}, \qquad T = \sum_i B_i, \qquad |\partial q|_B^2 = \sum_i B_i |q_i|^2.$$

Here subscripts denote frame derivatives, $U_{ki} = \nabla_i U_k$ and $U_{i\bar j} = \partial_i \partial_{\bar j} U$; the second derivatives U_{ki} need not be symmetric. The trace expressions below do not depend on the unitary frame.

Lemma 10.9.1 *There are fixed $\tau, \kappa > 0$ such that*

$$T \ge \tau, \qquad 0 \le \operatorname{tr}(B\mathcal{A}_U) \le h,$$
$$\mathcal{L}(U - V) \le h \quad (V \text{ admissible}), \qquad \mathcal{L}(\underline{U} - U) \ge -h.$$

Moreover, at every point at least one of the alternatives

$$\mathcal{L}(\underline{U} - U) \ge \kappa T, \qquad B \ge \kappa T \operatorname{Id}$$

holds. The constants depend only on the fixed data; in particular they are uniform for all right-hand sides in the family.

Proof If $\lambda(P) \in \Gamma$, then $\mathcal{A}_U + tP$ is admissible for $t \ge 0$. The function $t \mapsto F(\mathcal{A}_U + tP)$ is positive and concave on $[0, \infty)$, so its derivative at $t = 0$ cannot be negative; thus $\operatorname{tr}(BP) \ge 0$. Since F is concave and $F(0) = 0$, the tangent inequality at $\mathcal{A}_U$, evaluated at the origin, gives $\operatorname{tr}(B\mathcal{A}_U) \le h$. Choose $a_* > 0$ with $F(a_* \operatorname{Id}) > H_0 + 1$. Concavity gives

$$H_0 + 1 < F(a_* \operatorname{Id}) \le h + a_* T - \operatorname{tr}(B\mathcal{A}_U) \le H_0 + a_* T.$$

Thus $T \ge a_*^{-1}$. Since $\mathcal{L}(U - V) = \operatorname{tr}(B\mathcal{A}_U) - \operatorname{tr}(B\mathcal{A}_V)$ and $\mathcal{L}(\underline{U} - U) = \operatorname{tr}(B\mathcal{A}_{\underline{U}}) - \operatorname{tr}(B\mathcal{A}_U)$, the remaining two bounds follow from the nonnegativity of $\operatorname{tr}(B\mathcal{A}_V)$ and $\operatorname{tr}(B\mathcal{A}_{\underline{U}})$.

We derive the alternative from the strict gap. Fix r, H, δ from Lemma 10.8.1, and put $\mu = \lambda(\mathcal{A}_{\underline{U}})$. Compactness and the gap give one $S > r$ such that

$$f(\mu - 2r\mathbf{1} + Se_i) > H + 2\delta \qquad (1 \le i \le n)$$

everywhere. We first prove a scalar alternative. At a point of X, let $\lambda \in \Gamma$ satisfy $f(\lambda) = \sigma$, where $\sigma = h$ at that point, and consider the set

$$K = \{v \ge \mu - r\mathbf{1} : f(v) \le \sigma\}.$$

It is contained in Γ because $\mu - r\mathbf{1} \in \Gamma$, it is closed, and the matrix bound of Lemma 10.8.1, applied to diagonal matrices, makes it bounded; thus K is compact. When nonempty, it contains $\mu - r\mathbf{1}$ and is star-shaped about that point: moving along a segment toward it decreases each coordinate, hence decreases f. Thus K is connected. Let $N = \nabla f(\lambda)$, whose entries are positive, and let Π be the tangent hyperplane $N \cdot (v - \lambda) = 0$.

If $f(\mu - r\mathbf{1}) > \sigma$, concavity gives $N \cdot (\mu - \lambda) > r \sum_i N_i$. Otherwise $\mu - r\mathbf{1} \in K$. The diagonal ray $\mu - r\mathbf{1} + t\mathbf{1}$, $t \ge 0$, meets $\{f = \sigma\}$, since f diverges along it; at the meeting point v, the tangent inequality gives $N \cdot (v - \lambda) \ge 0$. If Π misses K, connectedness makes $N \cdot (v - \lambda)$ strictly positive throughout K, and in particular at $\mu - r\mathbf{1}$; this again gives $N \cdot (\mu - \lambda) > r \sum_i N_i$.

If $v \in \Pi \cap K$, put $z_i = v - r\mathbf{1} + Se_i$. Then $z_i \ge \mu - 2r\mathbf{1} + Se_i$, so $f(z_i) > \sigma$. The tangent inequality at λ gives

$$0 < N \cdot (z_i - v) = SN_i - r \sum_j N_j.$$

Thus $N_i > (r/S) \sum_j N_j$ for every i. We have proved that $N \cdot (\mu - \lambda) > r \sum_i N_i$ or $N_i > (r/S) \sum_j N_j$ for all i, at every positive level σ, with constants independent of σ.

To pass to matrices, take $\lambda = \lambda(\mathcal{A}_U)$, and order λ and μ decreasingly. By concavity and symmetry, the numbers $f_i(\lambda)$ are then ordered increasingly. In the eigenframe of $\mathcal{A}_U$, the diagonal of $\mathcal{A}_{\underline{U}}$ is a doubly stochastic average of permutations of μ, so the rearrangement inequality gives

$$\operatorname{tr}\big(B(\mathcal{A}_{\underline{U}} - \mathcal{A}_U)\big) \ge \sum_i f_i(\lambda)(\mu_i - \lambda_i).$$

Since $N = (f_i(\lambda))_i = (B_i)_i$, taking κ smaller than $\min\{r, r/S\}$ proves the matrix alternative. □

Lemma 10.9.2 *Put $Q = 1 + |\partial U|^2_\omega$. For any smooth real ξ, one has*

$$\begin{aligned} \mathrm{e}^{-\xi}\mathcal{L}(\mathrm{e}^{\xi}Q) \geq \sum_{i,k} B_i |U_{ki} + U_k\xi_i|^2 + \frac{1}{4}\sum_i B_i\lambda_i^2 + Q\mathcal{L}\xi + |\partial\xi|^2_B \\ + 2\,\mathrm{Re}\sum_i B_i\lambda_i U_i\xi_{\bar\imath} - 2\,\mathrm{Re}\sum_{i,k} B_i\chi_{i\bar k}U_k\xi_{\bar\imath} - C_gTQ - 2H_1|\partial U|_\omega, \end{aligned}$$

where C_g depends only on ω and χ.

Proof Write $\mathscr{T}^p_{ik}$ and $R^p_{i\bar\jmath k}$ for the torsion and curvature of the Chern connection. The commutation formula and the differentiated equation read

$$\begin{aligned} \nabla_{\bar\jmath}\nabla_i U_k &= \nabla_k U_{i\bar\jmath} + \sum_p \bigl(R^p_{i\bar\jmath k}U_p - \mathscr{T}^p_{ik}U_{p\bar\jmath}\bigr), \\ \sum_i B_i\nabla_k U_{i\bar\imath} &= h_k - \sum_i B_i\nabla_k\chi_{i\bar\imath}. \end{aligned}$$

The product rule for $|\partial U|^2$ gives both squares $\sum B_i|U_{ki}|^2$ and $\sum B_i|U_{k\bar\imath}|^2$, the term $2\,\mathrm{Re}\sum_k h_kU_{\bar k}$, a curvature error bounded by $CT|\partial U|^2$, and the errors from $\nabla\chi$ and torsion. The latter are bounded by

$$CT|\partial U| + CT|\partial U|^2 + C|\partial U|T^{1/2}\Bigl(\sum_{i,k} B_i|U_{k\bar\imath}|^2\Bigr)^{1/2}.$$

Absorb the last term into half of the mixed square. Since $U_{i\bar\jmath} = \lambda_i\delta_{ij} - \chi_{i\bar\jmath}$, the remaining half is at least $\frac{1}{4}\sum_i B_i\lambda_i^2 - CT$. Hence

$$\mathcal{L}|\partial U|^2 \geq \sum_{i,k} B_i|U_{ki}|^2 + \frac{1}{4}\sum_i B_i\lambda_i^2 - C_gTQ - 2H_1|\partial U|.$$

Finally,

$$\partial_i|\partial U|^2 = \sum_k U_{ki}U_{\bar k} + \lambda_iU_i - \sum_k \chi_{i\bar k}U_k.$$

In the product rule for $\mathrm{e}^{\xi}Q$, combine the cross term coming from the first sum with $|\partial U|^2|\partial\xi|^2_B$ and with the square $\sum B_i|U_{ki}|^2$. This gives $\sum B_i|U_{ki} + U_k\xi_i|^2$, while the remaining weight term is $|\partial\xi|^2_B$. □

Proposition 10.9.1 *There are constants $\eta, C > 0$, depending only on the fixed data and H_1, such that every smooth admissible V with $\|U - V\|_\infty \le \eta$ satisfies*

$$\|\partial U\|_\infty \le C\big(1 + \|\partial V\|_\infty^2\big).$$

The comparison radius η is independent of the derivatives of V.

Proof Let $a \ge 1$ and $\beta > 1$ be constants, to be chosen below. Assuming $\|U - V\|_\infty \le \beta^{-1}$, put

$$w = U - V - \beta^{-1}, \qquad \xi = a(\underline{U} - U) + \beta w^2, \qquad K_V = 1 + \|\partial \underline{U}\|_\infty + \|\partial V\|_\infty.$$

Then $-2\beta^{-1} \le w \le 0$ and

$$\xi_i = a(\underline{U}_i - V_i) + (-a + 2\beta w)(U_i - V_i), \qquad |-a + 2\beta w| \le a + 4.$$

Writing $D = |\partial(U - V)|_B^2$, the Cauchy–Schwarz inequality gives

$$\Big|2\,\mathrm{Re}\sum_i B_i \lambda_i U_i \xi_{\bar\imath}\Big| \le \frac{1}{8}\sum_i B_i \lambda_i^2 + C_a K_V^4 T + C_a(Q + K_V^2)D,$$

$$\Big|2\,\mathrm{Re}\sum_{i,k} B_i \chi_{i\bar k} U_k \xi_{\bar\imath}\Big| \le \tfrac{1}{2} Q D + C_a T + C_a K_V Q^{1/2} T.$$

For the first line, split ξ_i as above and use $\sum B_i |U_i|^2 \le 2D + 2K_V^2 T$; then apply Young's inequality to the resulting three products, each absorbing at most $\frac{1}{24}\sum B_i\lambda_i^2$. For the second line, use $|\partial\xi|_B \le a K_V T^{1/2} + (a+4)D^{1/2}$ and the bound for χ. In both lines, C_a depends on a but not on β or on the derivatives of V.

By Lemma 10.9.1 and $w \le 0$,

$$\mathcal{L}\xi \ge a\mathcal{L}(\underline{U} - U) - 4H_0 + 2\beta D.$$

Choose a so large that $(a\kappa - C_g - 2)\tau > 4H_0 + 2H_1 + 1$, and then $\beta \ge 2C_a + 2$. Combining the preceding bounds with Lemma 10.9.2, we obtain, at every point where $Q \ge C'(1 + K_V^4)$ for a suitable constant C',

$$\begin{aligned} \mathrm{e}^{-\xi}\mathcal{L}(\mathrm{e}^{\xi} Q) \ge{}& \frac{1}{8}\sum_i B_i \lambda_i^2 \\ &+ Q\big[a\mathcal{L}(\underline{U} - U) - (C_g + 2)T + \beta D - (4H_0 + 2H_1)\big]. \end{aligned}$$

Indeed, the coefficient of D before absorption is $(2\beta - C_a - 1/2)Q - C_a K_V^2$, which is at least βQ once C' is large enough. The other errors satisfy $C_a K_V^4 \le Q$ and $C_a + C_a K_V Q^{1/2} \le Q$, and they account for the additional term $-2T$ in the bracket.

Consider a maximum point of $\mathrm{e}^{\xi} Q$ at which $Q \ge C'(1 + K_V^4)$. In the first alternative of Lemma 10.9.1, the bracket is positive by the choice of a, since $T \ge \tau$. In the second, $D \ge \kappa T |\partial(U - V)|^2$. For $Q \ge 4(1 + K_V^2)$, the triangle inequality gives

$|\partial(U - V)|^2 \geq c_* Q$, where $c_* = (\sqrt{3} - 1)^2/4$. Since $\mathcal{L}(\underline{U} - U) \geq -H_0$, the bracket is then at least

$$(\beta \kappa c_* Q - C_g - 2)T - (a + 4)H_0 - 2H_1.$$

This is positive once C' is large enough, because $T \geq \tau$. In both cases $\mathcal{L}(\mathrm{e}^{\xi} Q) > 0$ at a maximum point, which contradicts the second derivative test. Thus $Q \leq C(1 + K_V^4)$ at the maximum point. The weight has uniformly bounded oscillation:

$$\operatorname{osc}_X \xi \leq a(\operatorname{osc}_X \underline{U} + \operatorname{osc}_X U) + 4/\beta.$$

By the potential bound in Proposition 10.8.1, this oscillation is bounded independently of V, so the estimate at the maximum point gives $Q \leq C(1 + K_V^4)$ everywhere. Taking square roots and setting $\eta = \beta^{-1}$ proves the assertion. □

Theorem 10.9.1 *There is a constant C, depending only on the fixed data and H_1, such that $\|\mathrm{d}u\|_{L^\infty(\omega)} \leq C$ for every normalized solution u whose right-hand side h lies in the family and satisfies $\|\partial h\|_\infty \leq H_1$. In particular, the bound is uniform as the positive right-hand sides tend to zero.*

Proof The right-hand sides in the family with $\|\partial h\|_\infty \leq H_1$ form an equicontinuous set. By Corollary 10.8.1, the corresponding functions U form a precompact subset of $C^0(X)$. Choose a finite η-net in this set, consisting of smooth admissible functions $V_1, \ldots, V_N$. Each solution is within η of some V_j, so Proposition 10.9.1 bounds its gradient by $C(1 + \max_j \|\partial V_j\|_\infty^2)$. The set of solutions, and hence the chosen finite net, depends only on the fixed data and H_1. Finally, $u = 2\pi U$, so the same conclusion holds for $\mathrm{d}u$. □

In Chapter 11 we return to the Monge–Ampère equation for $\omega + \mathrm{dd}^{\mathrm{c}} u$ and ask when two potentials with the same density agree up to a constant. The uniqueness of the normalization scalar does not determine the potential: where the density vanishes, the polarized linear equation for the difference can be degenerate.

Chapter 11
Uniqueness for degenerate equations

Throughout this chapter, X is a connected compact complex manifold of dimension $n \geq 1$, ω is a Hermitian form and $\mathrm{d}V$ is a smooth positive volume form on X. As before, $\omega_u = \omega + \mathrm{dd^c} u$, and for bounded ω-plurisubharmonic u we write $\mathrm{MA}_\omega(u) = \omega_u^n$ for the Bedford–Taylor product of Proposition 1.7.1. The preceding chapter shows that, for a nonnegative nonzero density $f \in L^p(X, \mathrm{d}V)$ with $p > 1$, the constant c in the equation $\omega_u^n = c\, f\, \mathrm{d}V$ is determined by f. We now ask when the potential is unique up to an additive constant.

For real potentials u, v, with the regularity stated in each result, set

$$A = \omega + \mathrm{dd^c} u, \qquad B = \omega + \mathrm{dd^c} v, \qquad w = u - v, \qquad T = \sum_{j=0}^{n-1} A^j \wedge B^{n-1-j}.$$

Then

$$\mathrm{dd^c} w \wedge T = A^n - B^n. \tag{11.1}$$

Thus, if $A^n = B^n$, the difference w solves the linear equation $\mathrm{dd^c} w \wedge T = 0$. When $A, B \geq 0$, the polarized cofactor T is semipositive, but it may be degenerate and need not be closed. For Sobolev or $C^{1,1}$ potentials, products of coefficients in these identities are understood almost everywhere.

For $C^{1,1}$ solutions with the same continuous density, strict positivity of the density gives local uniform ellipticity of this linear equation. The main issue is to locate the extrema of w in these elliptic regions and to decide whether their values propagate across the zero set of the density. A positive weight making T $\mathrm{dd^c}$-closed gives another route: a global energy identity forces the derivative of w to vanish in the directions of the cofactor. For bounded potentials, an energy measure replaces this pointwise calculation.

If the background has invariant mass, ordinary comparison proves uniqueness of bounded solutions for L^p densities, $p > 1$, without any connectedness condition on the set where the density is positive. For a general Hermitian background, however, two hypersurfaces on which the density vanishes can separate regions in which w attains different extremal values. The examples on $\mathbb{P}^3$ at the end of the chapter first

place this freedom in an open band where the density vanishes, and then keep it with a density having only quadratic zeros, which can even be chosen real analytic. They show that smallness of the zero set alone does not restore uniqueness.

11.1 Extrema and density sublevels

To apply the strong maximum principle to $w = u - v$, we first locate a maximum point and a minimum point of w in the region where the linear equation $\mathrm{dd^c} w \wedge T = 0$ is uniformly elliptic. Maximizing a small perturbation of w by a function χ with $\omega + \mathrm{dd^c}\chi > 0$ does this, even when the Hessians are only measurable. The strong maximum principle then makes w constant on the components of this region that contain these points, and w is constant if the closures of the two components meet.

In this section, $u, v \in C^{1,1}(X)$ satisfy $A, B \geq 0$ almost everywhere and

$$A^n = B^n = f\,\mathrm{d}V, \qquad f \in C^0(X), \qquad f \geq 0. \tag{11.2}$$

Fix a smooth positive $(1,1)$-form β, put $H = A + B$, and let E_{unif} be the set of points near which H is uniformly positive:

$$E_{\mathrm{unif}} = \left\{ x : \begin{array}{l} \text{there are a neighborhood } V \ni x \text{ and } c > 0 \\ \text{with } H \geq c\beta \text{ almost everywhere on } V \end{array} \right\}. \tag{11.3}$$

This open set does not depend on β or on the choice of representatives of the measurable coefficients.

Theorem 11.1.1 *Assume* (11.2). *If $\chi \in C^2(X, \mathbb{R})$ satisfies $C := \omega + \mathrm{dd^c}\chi > 0$, put*

$$P_\chi = \{x \in X : f(x)\mathrm{d}V_x \geq C_x^n\}, \qquad U = \{f > 0\}.$$

Then P_χ is a nonempty compact subset of U, and $U \subset E_{\mathrm{unif}}$. There are components G_+, G_- of E_{unif}, each meeting P_χ, such that $w = u - v$ satisfies

$$w \equiv \max_X w \quad \text{on } \overline{G_+}, \qquad w \equiv \min_X w \quad \text{on } \overline{G_-}. \tag{11.4}$$

If w is nonconstant, these closures are disjoint. Consequently w is constant if any one of the following holds:

(1) *every two components of E_{unif} meeting P_χ have intersecting closures;*
(2) *E_{unif} is connected;*
(3) *E_{unif} is dense and has at most two components.*

The assertions about components, including the three criteria, also hold with U in place of E_{unif}. In particular, w is constant when $\{f = 0\}$ is a nonempty connected embedded C^1 real hypersurface; this hypersurface need not be orientable or coorientable.

Since the Hessians of $C^{1,1}$ functions exist only almost everywhere, the contact argument must use points where they exist. The following lemma finds such points

near a maximum; it also provides the strict comparison step in the measurable strong maximum principle.

Lemma 11.1.1 *In Euclidean space $\mathbb{R}^m$, let $B(p,r)$ be the ball of center p and radius $r > 0$, and let I be the identity matrix. Let $g \in C^{1,1}$ near $\overline{B(p,r)} \subset \mathbb{R}^m$, suppose $g \le g(p)$ on the ball, and let E be any subset of full measure in the ball at whose points g has a second-order Taylor expansion. For every $\delta > 0$ and $0 < \rho < r$, there is $x \in E \cap B(p,\rho)$ such that*

$$D^2 g(x) \le 2\delta I.$$

Proof Put $g_\delta(x) = g(x) - \delta|x-p|^2$. The gradient map $F = \nabla g_\delta$ is Lipschitz on the ball, so it maps the null set $N = \overline{B(p,r)} \setminus E$ to a null set. Choose $s \in B(0,\delta\rho) \setminus F(N)$ and maximize $g_\delta(x) - s\cdot(x-p)$ on the closed ball. At any point with $|x-p| \ge \rho$, its value is strictly smaller than its value at p, because

$$g(x) - g(p) - \delta|x-p|^2 - s\cdot(x-p) \le -\delta|x-p|^2 + |s|\,|x-p| < 0.$$

Thus a maximizer x lies in $B(p,\rho)$. The first-order condition at x gives $F(x) = s$, so $x \notin N$. The second-order Taylor expansion at this upper contact point gives $D^2 g(x) \le 2\delta I$. Finally, sets E as in the statement exist: by Rademacher's theorem, applied to the Lipschitz gradient of g, the function g has a second-order Taylor expansion almost everywhere. □

Lemma 11.1.2 *Let $a = (a^{ij})$ be a measurable symmetric matrix field on a connected domain $\Omega \subset \mathbb{R}^m$. For each compact $K \Subset \Omega$, suppose there are constants $0 < \lambda_K \le \Lambda_K < \infty$ such that*

$$\lambda_K I \le a(x) \le \Lambda_K I$$

almost everywhere on K, where I is the identity matrix. Repeated indices $i, j = 1, \dots, m$ are summed, and $z_{ij} = \partial_i \partial_j z$. If $z \in W^{2,\infty}_{\mathrm{loc}}(\Omega)$, $a^{ij} z_{ij} \ge 0$ almost everywhere, and z attains its supremum at a point of Ω, then z is constant.

Proof We first prove strict weak comparison on a relatively compact domain: if $b \in C^{1,1}$, $Lb := a^{ij} b_{ij} \ge \kappa > 0$ almost everywhere, and $b \le M$ on the boundary, then $b \le M$ inside. Otherwise an interior maximum point lies in a closed ball on which $a \le \Lambda I$. Apply Lemma 11.1.1 to the set of full measure where both the differential inequality and the Taylor expansion hold. Choosing $2\delta m\Lambda < \kappa$ gives the contradiction $\kappa \le Lb \le 2\delta \operatorname{tr} a \le 2\delta m\Lambda$.

Take the $C^{1,1}$ representative of z, write $M = \sup_\Omega z$, and suppose that $K = \{z = M\}$ is a nonempty proper subset of Ω. Near a relative boundary point of K, choose $y \notin K$ so that the ball of radius $r = \operatorname{dist}(y,K) > 0$ is compactly contained in Ω and touches K at x_0. On the closed annulus $r/2 \le |x-y| \le r$, use fixed bounds $\lambda I \le a \le \Lambda I$ and set

$$b(x) = \mathrm{e}^{-\alpha|x-y|^2} - \mathrm{e}^{-\alpha r^2}.$$

For sufficiently large α,

$$Lb = \mathrm{e}^{-\alpha|x-y|^2}\bigl(4\alpha^2 a^{ij}(x_i - y_i)(x_j - y_j) - 2\alpha \operatorname{tr} a\bigr) \ge \kappa > 0$$

almost everywhere on the annulus. On its inner sphere $z < M$ uniformly; on its outer sphere $b = 0$. Choose $\eta > 0$ small enough that $z + \eta b \le M$ on both spheres. Strict weak comparison, applied to $z + \eta b$, gives this inequality throughout the annulus. At x_0, however, $z = M$, $b = 0$, $\nabla z = 0$, and b increases to first order in the inward radial direction, which contradicts that inequality. Thus K has no relative boundary point in Ω, and connectedness proves the assertion. The argument uses no derivatives of the measurable coefficients. □

At a point where A, B are semipositive, define the cofactor quadratic form on real cotangent vectors

$$Q_x(\xi)\mathrm{d}V_x = \mathrm{i}\,\xi^{1,0} \wedge \overline{\xi^{1,0}} \wedge T_x. \tag{11.5}$$

Here $\xi^{1,0}$ is the $(1,0)$-part of ξ, and forms of bidegree $(n-1, n-1)$ are ordered by testing against $\mathrm{i}\xi^{1,0} \wedge \overline{\xi^{1,0}}$ in this way. Mixed products of semipositive $(1,1)$-forms are semipositive in this order. Expanding H^{n-1}, where $H = A + B$, gives

$$2^{-(n-1)} H^{n-1} \le T \le H^{n-1}. \tag{11.6}$$

At a point, choose a β-unitary coframe $\mathrm{d}z_1, \dots, \mathrm{d}z_n$ that diagonalizes H, and write $\lambda_1, \dots, \lambda_n$ for the eigenvalues of H. For a $(1,0)$-covector $\alpha = \sum_{k=1}^{n} b_k\,\mathrm{d}z_k$ with complex coefficients b_k, the coefficient of $\mathrm{i}\alpha \wedge \bar{\alpha} \wedge H^{n-1}$ in this coframe is a positive constant depending only on n, times

$$\sum_{k=1}^{n} |b_k|^2 \prod_{\ell \ne k} \lambda_\ell. \tag{11.7}$$

For $n \ge 2$, (11.6) and (11.7) show that Q is locally uniformly elliptic exactly on E_{unif}, that is, where H has a local essential positive lower bound. The implication from ellipticity of Q to a lower bound for H uses the local upper bound for H: testing each eigendirection bounds every product $\prod_{\ell \ne k} \lambda_\ell$ below, and choosing k different from an index of a smallest eigenvalue then bounds that eigenvalue below. For $n = 1$ one has $T = 1$, so the linearized equation is elliptic everywhere.

Proof (of Theorem 11.1.1) We first locate the extrema. Fix $s > 0$ and consider a maximum point of

$$w - s(v - \chi). \tag{11.8}$$

For smooth data, the complex Hessian of this function is nonpositive at a maximum point, that is,

$$(1 + s)B \ge A + sC. \tag{11.9}$$

Since $sC > 0$, this gives $B > 0$, and since $A^n = B^n$, also $A > 0$. In a B-unitary frame put $J = B^{-1/2} A B^{-1/2}$, $K = B^{-1/2} C B^{-1/2}$. Since $\det J = 1$, arithmetic–geometric mean and (11.9) give

$$n + s \operatorname{tr} K \le \operatorname{tr} J + s \operatorname{tr} K \le n(1 + s).$$

Consequently $\operatorname{tr} K \le n$, $B \ge C/n$, and $\det K \le (\operatorname{tr} K/n)^n \le 1$. In particular $B^n \ge C^n$.

For $C^{1,1}$ potentials, fix a maximum point p of (11.8) and apply Lemma 11.1.1 on a coordinate ball, with radii tending to zero and errors $\delta_j \downarrow 0$. For the set of full measure in that lemma, take the points where both Hessians are defined and semipositive and have the common determinant given by (11.2). With $\beta_0 = \mathrm{dd}^{\mathrm{c}}|z|^2$, the resulting points $x_j \to p$ satisfy

$$A(x_j) + sC_j(x_j) \le (1+s)B(x_j), \qquad C_j = C - (\delta_j/s)\beta_0 > 0$$

for large j. The matrix argument just given yields $f(x_j)\mathrm{d}V_{x_j} \ge C_j(x_j)^n$. Since f, $\mathrm{d}V$ and C are continuous, letting $j \to \infty$ gives $p \in P_\chi$; no continuity of the Hessians is needed. Thus every maximum point of the perturbed function lies in P_χ. The set P_χ is closed, by continuity of f, $\mathrm{d}V$ and C, hence compact, and it is contained in U because $C^n > 0$. Letting $s \downarrow 0$, a limit point of these maximum points is a maximum point of w lying in P_χ. Applying the same argument to $-w$ gives a minimum point of w in P_χ as well. In particular, P_χ is nonempty.

On a relatively compact ball in U, the determinants of A and B have a positive lower bound, while their coefficients have an essential upper bound. Every eigenvalue is therefore bounded below by the determinant lower bound divided by a fixed power of the upper bound. Thus $U \subset E_{\mathrm{unif}}$.

By (11.1), w solves a linear equation in nondivergence form with measurable coefficients, whose principal quadratic form is a fixed positive multiple of Q. On each relatively compact coordinate ball in E_{unif}, these coefficients are uniformly elliptic. Lemma 11.1.2, applied to w and to $-w$, makes w constant on the component of E_{unif} containing the maximum point found above, and constant on the component containing the minimum point found above. Continuity extends the two constant values to the closures, proving (11.4). Distinct extrema force disjoint closures.

The same argument applies on U itself, since U contains the extremal points found in P_χ and the cofactor is locally uniformly elliptic on $U \subset E_{\mathrm{unif}}$. This proves the assertions with U in place of E_{unif}.

The component criteria are immediate except for the dense two-component case. If an open dense subset of connected X has at most two components with disjoint closures, those closures are disjoint nonempty closed sets whose union is X, contradicting connectedness. Finally, when $Z = \{f = 0\}$ is a connected embedded real hypersurface, flattening charts assign to each point of Z the unordered pair of components containing its two local sides. This pair is locally constant along Z, so connectedness makes it independent of the point; the two labels may coincide or be exchanged along a loop. Every component of $X \setminus Z$ has a nonempty boundary in Z, since otherwise it would be both open and closed in connected X. Near such a boundary point it contains a local side. Thus the pair accounts for every component, and U has at most two components. It is dense because a hypersurface has empty interior. This proves the last assertion without choosing a global side. □

In this argument, the $C^{1,1}$ bound controls the measurable coefficients, and continuity of the density places the limiting contact points in $\{f > 0\}$. The next criterion gives a quantitative condition for $\{f > 0\}$ to be connected.

11.1.1 A square-root threshold

A nonnegative $C^{1,1}$ density grows at most quadratically away from each of its zeros. If its zero set separates a small ball, a family of parallel segments crossing the zero set therefore contributes at least a constant times $\sqrt{t}$ to the volume of $\{f \le t\}$ for small $t > 0$. Excluding this lower bound makes $\{f > 0\}$ connected, and Theorem 11.1.1 then gives uniqueness.

Write $\mathrm{Vol}(E) = \int_E \mathrm{d}V$ for Borel sets E.

Theorem 11.1.2 *Let $u, v \in C^2(X)$ satisfy $A, B \ge 0$ and $A^n = B^n = f\,\mathrm{d}V$, where $f \ge 0$ is $C^{1,1}$. If*

$$\liminf_{t \downarrow 0} \frac{\mathrm{Vol}\{f \le t\}}{\sqrt{t}} = 0, \tag{11.10}$$

then $\{f > 0\}$ is connected and $u - v$ is constant. In particular this holds when $f^{-1/2} \in L^1(\mathrm{d}V)$, with $f^{-1/2} = +\infty$ on $\{f = 0\}$. The exponent $1/2$ is sharp in every dimension $n \ge 3$.

Proof Write $Z = \{f = 0\}$. Condition (11.10) first implies $\mathrm{Vol}(Z) = 0$. We show that the complement of Z in every sufficiently small coordinate ball is connected. Fix such a ball with convex Euclidean image. If the complement of Z in it were disconnected, choose points a, b in different components and small closed disks centered at a and b, perpendicular to the segment $[a, b]$ and contained in those respective components. By making the disks small, all parallel segments between corresponding points stay in the ball. Each segment meets Z, since otherwise it would connect the two components.

On a fixed coordinate region containing the closed ball, the gradient of f is Lipschitz with some constant $K > 0$. Since $f \ge 0$, we have $\nabla f(z) = 0$ at every zero z, hence

$$f(x) \le \frac{K}{2}|x - z|^2 \tag{11.11}$$

whenever the segment from z to x stays in that region. The endpoint disks are compact and disjoint from Z, so the parts of the segments near them contain no zeros. Thus every parallel segment contains a zero at a fixed positive distance from its endpoints. For small $t > 0$, (11.11) gives on that segment an interval of length $2\sqrt{2t/K}$ contained in $\{f \le t\}$. Integrating over the transverse disk, which has positive measure, and using that $\mathrm{d}V$ is comparable to coordinate volume, we obtain

$$\mathrm{Vol}\{f \le t\} \ge c\sqrt{t}$$

for all sufficiently small t, contradicting (11.10). This proves the local connectedness assertion.

For each such ball, the complement of Z in it is nonempty, since Z has zero volume, and it lies in one component of $U = X \setminus Z$. Two overlapping balls give the same component, because their open overlap contains a point outside Z. Since X is connected, all these balls give the same component. Hence U is connected, and Theorem 11.1.1 shows that $u - v$ is constant.

If $f^{-1/2} \in L^1$, then, outside the null zero set,

$$\frac{\operatorname{Vol}\{f \le t\}}{\sqrt{t}} \le \int_{\{f \le t\}} f^{-1/2}\, \mathrm{d}V \longrightarrow 0$$

by dominated convergence. This proves the sufficient integrability condition. The sharpness assertion follows from the examples in Section 11.9, as quantified at the end of that section. □

11.2 Polarized cofactors and propagation

Uniform ellipticity is sufficient for the propagation of an extremum, but it is not necessary: the directions in which the cofactor is positive may already connect enough points to force constancy. For C^2 potentials, the quadratic form Q in (11.5) is continuous, and its polarization defines $Q^\sharp : T^*X \to TX$ by $\eta(Q^\sharp \xi) = Q(\xi, \eta)$. The *reachable set* of a point consists of the endpoints of absolutely continuous curves starting there whose velocity lies in $\operatorname{im} Q^\sharp$ almost everywhere. The *control orbit* of a point consists of the endpoints of finite concatenations of flow lines, starting there, of locally Lipschitz vector fields with values in $\operatorname{im} Q^\sharp$.

A positive weight h satisfying $\mathrm{dd}^{\mathrm{c}}(hT) = 0$ gives an energy identity that controls $\mathrm{d}w$ everywhere. Without such a weight, a degenerate maximum principle gives propagation only from the extremal sets. This distinction accounts for the different density assumptions on reachable sets and on orbits in the following theorem.

Theorem 11.2.1 *Let $u, v \in C^2(X)$ satisfy $A, B \ge 0$ and $A^n = B^n$, and put $w = u - v$.*

(1) *If there is a continuous $h > 0$ such that $\mathrm{dd}^{\mathrm{c}}(hT) = 0$ in distributions, then*

$$\mathrm{i}\,\partial w \wedge \bar\partial w \wedge T \equiv 0. \tag{11.12}$$

It follows that w is constant if the set where T is strictly positive is dense, or if the reachable set of one point is dense.

(2) *Without the weight hypothesis, the sets where w attains its maximum and its minimum are invariant under the flow of every locally Lipschitz vector field with values in $\operatorname{im} Q^\sharp$. If every control orbit is dense, then w is constant. For smooth data it is enough that smooth vector fields with values in $\operatorname{im} Q^\sharp$, for example the columns of the symbol a in (11.18) below, together with their iterated Lie brackets, span TX at every point.*

11.2.1 Weighted energy

Testing the weighted cofactor against w^2 produces a nonnegative gradient integral. Only distributional $\mathrm{dd^c}$-closedness of hT is needed: for a continuous $h > 0$, the condition is

$$\int_X \mathrm{dd^c}\varphi \wedge hT = 0 \qquad (\varphi \in C^\infty(X, \mathbb{R})). \tag{11.13}$$

Proof (of Theorem 11.2.1(1)) The product rule gives

$$\mathrm{dd^c}(w^2) = 2w\mathrm{dd^c}w + 2\mathrm{d}w \wedge \mathrm{d^c}w = 2w\mathrm{dd^c}w + \frac{\mathrm{i}}{\pi}\partial w \wedge \bar\partial w. \tag{11.14}$$

Approximate w^2 in C^2 by smooth functions φ in (11.13). Since hT is continuous and $\mathrm{dd^c}w \wedge T = 0$ by (11.1), this gives

$$0 = \frac{1}{\pi}\int_X h\,\mathrm{i}\partial w \wedge \bar\partial w \wedge T. \tag{11.15}$$

The continuous integrand is nonnegative, so it vanishes identically, which is (11.12).

By (11.5), (11.12) says that $Q(\mathrm{d}w) = 0$. For the nonnegative quadratic form Q, this implies $Q(\mathrm{d}w, \eta) = 0$ for every η. Therefore

$$\mathrm{d}w_x\big(Q_x^\sharp \eta\big) = 0 \qquad (x \in X,\ \eta \in T_x^*X). \tag{11.16}$$

By the chain rule and (11.16), w is constant along every absolutely continuous curve whose velocity lies in $\operatorname{im} Q^\sharp$ almost everywhere. Thus w is constant on each reachable set, and by continuity one dense reachable set suffices. If instead Q is positive definite on a dense set, (11.15) gives $\mathrm{d}w = 0$ there, and hence everywhere. □

The argument uses only the test function w^2. For general test functions, integration by parts introduces derivatives of hT; the condition $\mathrm{dd^c}(hT) = 0$ alone does not make $L\varphi = (\mathrm{dd^c}\varphi \wedge T)/\mathrm{d}V$ a symmetric operator in divergence form.

11.2.2 The real symbol and exterior-ball propagation

To propagate an extremum without a weight, we write the linearized operator in real coordinates. Its symbol is continuous and semipositive. At a point where a ball outside the maximum set touches it, the normal direction must lie in the kernel of the symbol; this forces the maximum set to be invariant under the flows of vector fields with values in the range of the symbol.

In a holomorphic chart $z_j = x_j + \mathrm{i}y_j$, let C_{cf} be the Hermitian matrix characterized by

$$\frac{\big(\mathrm{i}\sum H_{j\bar k}\mathrm{d}z_j \wedge \mathrm{d}\bar z_k\big) \wedge T}{\mathrm{d}V} = \operatorname{Tr}(C_{\mathrm{cf}}H) \tag{11.17}$$

for every Hermitian matrix $H = (H_{j\bar{k}})$. Positivity of mixed products makes C_{cf} positive semidefinite. Write $C_{\mathrm{cf}} = P_{\mathrm{cf}} + \mathrm{i}Q_{\mathrm{cf}}$, where P_{cf} is real symmetric and Q_{cf} is real skew-symmetric.

In the real coordinate order $(x_1, \dots, x_n, y_1, \dots, y_n)$,

$$L\varphi := \frac{\mathrm{d}\mathrm{d}^{\mathrm{c}}\varphi \wedge T}{\mathrm{d}V} = \mathrm{Tr}(aD^2\varphi), \qquad a = \frac{1}{8\pi}\begin{pmatrix} P_{\mathrm{cf}} & Q_{\mathrm{cf}} \\ -Q_{\mathrm{cf}} & P_{\mathrm{cf}} \end{pmatrix}. \tag{11.18}$$

Indeed $\varphi_{j\bar{k}} = (\varphi_{x_jx_k} + \varphi_{y_jy_k} + \mathrm{i}\varphi_{x_jy_k} - \mathrm{i}\varphi_{y_jx_k})/4$; inserting this expression in (11.17) proves (11.18). For real coordinate vectors $\xi, \eta \in \mathbb{R}^n$, moreover,

$$(\xi, \eta)^T a(\xi, \eta) = \frac{1}{8\pi}(\xi - \mathrm{i}\eta)^* C_{\mathrm{cf}}(\xi - \mathrm{i}\eta) \geq 0.$$

Thus a is a continuous positive semidefinite principal symbol, the operator L has no first-order term in holomorphic coordinates, and the range of a is that of $Q^\sharp$.

An exterior-ball argument propagates the maximum for this operator. Let $W \in C^2$ satisfy $LW \geq 0$ in a chart, suppose $W \leq M$, and put $K = \{W = M\}$. If $z \in K$ is a point of K nearest to a point $y \notin K$ of the chart, then

$$(y - z)^T a(z)(y - z) = 0. \tag{11.19}$$

To prove this, suppose the left side is positive, set $r_0 = |y - z|$, and shrink the tangent ball toward z: $y' = z + \theta(y - z)$, $R = \theta r_0$, with $0 < \theta < 1$ small. The closed ball $\overline{B(y', R)}$ lies in the chart and meets K only at z. This follows from the triangle inequality; equality in $|k - y| \leq |k - y'| + |y' - y| \leq r_0$, for $k \in K$, forces $k = z$. For large $\alpha > 0$, the function

$$\psi(x) = \mathrm{e}^{-\alpha R^2} - \mathrm{e}^{-\alpha|x - y'|^2}$$

satisfies

$$L\psi = 2\alpha \mathrm{e}^{-\alpha|x-y'|^2}\big(\mathrm{tr}\, a - 2\alpha(x - y')^T a(x)(x - y')\big) < 0$$

in a neighborhood of z, because $z - y'$ is a nonzero multiple of $y - z$, so that $(z - y')^T a(z)(z - y') > 0$ by assumption. Choose a sufficiently small $r < R$, and consider the lens $D = B(z, r) \cap B(y', R)$. On the part of its boundary lying on the sphere $\partial B(y', R)$, we have $\psi = 0$ and $W - M \leq 0$. On the remaining compact boundary portion, $W - M < 0$, since the tangent ball meets K only at z. Hence, for sufficiently small $\varepsilon > 0$, $W - M \leq \varepsilon\psi$ on ∂D. At a positive interior maximum of $W - M - \varepsilon\psi$, the Hessian would be nonpositive, whereas $L(W - M - \varepsilon\psi) > 0$; this is impossible since $a \geq 0$. Hence the inequality $W - M \leq \varepsilon\psi$ holds in D. Outside the ball $B(y', R)$ we have $\psi \geq 0$, so this inequality holds in a full neighborhood of z. Since equality holds at z, the function $W - M - \varepsilon\psi$ has a local maximum at z, and therefore

$$0 \leq LW(z) \leq \varepsilon L\psi(z) < 0,$$

proving (11.19).

Since $a \geq 0$, its range is the orthogonal complement of its kernel, and (11.19) implies that $y - z$ lies in this kernel. Consequently $(y - z) \cdot Z(z) = 0$ for every vector field Z with values in the range of a. If Z is locally Lipschitz and γ is one of its flow curves starting in K, let $d(t)$ denote the squared distance from $\gamma(t)$ to K in a sufficiently small compact chart neighborhood. Shortening the time interval ensures that nearest points z_t lie in the chart interior. Write $D^+ d(t) = \limsup_{h \downarrow 0} (d(t+h) - d(t))/h$ for the upper right derivative. Holding such a nearest point fixed when differentiating the distance from above gives

$$\begin{aligned} D^+ d(t) &\leq 2(\gamma(t) - z_t) \cdot Z(\gamma(t)) \\ &= 2(\gamma(t) - z_t) \cdot \big(Z(\gamma(t)) - Z(z_t)\big) \leq 2 \operatorname{Lip}(Z) d(t). \end{aligned}$$

As $d(0) = 0$, Gronwall's inequality gives $d(t) = 0$. The same argument for $-Z$, followed by continuation, proves invariance under both signs of time and under finite concatenations of such flows.

Proof (of Theorem 11.2.1(2)) Apply the preceding argument to $W = w$ and to $W = -w$ in each chart; both satisfy $LW = 0$ by (11.1). The maximum set of w is nonempty, closed, and contains every control orbit starting in it. If every orbit is dense, this maximum set is all of X, proving constancy. The argument for the minimum set is identical.

It remains to prove the bracket criterion. Suppose that a family of smooth vector fields with values in $\operatorname{im} Q^\sharp$ is bracket generating. At p, let $\mathcal{D}_p$ be the span of the values of all original fields pushed forward by finite compositions of their local flows and inverse flows. This distribution contains the original fields and is invariant under their flows. Differentiation of pushed-forward fields along a flow shows that it contains their nested Lie brackets; finite-dimensional subspaces are closed, so the derivative remains in $\mathcal{D}_p$. Induction and the Jacobi identity give every iterated bracket. The assumed rank condition therefore gives $\mathcal{D}_p = T_p X$.

Choose $2n$ such pushed-forward fields independent at p. The flow of each is a conjugate of an original flow and hence preserves its orbit. The map obtained by successively flowing for $2n$ small times has invertible derivative at zero. The inverse function theorem puts a neighborhood of p in its orbit. All orbits are open, and their partition of connected X has only one member. This proves the Hörmander-type sufficient condition; it requires neither a constant-rank hypothesis nor a smooth matrix square root of a. In particular, the columns of a smooth symbol a may be used as the original vector fields. □

For $C^{2,1}$ potentials, the columns of a are locally Lipschitz, so the orbit criterion still applies to them. The bracket criterion requires smooth vector fields.

11.2.3 The unweighted energy defect

Integration against w^2 also measures the obstruction to using the unweighted cofactor, that is, the case $h = 1$. For smooth potentials, the error is exactly the pairing of w^2 with $\mathrm{dd^c}T$. On a surface, the Gauduchon condition makes this error vanish for every pair of potentials; in dimension three, $\mathrm{dd^c}T$ contains an additional term depending on the potentials.

Proposition 11.2.1 *Let $n \geq 2$, and let u, v be smooth ω-plurisubharmonic functions with $A^n = B^n = f\,\mathrm{d}V$ for a smooth function $f \geq 0$. Then*

$$\int_X \mathrm{d}w \wedge \mathrm{d^c}w \wedge T = \frac{1}{2}\int_X w^2 \mathrm{dd^c}T. \tag{11.20}$$

If $\mathrm{dd^c}T = 0$ and $\{f > 0\}$ is dense in X, then $u - v$ is constant.

Proof By (11.1), $\mathrm{dd^c}w \wedge T = 0$. Integrating (11.14) against T, and applying Stokes' theorem twice to the left-hand side, yields

$$\int_X \mathrm{dd^c}(w^2) \wedge T = \int_X w^2 \mathrm{dd^c}T.$$

Substitution proves (11.20).

For the uniqueness assertion, apply Theorem 11.2.1(1) with $h = 1$. At every point where $f > 0$, the form B is positive definite, so the term B^{n-1} makes the cofactor T strictly positive. The set where T is strictly positive is therefore dense, as required. □

Corollary 11.2.1 *Assume $n = 2$ and $\mathrm{dd^c}\omega = 0$. Let $f \geq 0$ be smooth, with a zero set of empty interior, and let $c > 0$. Then any two smooth ω-plurisubharmonic solutions of*

$$(\omega + \mathrm{dd^c}u)^2 = c f\,\mathrm{d}V$$

normalized by $\sup_X u = 0$ coincide.

Proof Here $T = A + B$ and $\mathrm{dd^c}T = 2\mathrm{dd^c}\omega = 0$. The set $\{f > 0\}$ is dense, so the proposition, applied to the density cf, makes the difference of the two solutions constant, and the normalization makes this constant zero. □

In dimension three, direct expansion gives

$$\mathrm{dd^c}T = 3\mathrm{dd^c}(\omega^2) + 3\mathrm{dd^c}\omega \wedge \mathrm{dd^c}(u + v).$$

The Gauduchon condition cancels the first term but need not cancel the second. For instance, take both potentials equal to the perturbation sv in Example 4.8.1. The common form $A = B$ is positive and satisfies $\mathrm{dd^c}(A^2) \neq 0$, so $\mathrm{dd^c}T = 3\mathrm{dd^c}(A^2) \neq 0$. Thus even for two equal positive solution forms, the cofactor need not be $\mathrm{dd^c}$-closed.

11.3 Integral rigidity in dimensions two and three

In dimensions two and three, if two positive forms A, B have equal determinants, an algebraic expression quadratic in $A - B$ has a strict sign unless the two forms agree. On a surface its integral vanishes because it is exact. On a threefold the integral is a term involving $\mathrm{dd^c}\omega$, so a sign condition on $\mathrm{dd^c}\omega$ leads to the same conclusion. Approximation in the Sobolev norm justifies the integral identities for $W^{2,n}$ potentials.

In this section $n \in \{2, 3\}$. Norms of coefficients of forms are taken with respect to a fixed smooth metric and $\mathrm{d}V$.

Theorem 11.3.1 *Let $u, v \in W^{2,n}(X, \mathbb{R})$, and assume that $A, B \geq 0$ almost everywhere and*

$$A^n = B^n = f\,\mathrm{d}V, \qquad f > 0 \quad \text{almost everywhere}.$$

If $n = 3$, assume in addition that

$$\mathrm{dd^c}\omega \wedge \mathrm{i}\eta \wedge \bar{\eta} \leq 0 \tag{11.21}$$

for every $(1,0)$-covector η; for $n = 2$ no condition on ω is needed. Then $\mathrm{dd^c}(u - v) = 0$ in the sense of distributions, and $u - v$ is almost everywhere constant. For the ω-plurisubharmonic representatives of u and v, the difference is constant everywhere.

Proof Put

$$s = (u + v)/2, \qquad D = \mathrm{dd^c}w = A - B,$$
$$C = (A + B)/2 = \omega + \mathrm{dd^c}s.$$

The coefficients of C and D lie in L^n, so their products of top degree are integrable by Hölder's inequality. At almost every point the common determinant is positive, so A and B are positive definite there, and we may diagonalize them simultaneously by congruence: for a suitable coframe of $(1,0)$-covectors $\theta_1, \dots, \theta_n$, write $A = \sum e_j$, $B = \sum \lambda_j e_j$, where $e_j = \mathrm{i}\theta_j \wedge \bar{\theta}_j$, $\lambda_j > 0$, and $\prod \lambda_j = 1$.

In dimension two,

$$D^2 = A^2 + B^2 - 2A \wedge B = 2(2 - \lambda_1 - \lambda_2)e_1 \wedge e_2 \leq 0, \tag{11.22}$$

with equality if and only if $A = B$. In dimension three,

$$2C \wedge D^2 = A^3 + B^3 - A^2 \wedge B - A \wedge B^2 \leq 0. \tag{11.23}$$

Indeed, with $E = e_1 \wedge e_2 \wedge e_3$, the four terms on the right are

$$6E, \qquad 6E, \qquad 2\Big(\sum_j \lambda_j\Big)E, \qquad 2\Big(\sum_{i<j} \lambda_i\lambda_j\Big)E.$$

By the arithmetic–geometric mean inequality and $\prod_j \lambda_j = 1$, each sum is at least three, and equality forces all $\lambda_j = 1$, that is, $A = B$.

Choose smooth real functions $w_k \to w$ in $W^{2,n}$ and set $D_k = \mathrm{dd^c}w_k$; such approximations are obtained by a partition of unity and convolution, and they need

not preserve semipositivity. For $n = 2$, Stokes' theorem gives $\int_X D_k^2 = 0$, since $D_k^2 = \mathrm{d}(\mathrm{d}^{\mathrm{c}} w_k \wedge D_k)$. For a fixed norm-comparison constant $C_0 > 0$,

$$\|D_k^2 - D^2\|_{L^1} \le C_0 \|D_k - D\|_{L^2} (\|D_k\|_{L^2} + \|D\|_{L^2}) \longrightarrow 0.$$

Thus $\int_X D^2 = 0$, and the nonpositive integrand in (11.22) vanishes almost everywhere. By the equality case, $D = 0$ almost everywhere.

For $n = 3$, also choose smooth functions $s_k \to s$ in $W^{2,3}$, and put $C_k = \omega + \mathrm{dd}^{\mathrm{c}} s_k$. We need the identity

$$\int_X C_k \wedge D_k^2 = \int_X \omega \wedge D_k^2 = -\int_X \mathrm{d}w_k \wedge \mathrm{d}^{\mathrm{c}} w_k \wedge \mathrm{dd}^{\mathrm{c}} \omega. \tag{11.24}$$

The first equality holds because $\mathrm{dd}^{\mathrm{c}} s_k \wedge D_k^2 = \mathrm{d}(\mathrm{d}^{\mathrm{c}} s_k \wedge D_k^2)$. For the second equality, including its sign, put $J_k = \mathrm{d}w_k \wedge \mathrm{d}^{\mathrm{c}} w_k$. Using $\mathrm{d}^{\mathrm{c}}\mathrm{d} = -\mathrm{dd}^{\mathrm{c}}$ and $(\mathrm{d}^{\mathrm{c}})^2 = 0$,

$$\mathrm{d}^{\mathrm{c}} J_k = -D_k \wedge \mathrm{d}^{\mathrm{c}} w_k, \qquad \mathrm{dd}^{\mathrm{c}} J_k = -D_k^2.$$

Stokes, first for $\mathrm{d}(\omega \wedge \mathrm{d}^{\mathrm{c}} J_k)$ and then for $\mathrm{d}^{\mathrm{c}}(\mathrm{d}\omega \wedge J_k)$, gives

$$\int_X \omega \wedge \mathrm{dd}^{\mathrm{c}} J_k = -\int_X \mathrm{d}\omega \wedge \mathrm{d}^{\mathrm{c}} J_k,$$
$$0 = -\int_X \mathrm{dd}^{\mathrm{c}} \omega \wedge J_k - \int_X \mathrm{d}\omega \wedge \mathrm{d}^{\mathrm{c}} J_k.$$

Combining them yields (11.24).

With a fixed norm-comparison constant $C_0 > 0$, strong L^3 convergence implies convergence in L^1 of all products of three factors. For example,

$$\|(C_k - C) \wedge D_k^2\|_1 \le C_0 \|C_k - C\|_3 \|D_k\|_3^2 \longrightarrow 0,$$

and

$$\|C \wedge (D_k^2 - D^2)\|_1 \le C_0 \|C\|_3 \|D_k - D\|_3 (\|D_k\|_3 + \|D\|_3) \longrightarrow 0.$$

Also $\mathrm{d}w_k \wedge \mathrm{d}^{\mathrm{c}} w_k \to \mathrm{d}w \wedge \mathrm{d}^{\mathrm{c}} w$ in $L^{3/2}$, so the right side of (11.24) converges. Consequently

$$\int_X C \wedge D^2 = -\int_X \mathrm{d}w \wedge \mathrm{d}^{\mathrm{c}} w \wedge \mathrm{dd}^{\mathrm{c}} \omega \ge 0. \tag{11.25}$$

The sign follows from $\mathrm{d}w \wedge \mathrm{d}^{\mathrm{c}} w = (\mathrm{i}/(2\pi)) \partial w \wedge \bar{\partial} w$ and (11.21). The integrand on the left is nonpositive by (11.23), so it vanishes almost everywhere, and the equality case, which applies where the common determinant is positive, gives $D = 0$ almost everywhere.

In both dimensions, therefore, $\mathrm{dd}^{\mathrm{c}} w = 0$ in the sense of distributions. By Proposition 1.1.1 with background zero, w has a plurisubharmonic representative on X. It attains its maximum on the compact manifold X, so the maximum principle and connectedness make it constant.

For the ω-plurisubharmonic representatives, Lemma 1.3.3 upgrades the almost-everywhere equality $u = v +$ constant to equality everywhere. In particular, normalizing the means gives equality in the Sobolev class, and normalizing the suprema gives equality of the plurisubharmonic representatives. □

Corollary 11.3.1 *Let $n \in \{2, 3\}$, and let $u, v \in C^2(X)$ satisfy $A, B \geq 0$ and $A^n = B^n = f\,\mathrm{d}V$, where $f \geq 0$ is continuous and positive on a dense set. If $n = 3$, assume (11.21); for instance, $\mathrm{dd}^c\omega = 0$ suffices. Then $u - v$ is constant.*

Proof Put $D = A - B$ and $C = (A + B)/2$. At a point where the common top power vanishes, the algebraic expressions in the proof of Theorem 11.3.1 are still nonpositive: in dimension two $D^2 = -2A \wedge B$, and in dimension three $2C \wedge D^2 = -A^2 \wedge B - A \wedge B^2$. The same integral identities force these continuous expressions to vanish everywhere. The equality cases give $D = 0$ on $\{f > 0\}$, and density and continuity then give $D = 0$ on X. As in the proof of the theorem, $u - v$ is then constant. □

For example, on the Hopf threefold X of Chapter 8, with projection $\pi : X \to \mathbb{P}^2$ and the semipositive form $\alpha = \pi^*\omega_{\mathrm{FS}}$, where ω_{FS} is the Fubini–Study form, the Hermitian metric ω satisfies $\mathrm{dd}^c\omega = -\alpha^2$, and hence (11.21). Theorem 11.3.1 therefore applies to this metric, even though its upper mass $v_+(\omega)$ of Definition 6.5.1 is infinite by Theorem 8.0.1. The following sections return to a general Hermitian background.

11.4 Bounded uniqueness and connectedness

Connectedness of the set where a continuous density is positive also gives uniqueness for bounded potentials. The missing differentiability is replaced by an energy measure of the difference $w = u - v$, whose pushforward to the real line under w has a Lipschitz density vanishing at the extreme values of w. This forces the sets where w attains its extreme values to have zero mass for the common Monge–Ampère measure. Smooth test potentials whose Monge–Ampère measures concentrate near such a set then contradict modified comparison.

Theorem 11.4.1 *Let $F \in C^0(X)$ satisfy $F \geq 0$, $F \not\equiv 0$, with $U = \{F > 0\}$ connected and dense. If bounded ω-plurisubharmonic functions u, v satisfy*

$$\omega_u^n = \omega_v^n = F\omega^n,$$

then $u - v$ is constant. In particular, $\sup_X u = \sup_X v$ implies $u = v$.

Continuity of F supplies the local positive lower bounds and the neighborhoods of the extremal set used below. The auxiliary test densities are chosen smooth independently of F. Bounded solutions are continuous by Corollary 10.4.1, so we may use pointwise extrema throughout the proof. We shall also use modified comparison in the following form. If b is continuous and $\omega_b \geq \varepsilon\omega$ for some $0 < \varepsilon < 1$, then $b/(1 - \varepsilon)$ is ω-plurisubharmonic, so Theorem 10.2.1 applies with $(1 - \varepsilon)v = b$.

Thus its thin-sublevel estimate applies directly to such a strictly positive comparison potential b, and the correction factor tends to one as the height of the sublevel set tends to zero, with ε fixed.

Proposition 11.4.1 *Let u, v be continuous ω-plurisubharmonic functions with $\omega_u^n = \omega_v^n = F\omega^n$, where $F \geq 0$ is bounded and measurable. Let q be a smooth strictly ω-plurisubharmonic function, and write $\omega_q^n = G\omega^n$. Then for every $0 < \kappa < 1$ and $\eta > 0$,*

$$F\omega^n\big(\{u - v < \min_X(u - v) + \eta\} \cap \{F > \kappa G\}\big) > 0. \tag{11.26}$$

The analogous assertion holds for the set $\{u - v > \max_X(u - v) - \eta\}$.

Proof Choose $\delta \in (0, 1]$ with $\omega_q \geq \delta\omega$. For $0 < t < 1$, put $b_t = (1 - t)v + tq$, $m_t = \min_X(u - b_t)$, and $E_s = \{u < b_t + m_t + s\}$. Then $\omega_{b_t} \geq t\delta\omega$. Write $\mu = F\omega^n$, $d = \kappa^{-1/n} - 1$, and $\gamma = nd$. By (1.12),

$$\omega_{b_t}^n \geq \big((1 - t)F^{1/n} + tG^{1/n}\big)^n\omega^n.$$

On $L = \{F \leq \kappa G\}$ this is at least $(1 + \gamma t)\mu$, since $G^{1/n} \geq (1 + d)F^{1/n}$ there, and on $R = \{F > \kappa G\}$ it is at least $(1 - nt)\mu$. Choose $s > 0$ so small that the reverse comparison factor in (10.2), with $\varepsilon = t\delta$, is at most $1 + \gamma t/2$. Modified comparison on E_s, with $x = \mu(E_s \cap L)$ and $y = \mu(E_s \cap R)$, gives

$$(1 + \gamma t)x + (1 - nt)y \leq (1 + \gamma t/2)(x + y), \qquad \text{and hence} \qquad y \geq \frac{1 - \kappa^{1/n}}{2}\,\mu(E_s).$$

The open set E_s is nonempty by the definition of m_t. As $\omega_{b_t}^n \geq (t\delta)^n\omega^n$, (10.2) forces $\mu(E_s) > 0$, hence $y > 0$.

Let $a = \min_X(u - v)$ and $\Lambda = \|v - q\|_\infty$. Since $u - b_t = u - v + t(v - q)$, we have $|m_t - a| \leq t\Lambda$ and $E_s \subset \{u - v < a + 2t\Lambda + s\}$. Given η, choose t and then s with $2t\Lambda + s < \eta$. Since $y = \mu(E_s \cap R) > 0$, this proves (11.26). Interchanging u and v gives the assertion for the near-maximum set. □

11.4.1 The energy of the difference

In this subsection, u, v are continuous ω-plurisubharmonic functions with $A^n = B^n = F\omega^n$ for a bounded measurable function $F \geq 0$, and $w = u - v$. Although the cofactor T is now only a current, its product with $\mathrm{d}w \wedge \mathrm{d}^c w$ still defines a positive measure. The identity $\mathrm{d}\mathrm{d}^c w \wedge T = 0$ determines how this energy is distributed over the level sets of w.

Proposition 11.4.2 *There is a finite positive measure $E = \mathrm{d}w \wedge \mathrm{d}^{\mathrm{c}}w \wedge T$, defined below as a limit of regularizations, with the following properties.*

For every smooth real function χ on $\mathbb{R}$,

$$\int_X \chi''(w)\,\mathrm{d}E = \int_X \chi(w)\,\mathrm{d}\mathrm{d}^{\mathrm{c}}T. \tag{11.27}$$

The signed current $\mathrm{d}\mathrm{d}^{\mathrm{c}}T$ is a finite measure. If $a = \min_X w$, $b = \max_X w$, and

$$k(t) = \int_X (w - t)_+\,\mathrm{d}\mathrm{d}^{\mathrm{c}}T,$$

then k is nonnegative, globally Lipschitz, supported on $[a, b]$, and

$$w_* E = k(t)\,\mathrm{d}t. \tag{11.28}$$

In particular, E charges no level set of w.

Let V be a relatively compact coordinate domain such that F has a positive essential lower bound on a neighborhood of $\overline{V}$. Then there is $C_V < \infty$ such that every piecewise C^1 Lipschitz function p on $[a, b]$ satisfies

$$\int_V |\mathrm{d}(p(w))|\,\mathrm{d}\lambda \le C_V \left(\int_V |p'(w)|^2\,\mathrm{d}E \right)^{1/2}, \tag{11.29}$$

where $\mathrm{d}\lambda$ is Euclidean coordinate volume.

Proof Locally, expand T into powers of the smooth form ω multiplied by closed Bedford–Taylor products of $\mathrm{d}\mathrm{d}^{\mathrm{c}}u$ and $\mathrm{d}\mathrm{d}^{\mathrm{c}}v$. The operator $\mathrm{d}\mathrm{d}^{\mathrm{c}}$ then acts only on the powers of ω, and the local mass bounds in Section 1.6 show that $\mathrm{d}\mathrm{d}^{\mathrm{c}}T$ is a finite signed measure.

We first construct E and prove (11.27). On a coordinate ball, convolve u, v and the coefficients of ω with a common nonnegative radial mollifier. Write the resulting smooth positive forms as $A_\rho = \omega_\rho + \mathrm{d}\mathrm{d}^{\mathrm{c}}u_\rho$ and $B_\rho = \omega_\rho + \mathrm{d}\mathrm{d}^{\mathrm{c}}v_\rho$, and let T_ρ be their mixed sum. On a slightly larger ball, add the same fixed multiple of $|z|^2$ to each potential to obtain plurisubharmonic functions. Their radial regularizations decrease to the originals, so Bedford–Taylor continuity applies to all closed Hessian products. Since u, v are continuous, u_ρ, v_ρ, w_ρ converge uniformly on compact subsets.

For a closed smooth product S_ρ appearing in T_ρ, the identity

$$\mathrm{d}w_\rho \wedge \mathrm{d}^{\mathrm{c}}w_\rho \wedge S_\rho = \tfrac{1}{2}\mathrm{d}\mathrm{d}^{\mathrm{c}}(w_\rho^2 S_\rho) - w_\rho \mathrm{d}\mathrm{d}^{\mathrm{c}}w_\rho \wedge S_\rho \tag{11.30}$$

has a distributional limit: both Hessian products on the right converge weakly with uniformly bounded local variation, and their weights converge uniformly. The same holds after multiplication by the convergent smooth factors coming from ω_ρ. Thus the positive measures $E_\rho = \mathrm{d}w_\rho \wedge \mathrm{d}^{\mathrm{c}}w_\rho \wedge T_\rho$ converge to a finite positive measure E. By (11.30), this limit does not depend on the regularization, so the local limits agree on overlapping charts.

For smooth regularizations, the chain rule gives

$$\mathrm{dd^c}\chi(w_\rho)\wedge T_\rho = \chi''(w_\rho)E_\rho + \chi'(w_\rho)\mathrm{dd^c}w_\rho\wedge T_\rho.$$

The last current tends to zero, because $\mathrm{dd^c}w_\rho\wedge T_\rho = A_\rho^n - B_\rho^n$ tends weakly to $A^n - B^n = 0$ with uniformly bounded variation, and $\chi'(w_\rho)$ converges uniformly. Passing to the limit and integrating by parts on the compact manifold X gives (11.27). A partition of unity justifies this passage without a global regularization; the terms containing derivatives of the cutoff functions cancel after summation.

Let $\sigma = w_*(\mathrm{dd^c}T)$ and $\nu = w_*E$. Equation (11.27) says that $\nu'' = \sigma$ as distributions on $\mathbb{R}$. Stokes' theorem and $\mathrm{dd^c}w\wedge T = 0$ give

$$\sigma(\mathbb{R}) = \int_X \mathrm{dd^c}T = 0, \qquad \int_{\mathbb{R}} s\,\mathrm{d}\sigma(s) = \int_X w\,\mathrm{dd^c}T = \int_X \mathrm{dd^c}w\wedge T = 0.$$

Consequently $k(t) = \int (s-t)_+\,\mathrm{d}\sigma(s)$ is globally Lipschitz and vanishes outside $[a,b]$. It satisfies $k'' = \sigma$, so the compactly supported distribution $\nu - k(t)\,\mathrm{d}t$ has second derivative zero and therefore vanishes. Positivity of ν and continuity of k imply $k\geq 0$. This proves (11.28), and the assertion about level sets follows because ν is absolutely continuous.

We now prove (11.29). On a coordinate neighborhood of $\overline{V}$, set $\beta = \mathrm{dd^c}|z|^2$ and choose $c_V > 0$ with $F\omega^n \geq c_V\beta^n$. Let A_{ac} denote the absolutely continuous part of the current A, whose coefficients are locally integrable functions. Applying Lemma 1.7.4 with the constant function $g = c_V^{1/n}$ and differentiating the coefficient measures, we obtain $\det_\beta A_{\mathrm{ac}} \geq c_V$ almost everywhere. The local Sobolev regularity in Section 1.6 gives $w_\rho \to w$ strongly in $W^{1,2}_{\mathrm{loc}}$, so a subsequence of the gradients converges almost everywhere. Moreover, $A_\rho \to A_{\mathrm{ac}}$ almost everywhere, by differentiation of the coefficient measures.

Since T_ρ contains the term A_ρ^{n-1} and all its terms are positive, Fatou's lemma, applied to E_ρ, yields the measure inequality

$$E \geq \mathrm{d}w\wedge\mathrm{d^c}w\wedge A_{\mathrm{ac}}^{n-1}. \tag{11.31}$$

The cofactor matrix of A_{ac} has smallest eigenvalue at least $\det A_{\mathrm{ac}}/\operatorname{tr}A_{\mathrm{ac}} \geq c_V/\operatorname{tr}A_{\mathrm{ac}}$, where traces and determinants are taken with respect to β. The trace is locally integrable because A has locally finite mass. The chain rule for Sobolev functions, (11.31) and the Cauchy–Schwarz inequality give

$$\int_V |\mathrm{d}(p(w))|\,\mathrm{d}\lambda \leq C\left(\int_V |p'(w)|^2\,\mathrm{d}E\right)^{1/2}\left(\int_V \frac{\operatorname{tr}A_{\mathrm{ac}}}{c_V}\,\mathrm{d}\lambda\right)^{1/2}.$$

The last factor is finite and is absorbed into C_V. The values of p' at the finitely many corners of p are immaterial, because E charges no level set of w. □

Lemma 11.4.1 *In the setting of Proposition 11.4.2, assume in addition that F is continuous and that $U = \{F > 0\}$ is connected and dense. If $w = u - v$ is nonconstant, then*

$$F\omega^n(\{w = \min_X w\}) = F\omega^n(\{w = \max_X w\}) = 0.$$

Proof Put $a = \min_X w < b = \max_X w$, and let k be the function of Proposition 11.4.2. It is Lipschitz and nonnegative, and $k(a) = 0$. Choose $\epsilon_j \downarrow 0$ with $a + \epsilon_j < b$. For $\delta > 0$, set

$$J_j(\delta) = \int_a^{a+\epsilon_j} \frac{\mathrm{d}t}{k(t) + \delta}.$$

If L is a Lipschitz constant for k, then $k(t) \le L(t - a)$ on this interval, so $J_j(\delta) \to \infty$ as $\delta \downarrow 0$. Choose $\delta_j > 0$ with $J_j = J_j(\delta_j) \ge j$. Let $p_j = 0$ on $(-\infty, a]$, $p_j = 1$ on $[a + \epsilon_j, \infty)$, and

$$p_j'(t) = \frac{1}{J_j(k(t) + \delta_j)} \quad (a < t < a + \epsilon_j).$$

The pushforward identity (11.28) gives

$$\int_X |p_j'(w)|^2 \, \mathrm{d}E = \frac{1}{J_j^2} \int_a^{a+\epsilon_j} \frac{k(t)}{(k(t) + \delta_j)^2} \, \mathrm{d}t \le \frac{1}{J_j} \longrightarrow 0.$$

Every point of U has a coordinate neighborhood V as in Proposition 11.4.2, since F is continuous. By (11.29), therefore, $\mathrm{d}(p_j(w)) \to 0$ in $L^1_{\mathrm{loc}}(U)$. The bounded functions $p_j(w)$ converge pointwise and in L^1_{loc} to $\mathbf{1}_{\{w>a\}}$, whose distributional gradient therefore vanishes on U. Since U is connected, this indicator function is almost everywhere constant on U. As w is nonconstant, $\{w > a\}$ is a nonempty open set, and its intersection with the dense open set U is nonempty and open; hence the constant is one. Thus $\{w = a\} \cap U$ has zero volume, and since $F = 0$ off U, the first assertion follows. Applying the argument to $-w$ gives the assertion for the maximum set. □

11.4.2 Concentrating smooth test potentials

The next proposition produces smooth test potentials whose Monge–Ampère density dominates a fixed multiple of a prescribed function g, with a constant independent of $\sup_X g$ and of the derivatives of g. This uniformity allows the test densities to concentrate near a set of measure zero.

Proposition 11.4.3 *For every $B_0 > \|1\|_{L^2(\omega^n)}$ there is $\varepsilon = \varepsilon(X, \omega, B_0) > 0$ such that every smooth function $g \geq 1$ with $\|g\|_{L^2(\omega^n)} \leq B_0$ admits a smooth strictly ω-plurisubharmonic function q satisfying*

$$\omega_q^n \geq \varepsilon g \omega^n. \tag{11.32}$$

Proof Choose finitely many coordinate balls $B_j = \{|z_j| < R_j\}$, with closures in their charts, such that the concentric smaller balls $\{|z_j| < r_j\}$ cover X. On B_j, let ψ_j solve the Dirichlet problem

$$(\mathrm{dd^c}\psi_j)^n = g\omega^n, \qquad \psi_j|_{\partial B_j} = 0. \tag{11.33}$$

The density of $g\omega^n$ with respect to coordinate volume is smooth and strictly positive. The classical smooth Dirichlet theorem therefore applies, since $C_j(|z_j|^2 - R_j^2)$ is a smooth strict subsolution with zero boundary values for sufficiently large $C_j > 0$. Thus ψ_j is smooth and strictly plurisubharmonic on $\overline{B}_j$, and the maximum principle gives $\psi_j \leq 0$.

We need a lower bound for ψ_j independent of $\sup_X g$. Write the coordinate equation as $\det(\partial_a \bar\partial_b \psi_j) = D_j$, and put $M_j = -\min_{B_j} \psi_j$. Let x_j be a minimum point. For each real slope p with $|p| < M_j/(2R_j)$, the function $\psi_j - p \cdot (x - x_j)$ attains its minimum at an interior point, because its value at x_j is $-M_j$, while its boundary values are larger than $-M_j$. At such a contact point the real Hessian S of ψ_j is nonnegative, and the gradient of ψ_j maps the contact set onto the ball of these slopes. The area formula and the matrix inequality

$$\det_{\mathbb{R}} S \leq 4^n \big(\det_{\mathbb{C}}(\partial_a \bar\partial_b \psi_j)\big)^2 = 4^n D_j^2$$

therefore give $M_j \leq C(n, R_j)\|D_j\|_{L^2(B_j)}^{1/n}$. To prove the matrix inequality, let J be the standard complex structure on the real coordinate space and average S with $J^{\mathsf{T}} S J$. Concavity of log det, and the fact that the eigenvalues of this J-invariant average occur in pairs, give the displayed factor; singular matrices are handled by approximation. Since the ratio of ω^n to coordinate volume is fixed and bounded, $\|D_j\|_2$ is controlled by B_0. Consequently

$$-M_0 \leq \psi_j \leq 0 \quad \text{on every } B_j, \tag{11.34}$$

where M_0 depends only on X, ω, B_0 and the chosen finite cover.

Next we glue the local solutions. Put $\beta_j = \mathrm{dd^c}|z_j|^2$. Choose $a_j > 0$ such that $a_j \beta_j \leq \omega/2$ on B_j, and let $t_j = (R_j^2 + r_j^2)/2$. Fix $\tau > 0$ so small that

$\tau M_0 < a_j(R_j^2 - r_j^2)/4$ for every j. The smooth function

$$s_j = \tau\psi_j + a_j(t_j - |z_j|^2)$$

is bounded below by a fixed positive constant on the smaller ball, negative on a collar of ∂B_j, and satisfies $\omega_{s_j} \geq \omega/2 + \tau dd^c\psi_j$. Choose a smooth convex function $\phi_j : \mathbb{R} \to \mathbb{R}$ approximating $s \mapsto \max(s, 0)$, equal to zero below a small negative threshold and to s above the corresponding positive threshold, with $0 \leq \phi_j' \leq 1$ and $\phi_j'' \geq 0$; the thresholds are chosen smaller in absolute value than both margins of s_j. Set $Q_j = \phi_j(s_j)$ on B_j and extend it by zero. This extension is smooth, and

$$\omega_{Q_j} = \phi_j'(s_j)\omega_{s_j} + \big(1 - \phi_j'(s_j)\big)\omega + \phi_j''(s_j)\, ds_j \wedge d^c s_j \geq \omega/2.$$

On the smaller ball, $Q_j = s_j$ and $\omega_{Q_j} \geq \tau dd^c\psi_j$. If N is the number of balls, put $q = N^{-1}\sum_j Q_j$. Then $\omega_q = N^{-1}\sum_j \omega_{Q_j} \geq \omega/2$ everywhere. Each point belongs to at least one smaller ball $\{|z_j| < r_j\}$, so positivity of the other summands and (11.33) give

$$\omega_q^n \geq (\tau/N)^n (dd^c\psi_j)^n = (\tau/N)^n g\omega^n.$$

Thus (11.32) holds with $\varepsilon = (\tau/N)^n$, independent of $\sup g$ and of all derivatives of g. □

Proof (of Theorem 11.4.1) By Corollary 10.4.1, u, v are continuous. In dimension one, $dd^c w = 0$, so the maximum principle makes w constant. Assume $n \geq 2$.

Suppose that $w = u - v$ is nonconstant. Let $a = \min_X w$, $K = \{w = a\}$, and $\mu = F\omega^n$. By Lemma 11.4.1, $\mu(K) = 0$. Choose $B_0 > \|1\|_{L^2(\omega^n)}$ and let $\varepsilon > 0$ be the constant from Proposition 11.4.3. Since $\mu(K) = 0$, the compact set $K_0 = K \cap \{F \geq \varepsilon/2\}$ has zero ω^n-volume. Fix $A > 1$ with $\varepsilon A > \max_X F$. By outer regularity of the smooth volume measure, choose an open neighborhood O of K_0 so small that

$$\int_X \omega^n + (A^2 - 1)\int_O \omega^n < B_0^2.$$

Take a smooth $0 \leq \chi \leq 1$ equal to one near K_0 and supported in O, and set $g = 1 + (A - 1)\chi$. If $K_0 = \varnothing$, take $\chi = 0$. Then $g \geq 1$, $g = A$ on K_0, and $\|g\|_{L^2(\omega^n)} < B_0$.

By Proposition 11.4.3, there is a smooth strictly ω-plurisubharmonic q with $\omega_q^n = G\omega^n \geq \varepsilon g\omega^n$. On K_0 we have $G \geq \varepsilon A > F$; on $K \setminus K_0$ we have $F < \varepsilon/2 < \varepsilon \leq G$. Thus $G > F$ throughout the compact set K. By compactness and continuity, we can choose $0 < \kappa < 1$ such that $F < \kappa G$ on K; put $W = \{F < \kappa G\}$. The complement of this open neighborhood of K is compact, and $w - a$ has a strictly positive minimum there if it is nonempty. Hence some $\eta > 0$ satisfies $\{w < a + \eta\} \subset W$.

Proposition 11.4.1 asserts that $\mu(\{w < a + \eta\} \cap \{F > \kappa G\}) > 0$. By the preceding inclusion, however, this set is empty. This contradiction shows that w is constant. If $\sup_X u = \sup_X v$, the constant is zero. □

For a bounded measurable density, a positive lower bound gives the same conclusion. In this case coercivity holds on all of X, and the concentrating test potential can dominate the essential upper bound of the density on a whole neighborhood of the extremal set.

Corollary 11.4.1 *If $0 < c_0 \le F \le C_0 < \infty$ almost everywhere and bounded ω-plurisubharmonic functions satisfy $\omega_u^n = \omega_v^n = F\omega^n$, then $u - v$ is constant.*

Proof The functions u, v are continuous by Corollary 10.4.1, and in dimension one the assertion follows from $\mathrm{dd}^{\mathrm{c}}(u - v) = 0$ and the maximum principle. Let $n \ge 2$, suppose that $w = u - v$ is nonconstant, and put $K = \{w = \min_X w\}$. The proof of Lemma 11.4.1 applies with $U = X$, since Proposition 11.4.2 gives the pushforward identity and local coercivity on every chart. Thus K has zero volume.

Fix $B_0 > \|1\|_{L^2(\omega^n)}$ and the corresponding ε in Proposition 11.4.3. Choose $A > 1$ with $\varepsilon A > C_0$, and a smooth cutoff function χ, equal to one on a neighborhood W of K and supported in an open set of volume so small that $g = 1 + (A - 1)\chi$ satisfies $\|g\|_2 < B_0$. The resulting test potential q has density $G \ge \varepsilon g$. Choose $\kappa < 1$ with $C_0 < \kappa\varepsilon A$. Then $F < \kappa G$ almost everywhere on W. By continuity of w, a sufficiently thin set $\{w < \min_X w + \eta\}$ lies inside W, which contradicts Proposition 11.4.1. Hence w is constant. □

11.5 Comparison and invariant mass

The preceding argument controls the extremal level sets of $u - v$ through connectedness of the set where the density is positive. When the background satisfies the Guan–Li condition below, invariance of the total mass gives the ordinary comparison principle instead. An auxiliary solution whose density is larger on a strict sublevel set of $u - v$ then forces this set to have zero mass for the common Monge–Ampère measure, and the domination principle proves uniqueness.

Set $V = \int_X \omega^n$. The *Guan–Li condition*

$$\mathrm{dd}^{\mathrm{c}}\omega = 0, \qquad \mathrm{dd}^{\mathrm{c}}(\omega^2) = 0 \tag{11.35}$$

is equivalent to invariance of the total mass $\int_X \mathrm{MA}_\omega(u)$ by Lemma 2.1.2 and Theorem 2.2.2. In dimension one it holds automatically, for degree reasons.

Theorem 11.5.1 *Assume* (11.35)*, let* $p > 1$*, and let* $f \geq 0$ *belong to* $L^p(X, \omega^n)$ *with positive integral. Then there is exactly one pair* (c, u)*, with* $c > 0$*,* $u \in \mathrm{PSH}(X, \omega) \cap L^\infty(X)$ *and* $\sup_X u = 0$*, satisfying*

$$(\omega + \mathrm{dd}^c u)^n = c f \omega^n.$$

Moreover

$$c = \frac{\int_X \omega^n}{\int f \omega^n},$$

and u *is continuous. Thus two bounded solutions with the same* L^p *density differ by a constant, without any positive lower bound on* f*.*

We first show that the ordinary comparison principle is equivalent to invariance of the mass.

Theorem 11.5.2 *Condition* (11.35) *holds if and only if every pair of bounded* ω*-plurisubharmonic functions* a, b *satisfies*

$$\int_{\{a<b\}} \mathrm{MA}_\omega(b) \leq \int_{\{a<b\}} \mathrm{MA}_\omega(a). \tag{11.36}$$

For the converse implication, it suffices to require this inequality for smooth potentials.

Proof Under (11.35), Theorem 2.2.2 gives $\int_X \mathrm{MA}_\omega(a) = V$ for every bounded potential a; for $n = 1$ this is Stokes' theorem.

Set $q = \max(a, b)$. On $\{a < b\}$, plurifine locality gives $\mathrm{MA}_\omega(q) = \mathrm{MA}_\omega(b)$. On $\{a \geq b\}$, one has $a = q$, and $a \leq q$ everywhere, so bounded ordered contact (Lemma 1.7.1) gives

$$\mathbf{1}_{\{a \geq b\}} \mathrm{MA}_\omega(a) \leq \mathbf{1}_{\{a \geq b\}} \mathrm{MA}_\omega(q).$$

The total masses of a, b and q all equal V. Hence

$$\int_{\{a<b\}} \mathrm{MA}_\omega(b) = V - \int_{\{a \geq b\}} \mathrm{MA}_\omega(q) \leq V - \int_{\{a \geq b\}} \mathrm{MA}_\omega(a) = \int_{\{a<b\}} \mathrm{MA}_\omega(a),$$

which is (11.36).

Conversely, comparison for smooth potentials implies that all smooth potentials have the same mass: given a smooth pair a, b, add to b a constant so large that $\{a < b\} = X$, apply (11.36), and then interchange the roles of a and b. Comparison with the zero potential shows that the common mass is V. By Theorem 2.2.2 and Lemma 2.1.2, this implies (11.35) when $n \geq 2$; for $n = 1$ that condition holds for degree reasons. □

For the uniqueness argument we need, in addition to comparison, auxiliary solutions and the mixed inequality (1.12). The auxiliary solutions come from continuous existence: if $G \geq 0$ lies in $L^p(X, \omega^n)$ and $\int_X G\omega^n = V$, Theorem 10.1.1 gives

a continuous solution of $\mathrm{MA}_\omega(\rho) = cG\omega^n$ with a constant $c > 0$, and since all bounded potentials have mass V, this constant equals one. Thus

$$\mathrm{MA}_\omega(\rho) = G\omega^n \tag{11.37}$$

has a continuous solution ρ for every such G, in particular for the density with an indicator factor used below.

Proof (of Theorem 11.5.1) We use the domination principle in the form of the case $c = 0$ of Theorem 10.2.2: if $\mathrm{MA}_\omega(a)(\{a < b\}) = 0$ for bounded ω-plurisubharmonic functions a, b, then $a \geq b$.

We first prove that two bounded solutions u, v of $\mathrm{MA}_\omega(u) = \mathrm{MA}_\omega(v) = \mu = F\omega^n$, with $F \in L^p$, $p > 1$, differ by a constant. The mass identity gives $\mu(X) = V$. If $u - v$ is nonconstant, add a constant to u so that $u - v$ has supremum $s > 0$ and infimum $-s$. Since $\{v < u\}$ and $\{u < v\}$ are disjoint, after interchanging u and v if necessary, the set $S = \{v < u\}$ satisfies $\mu(S) \leq V/2$. Define

$$b_0 = \frac{V - 2\mu(S)}{V} \geq 0, \qquad G = 2F\mathbf{1}_S + b_0.$$

This nonnegative L^p function has total integral V, so we can choose a continuous solution ρ of (11.37). Take C_0 with $\rho - C_0 \leq u$, and set

$$q_\delta = (1 - \delta)u + \delta(\rho - C_0), \qquad E_\delta = \{v < q_\delta\} \subset S, \qquad 0 < \delta < 1.$$

Since $G \geq 2F$ on S, the mixed inequality (1.12) gives, on S,

$$\mathrm{MA}_\omega(q_\delta) \geq \left((1 - \delta) + \delta 2^{1/n}\right)^n \mu =: A_\delta \mu, \qquad A_\delta > 1. \tag{11.38}$$

Ordinary comparison (11.36), applied to the pair v, q_δ, yields

$$A_\delta \mu(E_\delta) \leq \int_{E_\delta} \mathrm{MA}_\omega(q_\delta) \leq \int_{E_\delta} \mathrm{MA}_\omega(v) = \mu(E_\delta).$$

Thus $\mu(E_\delta) = 0$, that is, $\mathrm{MA}_\omega(v)(\{v < q_\delta\}) = 0$. Bounded domination gives $v \geq q_\delta$ everywhere, and letting $\delta \downarrow 0$ gives $v \geq u$, which contradicts $\sup_X(u - v) = s > 0$. Therefore $u - v$ is constant. The argument never divides by F, so F may vanish on an open set.

Finally, for the density f in the theorem, put $I = \int_X f\omega^n > 0$ and $c = V/I$. By (11.37) with $G = cf$, there is a continuous solution, which we normalize by subtracting its supremum. Any other bounded solution, with constant c', satisfies $V = c'I$ by mass invariance, hence $c' = c$; the uniqueness just proved and the common normalization then identify the potentials. In particular, every bounded solution with this L^p density is continuous, although continuity was not assumed. □

Remark 11.5.1 Theorem 11.5.2 is an equivalence between a differential condition, the comparison principle and mass invariance. It is not an equivalence between the Guan–Li condition and uniqueness: the other criteria in this chapter apply without

that condition on the background. On the other hand, imposing the Guan–Li condition on an auxiliary metric rather than on ω does not give (11.36) for MA_ω.

11.6 Smooth nonuniqueness for a degenerate density

The first example places the freedom in the potential inside an open region where the density vanishes. Three independent semipositive forms of rank one reduce equality of the Monge–Ampère measures to equality of products of three scalar coefficients. We construct two semipositive forms with the same cube, and then add the same exact correction to both to obtain a strictly positive background.

In this section and the following ones, $X = \mathbb{P}(\mathbb{C}^2 \oplus \mathbb{C}^2) = \mathbb{P}^3$, with block homogeneous coordinates $[A : B]$, where $A, B \in \mathbb{C}^2$, and ω_X is its Fubini–Study form. Here A and B denote coordinates, not the forms of (11.1); the two solution forms will be written A_0 and B_0.

Theorem 11.6.1 *On $X = \mathbb{P}^3$ there exist a smooth Hermitian form ω with $\mathrm{d}\omega \neq 0$, a smooth nonnegative nonzero function f, and distinct smooth functions $u, v \in \mathrm{PSH}(X, \omega)$ such that*

$$\sup_X u = \sup_X v = 0, \qquad (\omega + \mathrm{dd^c} u)^3 = f\omega_X^3 = (\omega + \mathrm{dd^c} v)^3.$$

The density vanishes on a nonempty open set, and both potentials have minimal singularities.

11.6.1 Three rank-one directions

On $U = \{A \neq 0, B \neq 0\}$ put

$$r = \log \frac{|A|^2}{|B|^2}, \qquad P = \mathrm{dd^c} \log |A|^2, \quad Q = \mathrm{dd^c} \log |B|^2, \quad R = \mathrm{d}r \wedge \mathrm{d^c} r.$$

The logarithms are computed in a local homogeneous lift, but their Hessians do not depend on the lift. The forms P, Q are pullbacks of Fubini–Study forms from the two projective lines $\mathbb{P}(\mathbb{C}^2)$. All three forms are semipositive of rank one, and

$$P^2 = Q^2 = R^2 = 0, \qquad P \wedge Q \wedge R > 0. \tag{11.39}$$

Indeed, in local coordinates $A = (1, a)$ and $B = \tau(1, b)$, P and Q are positive multiples of $\mathrm{i}\,\mathrm{d}a \wedge \mathrm{d}\bar{a}$ and $\mathrm{i}\,\mathrm{d}b \wedge \mathrm{d}\bar{b}$, while

$$\partial r = \frac{\bar{a}\,\mathrm{d}a}{1 + |a|^2} - \frac{\mathrm{d}\tau}{\tau} - \frac{\bar{b}\,\mathrm{d}b}{1 + |b|^2}.$$

Its $\mathrm{d}\tau$ component is nonzero, so the three rank-one forms correspond to independent directions. In particular, for nonnegative x, y, z,

$$(xP + yQ + zR)^3 = 6xyz\, P \wedge Q \wedge R, \tag{11.40}$$

and the form is positive exactly when all three coefficients are positive.

Since $\mathrm{dd^c} r = P - Q$, the chain rule gives, for a smooth function $G : \mathbb{R} \to \mathbb{R}$,

$$\mathrm{dd^c} G(r) = G'(r)(P - Q) + G''(r)R. \tag{11.41}$$

Let $\sigma(r) = \mathrm{e}^r/(1 + \mathrm{e}^r)$. Since $\log(|A|^2 + |B|^2) = \log|B|^2 + \log(1 + \mathrm{e}^r)$, we have

$$\omega_X = \sigma(r)P + \sigma(-r)Q + \sigma'(r)R. \tag{11.42}$$

A function of r that is constant near each end of $\mathbb{R}$ extends smoothly across $X \setminus U$. A form $xP + yQ + zR$ whose coefficients equal those of (11.42) for $|r| \geq 2$ extends smoothly by ω_X across $X \setminus U$.

11.6.2 The scalar coefficients

On the central interval $-1 \leq r \leq 1$, the coefficients will make a different rank-one factor vanish in each of the two solution forms. Outside a larger interval they coincide with the Fubini–Study coefficients, so the resulting forms extend across the omitted projective lines. Primes denote derivatives with respect to r.

Choose an even smooth function β supported in $[-1, 1]$, strictly positive on $(-1, 1)$, with $\beta' > 0$ on $(-1, 0)$, and normalized by $\int_{-1}^{1} \beta = 2$; for instance, a positive multiple of $\exp(-1/(1 - r^2))$ on $(-1, 1)$, extended by zero. Define

$$F(r) = -1 + \int_{-1}^{r} \beta(t)\,\mathrm{d}t \quad (-1 < r < 1), \qquad F = -1 \ (r \leq -1), \quad F = 1 \ (r \geq 1),$$

and put $p = \beta/2$, $q = \beta'/2$. Then F is smooth and odd, p is even, and q is odd, positive on $(-1, 0)$ and negative on $(0, 1)$. Both p and q vanish to infinite order at the endpoints.

Take smooth $a \geq 0$ with $a = 1$ on $(-\infty, -2/3]$ and $a = 0$ on $[-1/3, \infty)$, and put $b(r) = a(-r)$. Choose an even nonnegative $\chi \in C_c^\infty((-1/3, 1/3))$ with $\chi(0) > 0$. On $[-1, 1]$ set

$$z_0 = (q^2 + \chi^2)^{1/2}.$$

It is smooth: the expression under the square root is positive in the interior, and near each endpoint $z_0 = |q|$, where q has a fixed sign. It is positive in the interior and vanishes to infinite order at the endpoints. Also,

$$z_0 \geq |q|, \qquad a(z_0 - q) = 0, \qquad b(z_0 + q) = 0. \tag{11.43}$$

The first cancellation holds because $\chi = 0$ on the support of a and $q \geq 0$ there; the second follows by reflection.

On $(-\infty, -1]$ choose smooth functions ℓ, s such that $0 \leq \ell \leq 1$, $\ell = 0$ on $(-\infty, -2]$, $\ell = 1$ on $[-3/2, -1]$, while $s > 0$ for $r < -1$, $s = 1$ on $(-\infty, -3/2]$, and s vanishes to infinite order at -1. Such functions are easily obtained from smooth cutoff functions and a function like $\exp(-1/(r+1)^2)$. Define

$$\begin{aligned} &x = (1-\ell)\sigma + \ell, \quad y = (1-\ell)\sigma(-r) + \ell s, \quad z = (1-\ell)\sigma' + \ell s \quad (r \leq -1), \\ &x = p + a, \qquad\qquad y = p + b, \qquad\qquad z = z_0 \qquad\qquad (-1 \leq r \leq 1), \end{aligned}$$

and for $r \geq 1$ use $x(r) = y(-r)$, $y(r) = x(-r)$, $z(r) = z(-r)$.

The definitions join smoothly: at -1 both definitions give the values $(1, 0, 0)$, and their differences vanish to infinite order there, since $a = 1$ and $b = 0$ near -1. The central definitions are symmetric under reflection, so the same holds at 1. We have

$$x, y, z > 0 \quad \text{for } r \neq \pm 1, \qquad (x, y, z)(-1) = (1, 0, 0), \quad (x, y, z)(1) = (0, 1, 0).$$

For $|r| \geq 2$ their values are $(\sigma(r), \sigma(-r), \sigma'(r))$.

11.6.3 Two forms with the same cube

The cancellation identities now turn the scalar coefficients into two semipositive forms with the same cube. Their average is strictly positive except at the two ends of the central interval.

By the extensions described above, the form and the function

$$\omega_0 = x(r)P + y(r)Q + z(r)R, \qquad w = F(r)$$

are smooth on X. The form is semipositive, and positive except on the hypersurfaces $M_- = \{r = -1\}$ and $M_+ = \{r = 1\}$. Put

$$H = \tfrac{1}{2} \mathrm{dd^c} w = p(P - Q) + qR, \qquad A_0 = \omega_0 - H, \quad B_0 = \omega_0 + H.$$

For $|r| \geq 1$ we have $H = 0$. On $|r| < 1$,

$$A_0 = aP + (2p + b)Q + (z_0 - q)R, \qquad B_0 = (2p + a)P + bQ + (z_0 + q)R.$$

All coefficients are nonnegative, and by (11.40) and (11.43), $A_0^3 = B_0^3 = 0$ on this band. Outside it both cubes equal ω_0^3. Thus A_0, B_0 are smooth semipositive forms on X with equal cubes. This common top-degree form vanishes on the closed band $|r| \leq 1$ and is positive on its complement, including near $X \setminus U$.

11.6.4 Restoring strict positivity of the background

The forms A_0, B_0 already have the required common measure. We obtain a Hermitian background by adding an exact correction $\mathrm{dd^c}\rho$ to their average ω_0 and subtracting ρ from both potentials. The correction must restore positivity at $M_\pm$ while preserving it in the transition regions.

Take $\kappa \in C_c^\infty((-2,2))$, equal to one on $[-3/2, 3/2]$. For a parameter $\varepsilon > 0$ to be chosen, set

$$\rho(r) = \varepsilon(r^2 - 1)\kappa(r), \qquad \omega = \omega_0 + \mathrm{dd^c}\rho.$$

By (11.41), its coefficients on U are $x + \rho'$, $y - \rho'$ and $z + \rho''$. On $[-3/2, 3/2]$ one has $\rho' = 2\varepsilon r$ and $\rho'' = 2\varepsilon$, so the last coefficient is positive there. For $r \geq 0$, $x + 2\varepsilon r$ is positive, including at $r = 0$ since $x(0) = p(0) > 0$. On $[-3/2, 0]$, the function x has a positive minimum m, so $x + 2\varepsilon r \geq m - 3\varepsilon > 0$ for small ε. Reflection gives the corresponding estimate for $y - 2\varepsilon r$. On the compact region $3/2 \leq |r| \leq 2$, all three original coefficients have a positive minimum and the perturbations are $O(\varepsilon)$. For $|r| \geq 2$ and near $X \setminus U$, the form is exactly ω_X. Hence ω is strictly positive on X for sufficiently small $\varepsilon > 0$.

The form ω is not closed. Indeed, since $\mathrm{d}R = -\mathrm{d}r \wedge (P - Q)$,

$$\mathrm{d}\omega = \mathrm{d}\omega_0 = \mathrm{d}r \wedge \big((x' - z)P + (y' + z)Q\big). \tag{11.44}$$

At $r = 0$, $x' = y' = 0$ and $z = \chi(0) > 0$. Hence $\mathrm{d}\omega = z\,\mathrm{d}r \wedge (Q - P) \neq 0$ there. The nonzero $\mathrm{d}\tau$ component used in (11.39) also shows that $\mathrm{d}r \wedge P$ and $\mathrm{d}r \wedge Q$ are linearly independent.

Proof (of Theorem 11.6.1) Set $\widetilde{u} = -w/2 - \rho$ and $\widetilde{v} = w/2 - \rho$. Since $\mathrm{dd^c}w = 2H$, the construction gives

$$\omega + \mathrm{dd^c}\widetilde{u} = A_0 \geq 0, \qquad \omega + \mathrm{dd^c}\widetilde{v} = B_0 \geq 0.$$

Subtracting their respective suprema gives u, v. Their Hessians are unchanged, and $v - u = w +$ constant is nonconstant. The function $f = A_0^3/\omega_X^3 = B_0^3/\omega_X^3$ is smooth, nonnegative and nonzero, and it vanishes on the nonempty open band $|r| < 1$. Both potentials are smooth, hence bounded, so they have minimal singularities: for a Hermitian background, the envelope V_ω of Section 1.19 is zero. □

Every Hermitian background on $\mathbb{P}^3$ has the bounded mass property of Definition 6.5.1: since the Fubini–Study form is closed, Stokes' theorem for bounded potentials shows that all its bounded potentials have the same mass, and Proposition 6.5.1 shows that the property does not depend on the metric. This applies to all the backgrounds on $\mathbb{P}^3$ constructed below.

The linearized equation also explains why the maximum principle argument fails. The form

$$T = A_0^2 + A_0 \wedge B_0 + B_0^2$$

satisfies $\mathrm{dd}^c w \wedge T = B_0^3 - A_0^3 = 0$, but $T = 0$ on $M_\pm$, where $A_0 = B_0 = \omega_0$ has rank one. Thus the linear equation for w is not elliptic everywhere, even though both potentials and their common density are smooth.

11.6.5 A continuum of radial solutions

The open band where the density vanishes allows more solutions than the two smooth ones constructed above. Writing a further potential as $G(r) - \rho$, with G a function of one real variable, reduces the equation on the band to choosing the slope G' so that one of the three coefficients vanishes. Switching the vanishing coefficient at two suitable levels produces a continuum of $C^{1,1}$ solutions for the same background ω and density f.

Recall that $q = p'$ and $z_0 \geq |q|$. The strict inequality $z_0 > |p'|$ near zero, where $\chi > 0$, gives

$$\int_0^1 z_0(r)\,\mathrm{d}r > \int_0^1 |p'(r)|\,\mathrm{d}r = p(0). \tag{11.45}$$

Proposition 11.6.1 *For the smooth background ω and the smooth density f of Theorem 11.6.1, the equation*

$$\mathrm{MA}_\omega(u) = f\omega_X^3$$

has uncountably many distinct $C^{1,1}$ solutions normalized by $\sup_X u = 0$. If the cutoff κ defining ρ is chosen even, one of them, constructed explicitly, is invariant under the block exchange $\iota[A : B] = [B : A]$.

Proof Consider pairs $-1 < I < 0 < J < 1$ satisfying

$$\int_I^J z_0(r)\,\mathrm{d}r = p(I) + p(J). \tag{11.46}$$

We first show that such pairs exist, with I ranging over an interval. Define

$$K(I, J) = \int_I^J z_0(r)\,\mathrm{d}r - p(I) - p(J).$$

We have $K(0, 0) = -2p(0) < 0$ and $K(0, 1) > 0$ by (11.45). By continuity, there is $\epsilon > 0$ such that $K(I, 0) < 0 < K(I, 1)$ for every $I \in [-\epsilon, 0]$. For $0 < J < 1$,

$$\partial_J K(I, J) = z_0(J) - p'(J) > 0.$$

The intermediate value theorem therefore gives a unique $J = J(I) \in (0, 1)$ satisfying (11.46) for every $I \in [-\epsilon, 0)$; we may assume $\epsilon < 1$.

For any pair satisfying (11.46), define the slope on $[-1, 1]$ by

$$h_{I,J}(r) = \begin{cases} p(r), & -1 \le r \le I, \\ p(I) - \displaystyle\int_I^r z_0(s)\,\mathrm{d}s, & I \le r \le J, \\ -p(r), & J \le r \le 1, \end{cases}$$

and extend it by zero outside that interval. The balance identity makes it continuous at J, and continuity at I is immediate. Each piece has bounded derivative, so $h_{I,J}$ is Lipschitz on $\mathbb{R}$; it vanishes to infinite order at ± 1. Let $G_{I,J}$ be a primitive of $h_{I,J}$. It is $C^{1,1}$ and constant near each end of the real line. Consequently $G_{I,J}(r)$ extends to a $C^{1,1}$ function on X that is smooth near $X \setminus U$.

On the middle interval $[I, J]$ the slope lies between $-p$ and p. Indeed,

$$(h_{I,J} - p)' = -z_0 - p' \le 0, \qquad (h_{I,J} + p)' = -z_0 + p' \le 0.$$

The first difference vanishes at I, and the second vanishes at J. Since both are nonincreasing, $h_{I,J} \le p$ and $h_{I,J} \ge -p$ on $[I, J]$.

Put $\widetilde{u}_{I,J} = G_{I,J}(r) - \rho$. By (11.41), almost everywhere on U,

$$\omega + \mathrm{dd^c}\widetilde{u}_{I,J} = \omega_0 + \mathrm{dd^c}G_{I,J}(r) = (x + h_{I,J})P + (y - h_{I,J})Q + (z + h'_{I,J})R. \quad (11.47)$$

On $I < r < J$, the first two coefficients are nonnegative because $x = p + a$, $y = p + b$ and $-p \le h_{I,J} \le p$, and the third is zero. On $-1 < r < I$, we have $h_{I,J} = p$ and $b = 0$, since $I < 0$; so the second coefficient is zero, and the others are nonnegative because $z_0 + p' \ge 0$. On $J < r < 1$, we have $h_{I,J} = -p$ and $a = 0$; so the first coefficient is zero, and the others are nonnegative because $z_0 - p' \ge 0$. Outside the band, $h_{I,J} = h'_{I,J} = 0$, so the form equals ω_0.

Formula (11.47) has no additional term supported on the hypersurfaces $r = I$ and $r = J$: the function $G_{I,J}$ is $C^{1,1}$, so its first derivative is continuous at both transition points, and its distributional Hessian is its bounded almost-everywhere Hessian. The preceding coefficient inequalities therefore prove $\omega + \mathrm{dd^c}\widetilde{u}_{I,J} \ge 0$ as a current.

By Proposition 1.7.2, its Monge–Ampère measure is the pointwise cube of (11.47), computed almost everywhere. By the rank-one identities (11.39) and (11.40), this cube is zero almost everywhere on the band, since one coefficient vanishes there, and it equals ω_0^3 off the band. These are exactly the values of $f\omega_X^3$ in the preceding construction. Thus $\widetilde{u}_{I,J}$ solves the equation, and subtracting its supremum gives a normalized solution $u_{I,J}$.

Different values of $I \in [-\epsilon, 0)$ give different normalized solutions. If $I_1 < I_2 < 0$ and $I_1 < r < I_2$, then the slope belonging to I_2 is $p(r)$, whereas

$$p(r) - h_{I_1,J(I_1)}(r) = \int_{I_1}^r (p'(s) + z_0(s))\,\mathrm{d}s > 0,$$

because $p' > 0$ on $(-1, 0)$. The two primitives therefore do not differ by a constant. Since the interval $[-\epsilon, 0)$ is uncountable, this proves the first assertion. None of these slopes equals p or $-p$ on all of $(-1, 1)$, so the constructed solutions are also distinct from the two smooth solutions of Theorem 11.6.1.

Finally, the function

$$L(t) = \int_0^t z_0(r)\,\mathrm{d}r - p(t), \qquad 0 \le t \le 1,$$

is negative at zero, positive at one, and strictly increasing on $(0, 1)$. Its unique zero t_* gives a symmetric pair $I = -t_*$, $J = t_*$ satisfying (11.46). Since z_0 and p are even, $h_{I,J}$ is odd: on the middle interval it equals $-\int_0^r z_0(s)\,\mathrm{d}s$. Choose its primitive even. Since ι changes r into $-r$, if ρ is even, the potential $G_{I,J}(r) - \rho$ and its normalization are fixed by ι. This proves the last assertion. □

For these symmetric data, the normalized solutions of the equations with a positive exponent converge, as the exponent tends to zero, to the symmetric solution just constructed; see Theorem 14.19.1.

11.7 Nonuniqueness with a zero set of empty interior

We now keep the Hermitian background of Theorem 11.6.1, but change the density so that it is positive off $M_- \cup M_+$, where $M_\pm = \{r = \pm 1\}$. For potentials of the form $G(r) - \rho$, the equation on the middle band becomes a first-order ordinary differential equation for the slope G'. Barriers keep its solutions between the admissible slopes, and infinite-order vanishing at the endpoints then makes their extensions by zero smooth.

Theorem 11.7.1 *There are a smooth nonclosed Hermitian form ω on $\mathbb{P}^3$ and a smooth nonnegative density g, positive off two disjoint smooth real hypersurfaces, such that the equation*

$$\mathrm{MA}_\omega(u) = g\omega_X^3$$

has uncountably many distinct smooth solutions normalized by $\sup_X u = 0$. The background ω has bounded mass.

Thus a zero set with empty interior, even one of measure zero, does not ensure uniqueness of smooth normalized solutions.

We use the coefficients of Section 11.6.2, with the explicit choice

$$p(r) = C\exp\!\left(-\frac{1}{1-r^2}\right), \qquad -1 < r < 1, \qquad \int_{-1}^{1} p(r)\,\mathrm{d}r = 1,$$

extended by zero, where the integral condition determines $C > 0$; then $q = p'$. Fix $0 < s < 1$, and set

$$k_s(r) = (x(r) + sp(r))(y(r) - sp(r))(z(r) + sq(r)).$$

For $|r| > 1$ this is xyz. If $G' = sp$, then the potential $G(r) - \rho$ has $\omega + \mathrm{dd}^{\mathrm{c}}(G(r) - \rho) = \omega_0 + sH$. This form is strictly positive for $-1 < r < 1$, since

$$x + sp = a + (1+s)p > 0, \quad y - sp = b + (1-s)p > 0, \quad z_0 + sq \geq (1-s)z_0 > 0.$$

It is also strictly positive outside the closed band, and at $r = \pm 1$ it equals the rank-one form ω_0. Consequently

$$g\omega_X^3 = (\omega_0 + sH)^3 \tag{11.48}$$

defines a smooth density g that is positive exactly off $M_- \cup M_+$. These hypersurfaces have measure zero and empty interior. On the band $|r| < 1$, a potential $G(r) - \rho$ with slope $h = G'$ solves the equation exactly when $(x + h)(y - h)(z + h') = k_s$, which is the differential equation (11.49) below.

Lemma 11.7.1 *There exists $\eta_0 > 0$ such that for every $0 < \eta < \eta_0$ the initial-value problem*

$$h' = \frac{k_s(r)}{(x(r) + h)(y(r) - h)} - z(r), \qquad h(0) = sp(0) - \eta, \tag{11.49}$$

has a smooth solution on $(-1, 1)$ with $-x < h < y$ and $h < sp$. Moreover, on some fixed endpoint neighborhoods there are constants $0 < c_L < s < t < 1$, independent of η, such that

$$c_L p < h < sp \quad \textit{near } -1, \qquad -tp < h < sp \quad \textit{near } 1.$$

Proof The function $h_s = sp$ solves (11.49) and lies strictly between $-x$ and y throughout $(-1, 1)$. Write $F_s(r, h)$ for the right-hand side of the equation, which is smooth on the open domain $-x(r) < h < y(r)$.

Near -1 the coefficients are exactly

$$x = 1 + p, \qquad y = p, \qquad z = q > 0.$$

For a constant $c \in (-1, 1)$, the product of coefficients for the trial slope cp is

$$k_c = (1 - c^2)\big(1 + (1 + c)p\big)pq.$$

Fix $c_L \in (0, s)$. At $p = 0$, the factor preceding pq for $c = c_L$ exceeds that for $c = s$ by $s^2 - c_L^2 > 0$. Thus, on a sufficiently small fixed neighborhood of the left endpoint,

$k_{c_L} > k_s$ and

$$F_s(r, c_L p) - (c_L p)' = \frac{k_s - k_{c_L}}{(x + c_L p)(y - c_L p)} < 0. \tag{11.50}$$

Thus $c_L p$ is a lower barrier when the equation is solved backward, that is, toward -1.

Near 1 the exact coefficients are

$$x = p, \qquad y = 1 + p, \qquad z = -q > 0,$$

and the trial slope cp has product of coefficients

$$k_c = (1 - c^2)\big(1 + (1 - c)p\big)p(-q).$$

Fix $s < t < 1$. At $p = 0$, the factor for $c = s$ exceeds that for $c = -t$ by $t^2 - s^2 > 0$. On a sufficiently small fixed neighborhood of the right endpoint, therefore, $k_s > k_{-t}$, so

$$F_s(r, -tp) - (-tp)' = \frac{k_s - k_{-t}}{(x - tp)(y + tp)} > 0. \tag{11.51}$$

Thus $-tp$ is a lower barrier when the equation is solved forward, toward 1.

Choose $r_L < 0 < r_R$ in these respective neighborhoods. The graph of h_s over $[r_L, r_R]$ is a compact subset of the domain of F_s. Existence and continuous dependence on initial values for smooth ordinary differential equations therefore give $\eta_0 > 0$ such that, for every $0 < \eta < \eta_0$, the solution with initial value $sp(0) - \eta$ exists on $[r_L, r_R]$, stays in the domain, and satisfies

$$h(r_L) > c_L p(r_L), \qquad h(r_R) > -tp(r_R).$$

By local uniqueness, two solutions of the equation cannot cross. Since $h(0) < h_s(0)$, we have $h < h_s$ wherever h exists.

Follow the solution backwards from r_L; it cannot cross $c_L p$. Indeed, at a first crossing point the difference $h - c_L p$ would vanish and be positive immediately to its right, so its derivative there would be nonnegative, whereas (11.50) shows that this derivative is strictly negative. Thus $c_L p < h < sp$ on the part of the interval of existence to the left of r_L. Likewise, (11.51) prevents a first downward crossing of $-tp$ to the right of r_R, giving $-tp < h < sp$ there.

These bounds also show that the maximal interval of existence is all of $(-1, 1)$. Indeed, near a possible endpoint inside $(-1, 1)$, the factors $x + h$ and $y - h$ stay bounded away from zero, so the graph of h stays in a compact subset of the domain of F_s, and the continuation theorem for ordinary differential equations extends the solution beyond that endpoint. Hence the solution exists on $(-1, 1)$ and satisfies the claimed bounds. □

Lemma 11.7.2 *Every solution furnished by Lemma 11.7.1, extended by zero outside* $(-1,1)$*, is smooth on* $\mathbb{R}$ *and vanishes to infinite order at* ± 1.

Proof Let h be one of the solutions in Lemma 11.7.1. On either endpoint neighborhood put $\xi = h/p$; since $p > 0$ on $(-1,1)$, this quotient is smooth there, and the trapping bounds place ξ in a fixed compact subinterval of $(-1,1)$. Define the rational functions

$$R_L(p,\xi) = \frac{(1-s^2)(1+(1+s)p)}{(1+(1+\xi)p)(1-\xi)} - 1,$$

$$R_R(p,\xi) = 1 - \frac{(1-s^2)(1+(1-s)p)}{(1+\xi)(1+(1-\xi)p)}.$$

The explicit formulas for the coefficients near the endpoints give

$$h' = q\,R_L(p,\xi) \quad \text{on the left,} \qquad h' = q\,R_R(p,\xi) \quad \text{on the right.}$$

Both rational functions are smooth, with all derivatives bounded, on a neighborhood of the relevant set of pairs (p,ξ) with $p \geq 0$ small and ξ in the compact interval above. Writing $R_{L/R}$ for the function corresponding to the endpoint under consideration, we obtain from $h' = p'\xi + p\xi'$ and $q = p'$

$$\xi' = \frac{p'}{p}\big(R_{L/R}(p,\xi) - \xi\big). \tag{11.52}$$

For the chosen bump,

$$\frac{p'}{p} = -\frac{2r}{(1-r^2)^2}.$$

This rational function and each of its derivatives grow at most like a power of the inverse distance to the endpoint. Moreover, each derivative of p is p times a rational function with the same property.

An induction using (11.52) shows that every derivative $\xi^{(j)}$ grows at most polynomially in the inverse distance to the endpoint. The case $j = 0$ is the trapping bound on ξ. For the induction step, differentiate the right-hand side of (11.52), including its term $-\xi$, j times. Every resulting term is a product of a derivative of p'/p, a bounded partial derivative of $R_{L/R}$, and derivatives of p and of ξ of order at most j. All of these factors have polynomial bounds, by the induction hypothesis for the derivatives of ξ and since every derivative of p is bounded. This gives the bound for $\xi^{(j+1)}$.

Leibniz' rule for $h = p\xi$ now gives, for each j, constants C_j, N_j such that

$$|h^{(j)}(r)| \leq C_j\,p(r)\,(1-|r|)^{-N_j}$$

near the endpoints. The right-hand side tends to zero at the endpoints, because p decays exponentially in the inverse distance to the endpoint. Thus all derivatives of h tend to zero at ± 1. Extend each derivative by zero outside $(-1,1)$. By the mean value theorem, the difference quotient of $h^{(j)}$ at an endpoint tends to the limit of $h^{(j+1)}$,

which is zero. Hence these extensions are the successive derivatives of the extension of h, which is therefore smooth and vanishes to infinite order at ± 1. □

Proof (of Theorem 11.7.1) Let η_0 be as in Lemma 11.7.1, and for $0 < \eta < \eta_0$ denote by h_η the solution with initial value $sp(0) - \eta$. Extend h_η by zero, which gives a smooth function by the preceding lemma, and take a primitive G_η. It is constant near each end of the real line, so $G_\eta(r)$ extends smoothly to all of $\mathbb{P}^3$, including the two omitted projective lines. Set

$$\widetilde{u}_\eta = G_\eta(r) - \rho.$$

On the open band,

$$\omega + \mathrm{dd}^c \widetilde{u}_\eta = (x + h_\eta)P + (y - h_\eta)Q + (z + h'_\eta)R.$$

The coefficients of P and Q are strictly positive by Lemma 11.7.1, while the equation gives

$$z + h'_\eta = \frac{k_s}{(x + h_\eta)(y - h_\eta)} > 0.$$

Outside the band the form is ω_0, and on the two boundary hypersurfaces it is also the rank-one form ω_0, since h_η vanishes to infinite order there. It is therefore semipositive on X, and by (11.40) its cube equals $6k_s P \wedge Q \wedge R = (\omega_0 + sH)^3$ on the band and $\omega_0^3 = (\omega_0 + sH)^3$ elsewhere. Thus its cube is everywhere the measure $g\omega_X^3$ of (11.48). Finally, normalize by subtracting $\sup_X \widetilde{u}_\eta$.

Distinct values of η give different slopes at $r = 0$, so the corresponding potentials do not differ by a constant, and their normalized versions are distinct. This gives an uncountable family. The background is that of Theorem 11.6.1, so it has bounded mass. □

The density vanishes to infinite order on the two hypersurfaces. Their complement has three components, and on each of the two outer components, two different solutions differ by a constant, with different constants on the two components. The differential equation on the middle component joins these constants smoothly across the degenerate hypersurfaces. This is why ellipticity at every point of the positive-density set does not give a maximum principle argument across its boundary.

11.8 Quadratic density zeros

Infinite-order vanishing of the density is not needed for smooth nonuniqueness. We change the coefficients of ω_0 so that its coefficient of R stays positive and one of its coefficients of P and Q vanishes quadratically at each of the two hypersurfaces $M_\pm$. The resulting singular differential equation forces the slopes of differences of solutions to decay like $\exp(-A/d)$, where d is the distance to the hypersurface and $A > 0$. The slopes therefore extend smoothly by zero, even though the density vanishes only to finite order.

Theorem 11.8.1 *On $\mathbb{P}^3$ there exist a smooth nonclosed Hermitian form ω and a smooth nonnegative density g such that:*

(1) *The zero set of g consists of two disjoint smooth real hypersurfaces. Near either hypersurface, g is the square of a smooth defining function times a smooth strictly positive function.*
(2) *The equation $(\omega + \mathrm{dd^c} u)^3 = g\omega_X^3$ has uncountably many distinct smooth ω-plurisubharmonic solutions normalized by $\sup_X u = 0$.*

The background ω has bounded mass.

We keep the rank-one forms P, Q, R and the function r of Section 11.6.1, and use new scalar coefficients.

Choose a smooth function a valued in $[0,1]$, equal to one for $r \le -2/3$ and zero for $r \ge -1/3$, and put $b(r) = a(-r)$. Choose a smooth even cutoff χ valued in $[0,1]$, zero for $|r| \le 5/4$ and one for $|r| \ge 3/2$. Set $p(r) = (1-r^2)^2$ and

$$\begin{aligned} x &= (1-\chi)(p+a) + \chi\sigma, \\ y &= (1-\chi)(p+b) + \chi(1-\sigma), \\ z &= 1 - \chi + \chi\sigma', \qquad \omega_0 = xP + yQ + zR. \end{aligned} \tag{11.53}$$

Since these coefficients coincide with those of (11.42) for $|r| \ge 3/2$, the form ω_0 extends by ω_X across the two omitted projective lines. The coefficient z is strictly positive, and x, y are strictly positive except that $y(-1) = 0$ and $x(1) = 0$. Thus ω_0 is positive off $M_\pm = \{r = \pm 1\}$ and has rank two there.

Choose a smooth cutoff $\kappa \in C_c^\infty((-2,2))$ equal to one on $[-3/2, 3/2]$. For a parameter $\varepsilon > 0$ to be chosen, define the correction

$$\rho = \varepsilon(r^2 - 1)\kappa(r), \qquad \omega = \omega_0 + \mathrm{dd^c}\rho.$$

For sufficiently small $\varepsilon > 0$, the form ω is strictly positive. Indeed, on $[-3/2, 3/2]$ its coefficients are $x + 2\varepsilon r$, $y - 2\varepsilon r$ and $z + 2\varepsilon$. The first is positive for $r \ge 0$, and on $[-3/2, 0]$ the function x has a positive minimum, so it remains positive for small ε. Reflection gives the positivity of the second coefficient, and that of the third is immediate. On $3/2 \le |r| \le 2$, the form ω_0 is strictly positive on a compact set and the correction is $O(\varepsilon)$. Near the projective ends there is no correction. The form ω is not closed: at $r = 0$, $x' = y' = 0$ and $z = 1$, so by (11.44)

$$\mathrm{d}\omega = \mathrm{d}r \wedge \big((x' - z)P + (y' + z)Q\big) \ne 0.$$

Define the density g by

$$g\omega_X^3 = \omega_0^3.$$

It is smooth and positive exactly off $M_- \cup M_+$. By (11.42) and (11.40), $g = xyz/(\sigma(r)(1-\sigma(r))\sigma'(r))$. Near either hypersurface, $xyz = (1+p)p$, and hence

$$g(r) = \frac{(1+p(r))(1-r^2)^2}{\sigma(r)(1-\sigma(r))\sigma'(r)}.$$

The denominator is smooth and strictly positive at ± 1, and $1 - r^2$ is a defining function for $M_\pm$ near these hypersurfaces. This proves the asserted quadratic vanishing. The potential $-\rho$ is one smooth solution.

Lemma 11.8.1 *For every sufficiently small $\eta > 0$, the equation*

$$h' = \frac{xyz}{(x+h)(y-h)} - z, \qquad h(0) = -\eta \tag{11.54}$$

has a smooth solution on $(-1, 1)$ with $-x < h < y$ and $h < 0$. There are a constant $0 < c < 1$ and fixed neighborhoods of both endpoints, independent of η, on which

$$-cp < h < 0.$$

Every such solution, extended by zero, is a smooth function on $\mathbb{R}$ that vanishes to infinite order at ± 1.

Proof The right-hand side $F(r, h)$ is smooth on $-x < h < y$, and $h = 0$ is a solution. Near -1, $(x, y, z) = (1 + p, p, 1)$; near 1, $(x, y, z) = (p, 1 + p, 1)$. Fix $0 < c < 1$. For the trial function $-cp$, near the left endpoint

$$F(r, -cp) + cp' = \frac{1+p}{(1+(1-c)p)(1+c)} - 1 + cp' \longrightarrow -\frac{c}{1+c} < 0,$$

whereas near the right endpoint

$$F(r, -cp) + cp' = \frac{1+p}{(1-c)(1+(1+c)p)} - 1 + cp' \longrightarrow \frac{c}{1-c} > 0.$$

as $r \to \pm 1$, since $p, p' \to 0$ at both endpoints. The strict inequalities therefore hold on fixed neighborhoods of the endpoints, and $-cp$ is a lower barrier for the equation solved backwards near -1 and forwards near 1.

Choose a compact interval $[r_L, r_R] \ni 0$ with endpoints in those neighborhoods. Continuous dependence on initial values, around the solution $h = 0$, gives $\eta_0 > 0$ such that for every $0 < \eta < \eta_0$ the solution exists on $[r_L, r_R]$, stays in the domain of F, and lies above $-cp$ at r_L and r_R. By uniqueness of solutions, it cannot meet the solution zero, so $h < 0$. The barrier argument used in the proof of Lemma 11.7.1 then gives $-cp < h < 0$ near both ends. On each compact subinterval of $(-1, 1)$ the trapped graph stays at a positive distance from the boundary of the domain of F; hence, by the continuation theorem, the solution exists on all of $(-1, 1)$.

The equation factors as

$$h' = h\, L(r, h), \qquad L(r, h) = \frac{z(x - y + h)}{(x+h)(y-h)}. \tag{11.55}$$

Since $h < 0$, we have $(\log(-h))' = L(r, h)$. Near the left endpoint, the trapping bounds and the explicit coefficients imply

$$L(r,h) = \frac{1+h}{(1+p+h)(p-h)} \geq \frac{C_1}{p}$$

after shrinking that neighborhood, with $C_1 > 0$. Near the right endpoint they give

$$L(r,h) = \frac{-1+h}{(p+h)(1+p-h)} \leq -\frac{C_2}{p}, \qquad C_2 > 0.$$

Indeed, on the left, $1+h \geq 1-cp \geq 1/2$ and the denominator is at most $(1+p)(1+c)p$; on the right, the numerator is at most -1, and the denominator is at most $p(1+(1+c)p)$. Since p is comparable to the square of the distance $d = 1-|r|$ to the endpoint, integrating these inequalities backwards on the left and forwards on the right gives, for some $A > 0$,

$$|h(r)| \leq C\mathrm{e}^{-A/d} \tag{11.56}$$

near either endpoint. The constants may depend on the solution; uniformity in η is not needed for the smooth extension.

It remains to control all derivatives. On the trapped graph, all partial derivatives in (r,h) of the rational function L grow at most polynomially in d^{-1}. Indeed, near an endpoint x, y are polynomials in r, $z = 1$, h is bounded, and of the two factors in the denominator, one is bounded below by a positive constant and the other by $(1-c)p$. Repeated differentiation of the quotient therefore only introduces finite powers of p^{-1}.

Inductively, for every $j \geq 0$ there are constants C_j, N_j with

$$|h^{(j)}(r)| \leq C_j \mathrm{e}^{-A/d} d^{-N_j}.$$

The case $j = 0$ is (11.56). Differentiate $h' = hL(r,h(r))$ j times. Every resulting term is the product of a derivative of the factor h, of order at most j, and a derivative of the composite function $L(r,h(r))$. The latter involves only partial derivatives of L and derivatives of h of order at most j, which are polynomially bounded by the induction hypothesis, while the first factor has the exponential bound. This proves the case $j+1$. All derivatives of h therefore tend to zero at ± 1. Extending them by zero and applying the mean value theorem to the difference quotients at the endpoints, as in Lemma 11.7.2, shows that the extension of h by zero is smooth and vanishes to infinite order at ± 1. □

Proof (of Theorem 11.8.1) Let $\eta_0 > 0$ be such that Lemma 11.8.1 applies for $0 < \eta < \eta_0$, and let h_η denote the solution with $h_\eta(0) = -\eta$. Take a primitive G_η of its extension by zero. Since G_η is constant near each end of the real line, $G_\eta(r)$ defines a smooth function on X. The potential $u_\eta = G_\eta(r) - \rho$ satisfies

$$\omega + \mathrm{dd^c} u_\eta = (x+h_\eta)P + (y-h_\eta)Q + (z+h_\eta')R.$$

Inside the band, the first two coefficients are positive by the lemma, and the equation gives

$$z + h_\eta' = \frac{xyz}{(x+h_\eta)(y-h_\eta)} > 0.$$

Outside the band the form is ω_0, and on the two boundary hypersurfaces it is also the rank-two form ω_0, since h_η vanishes to infinite order there. Thus it is semipositive on X, and by (11.40) its cube is $6xyzP \wedge Q \wedge R = \omega_0^3 = g\omega_X^3$. Different initial values give potentials that do not differ by constants, so after normalization by the supremum we obtain an uncountable family. Bounded mass follows from Proposition 6.5.1, as for Theorem 11.6.1. □

At each of the hypersurfaces $M_\pm$, the difference of two of these solutions agrees to infinite order with a constant, because its derivative is a difference of slopes that vanish to infinite order there. The constants at the two hypersurfaces need not agree. Thus the singular differential equation produces differences that are flat at $M_\pm$, even though the density has only quadratic zeros.

11.9 A real analytic density

The last construction prescribes a globally real analytic density before the background is chosen. The density is a polynomial in a real analytic function on projective space. We first choose a symmetric pair of perturbations, depending only on r, whose determinants equal that density, and then extend the construction across the projective ends by patching coefficients while preserving the determinant. The two hypersurfaces on which the density vanishes quadratically still separate regions where the difference of the two solutions takes different extremal values.

Theorem 11.9.1 *On $X = \mathbb{P}^3$, with block homogeneous coordinates $[A : B]$ and Fubini–Study form ω_X, put*

$$t = \frac{|A|^2}{|A|^2 + |B|^2}, \qquad a = \frac{1}{1+\mathrm{e}}, \qquad b = \frac{\mathrm{e}}{1+\mathrm{e}}, \qquad f_*(t) = (t-a)^2(t-b)^2.$$

There exist a smooth nonclosed Hermitian form ω and distinct smooth ω-plurisubharmonic functions u, v, normalized by $\sup_X u = \sup_X v = 0$, with

$$(\omega + \mathrm{dd^c} u)^3 = (\omega + \mathrm{dd^c} v)^3 = f_*(t)\omega_X^3. \tag{11.57}$$

Both solution forms are positive away from the two connected real analytic hypersurfaces $\{t = a\}$, $\{t = b\}$, and have complex rank two on them. The density is real analytic on X, and it vanishes exactly to second order in the direction transverse to these hypersurfaces. For every $n \geq 4$ the same assertions hold on $\mathbb{P}^3 \times \mathbb{P}^{n-3}$, with the pulled-back density and the product Fubini–Study volume, and with rank $n-1$ on the two product hypersurfaces.

Proof We use the forms P, Q, R and the function r of Section 11.6.1. By (11.40), the construction reduces to finding scalar coefficients with a prescribed product. By (11.42),

$$\omega_X^3 = 6(\sigma')^2 P \wedge Q \wedge R, \qquad \sigma' = \sigma(r)\sigma(-r) > 0. \tag{11.58}$$

11.9.1 Prescribing the determinant

On U, one has $t = \sigma(r)$. We first construct two triples of coefficients, positive on the middle band, with product $f_*(\sigma)(\sigma')^2$. At each endpoint of the band, exactly one of the coefficients of P and Q will vanish.

Put $d_*(r) = f_*(\sigma(r))(\sigma'(r))^2$. Since $a = \sigma(-1)$, $b = \sigma(1)$, define the positive smooth divided differences

$$k_-(r) = \int_0^1 \sigma'(-1 + s(r+1))\,\mathrm{d}s, \qquad k_+(r) = \int_0^1 \sigma'(1 + s(r-1))\,\mathrm{d}s,$$

and $H_*(r) = k_-(r)k_+(r)\sigma'(r) > 0$. The fundamental theorem of calculus gives

$$\sigma(r) - a = (r+1)k_-(r), \quad \sigma(r) - b = (r-1)k_+(r), \quad d_* = (1-r^2)^2 H_*^2. \tag{11.59}$$

These formulas show that H_* is smooth and positive also at the endpoints, without any division by a vanishing function. The symmetry $\sigma(-r) = 1 - \sigma(r)$ makes d_*, and hence H_*, even.

Choose the function

$$p(r) = \begin{cases} \mathrm{e}^{-1/(1-r^2)}, & |r| < 1, \\ 0, & |r| \geq 1, \end{cases} \qquad q = p'.$$

All its derivatives vanish at $r = \pm 1$: each derivative is a finite sum of polynomials in r times powers of $(1-r^2)^{-1}$, multiplied by the exponential, and the exponential factor dominates every such power. On $|r| < 1$, $q = -2rp/(1-r^2)^2$. Define

$$z_b = \sqrt{q^2 + 2H_*^2}, \qquad S_* = \sqrt{r^2 + 4p^2 + 2z_b(1-r^2)^2}, \tag{11.60}$$

$$x_b = (S_* - r)/2, \qquad y_b = (S_* + r)/2. \tag{11.61}$$

Both radicands are strictly positive everywhere, so these formulas define smooth functions on $\mathbb{R}$, including at the endpoints. They satisfy

$$z_b > |q|, \qquad x_b - y_b = -r, \qquad x_b y_b = p^2 + \frac{z_b}{2}(1-r^2)^2. \tag{11.62}$$

The coefficients x_b, y_b are nonnegative, positive away from the endpoints, with values $(1,0)$ at -1 and $(0,1)$ at 1. On the open band,

$$S_*^2 - (2p + |r|)^2 = 2(1-r^2)^2(z_b - |q|) > 0,$$

so $x_b > p$, $y_b > p$. Consequently both triples

$$(x_b - p, y_b + p, z_b - q), \qquad (x_b + p, y_b - p, z_b + q) \tag{11.63}$$

are strictly positive there.

We now verify that the two triples have the same product. Set $D_* = x_b y_b - p^2$, $E_* = p(x_b - y_b) = -rp$. Equations (11.62) and the formula for q give

$$D_* = (z_b/2)(1-r^2)^2, \qquad qD_* = z_b E_*.$$

The two products in (11.63) therefore equal

$$(D_* + E_*)(z_b - q) = (D_* - E_*)(z_b + q) = \frac{D_*}{z_b}(z_b^2 - q^2) = d_*. \tag{11.64}$$

For $|r| \geq 1$, $p = q = 0$ and the same identity reads $x_b y_b z_b = d_*$. Thus both triples have exactly the prescribed product, and at the endpoints exactly one of their entries vanishes.

11.9.2 Extension over the projective ends

The coefficients just constructed have the right product but need not extend across the projective ends. Away from the zero levels of $f_*(t)$, we interpolate the coefficients of P and Q to those of $f_*(t)^{1/3}\omega_X$, and determine the coefficient of R by the prescribed product.

Choose a smooth even cutoff $0 \leq \eta \leq 1$, equal to one on $|r| \leq 3/2$ and zero on $|r| \geq 2$. On $|r| < 3/2$ set $(x, y, z) = (x_b, y_b, z_b)$. On $|r| > 5/4$, where $f_*(\sigma(r)) > 0$, put

$$\begin{aligned} \kappa &= f_*(\sigma(r))^{1/3}, \\ x &= \eta x_b + (1-\eta)\kappa\sigma(r), \\ y &= \eta y_b + (1-\eta)\kappa\sigma(-r), \qquad z = d_*/(xy). \end{aligned}$$

These coefficients are smooth and positive on the outer region. On the overlap $5/4 < |r| < 3/2$, we have $\eta = 1$, $p = q = 0$ and $x_b y_b z_b = d_*$, so the two definitions agree. For $|r| \geq 2$ they equal $\kappa(\sigma(r), \sigma(-r), \sigma'(r))$. Thus

$$\omega_0 = xP + yQ + zR$$

extends smoothly across both omitted projective lines, being equal near them to $f_*(t)^{1/3}\omega_X$, which is smooth and positive there since $f_*(0) = f_*(1) = a^2 b^2 > 0$. On X, the form ω_0 is semipositive, positive away from $r = \pm 1$, and of rank two on these levels.

The function

$$F(r) = 2\int_0^r p(s)\,\mathrm{d}s$$

is constant on each of the intervals $(-\infty, -1]$ and $[1, \infty)$, and so $F(r)$ extends to a smooth nonconstant function on X. By (11.41), half of its complex Hessian is $H_0 = \mathrm{dd^c}F/2 = p(P - Q) + qR$. By (11.64) and (11.58), the forms $A_0 = \omega_0 - H_0$,

$B_0 = \omega_0 + H_0$ satisfy

$$A_0^3 = B_0^3 = f_*(t)\omega_X^3$$

on U, and hence on X. Their ranks and positivity were determined above, after (11.63). The construction is symmetric: $x(-r) = y(r)$, and z is even.

11.9.3 A positive equation background

As in the first example, an exact correction makes the average form strictly positive without changing the two solution forms. Here the coefficient of R is already positive, and the correction restores the missing coefficient of P or Q at each endpoint. Let $\varepsilon > 0$ be a parameter, restricted below.

Let $h(r) = (r^2 - 1)\eta(r)$, extend it by zero on the tails, and set $\rho = \varepsilon h$. The coefficients of $\omega = \omega_0 + \mathrm{dd}^{\mathrm{c}}\rho$ are

$$(x + \varepsilon h',\ y - \varepsilon h',\ z + \varepsilon h''). \tag{11.65}$$

On $|r| \le 3/2$, we have $h' = 2r$ and $h'' = 2$. For $0 \le r \le 3/2$, $x + 2\varepsilon r > 0$, since the only zero of x there is at $r = 1$, where the correction is positive. On $[-3/2, 0]$, x has a positive minimum m_0, so positivity holds if $3\varepsilon < m_0$. Reflection proves positivity of the second coefficient, and the third is $z + 2\varepsilon > 0$. On the compact transition region $3/2 \le |r| \le 2$, all original coefficients have a common positive lower bound m_1. If M_1 bounds $|h'| + |h''|$, taking also $\varepsilon < m_1/(M_1 + 1)$ preserves their positivity there. For $|r| \ge 2$, the background equals $f_*(t)^{1/3}\omega_X > 0$. Hence ω is strictly positive on X.

The correction is exact, so $\mathrm{d}\omega = \mathrm{d}\omega_0$. At $r = 0$, where $x = x_b$ and $y = y_b$, evenness of S_* gives $x'(0) = -1/2$ and $y'(0) = 1/2$. Hence (11.44) gives

$$\mathrm{d}\omega_0 = (z_b(0) + 1/2)\,\mathrm{d}r \wedge (Q - P) \neq 0.$$

Indeed, if $\mathrm{d}r \wedge (Q - P) = 0$, wedging with P and $\mathrm{d}^{\mathrm{c}}r$ would contradict $P \wedge Q \wedge R > 0$. Thus the Hermitian background ω is not closed.

Now put $\widetilde{u} = -F/2 - \rho$ and $\widetilde{v} = F/2 - \rho$. Then $\omega + \mathrm{dd}^{\mathrm{c}}\widetilde{u} = A_0$, $\omega + \mathrm{dd}^{\mathrm{c}}\widetilde{v} = B_0$. Subtracting their respective suprema gives u, v with $\sup_X u = \sup_X v = 0$, and (11.57) holds. Their difference is nonconstant because F is nonconstant.

11.9.4 Zeros and higher dimensions

It remains to examine the regularity of the density and the geometry of its zero levels. Taking a product with projective space then preserves the equality of the Monge–Ampère measures and gives examples in every higher dimension.

The function t is real analytic in every affine chart of X, being a quotient of real polynomials with positive denominator. Hence $f_*(t)$ is real analytic on X. Its two

zero levels are regular hypersurfaces because $t = \sigma(r)$, $\sigma' > 0$, and $\mathrm{d}r \neq 0$. Each level is connected, since it is the quotient of the product of two three-spheres of fixed nonzero radii by the diagonal action of the circle. Each level is compact and has zero volume. The divided differences in (11.59) show near the two levels that

$$f_*(\sigma(r)) = (r+1)^2 g_-(r), \qquad f_*(\sigma(r)) = (r-1)^2 g_+(r), \tag{11.66}$$

respectively, with smooth strictly positive functions $g_\pm$.

For $n \geq 4$, let θ be the Fubini–Study form on $Y = \mathbb{P}^{n-3}$, let $\pi_1 : X \times Y \to X$ and $\pi_2 : X \times Y \to Y$ be the projections, and set, on $X \times Y$,

$$\omega_n = \pi_1^* \omega + \pi_2^* \theta, \qquad \Omega_n = \pi_1^* \omega_X + \pi_2^* \theta, \qquad u_n = \pi_1^* u, \quad v_n = \pi_1^* v.$$

In the expansion of an n-fold product, only the terms with exactly three factors pulled back from X survive. Consequently

$$(\omega_n + \mathrm{dd^c} u_n)^n = \binom{n}{3} \pi_1^*(A_0^3) \wedge \pi_2^*(\theta^{n-3}) = f_*(\pi_1^* t) \Omega_n^n,$$

and the same holds for v_n. On the two product levels, the solution forms have rank $2 + (n-3) = n - 1$. Restriction to a slice $X \times \{y\}$ recovers $\mathrm{d}\omega \neq 0$, so ω_n is not closed. Normalization, distinctness and real analyticity are preserved by pullback.□

Write Vol for the volume with respect to ω_X^3, or Ω_n^n in dimension n. The quadratic zeros complete the proof of the sharpness assertion in Theorem 11.1.2. In finitely many tubular charts around the zero levels, the density is bounded above and below by positive multiples of the square of a real transverse coordinate, and the volume form has a bounded positive density with respect to coordinate volume. Away from these charts, the density is bounded below by a positive constant. Thus, for $s > 0$ and $\alpha > 0$,

$$\mathrm{Vol}\{f_* \leq s\} \asymp \sqrt{s} \quad (s \downarrow 0), \qquad f_*^{-\alpha} \in L^1 \quad \Longleftrightarrow \quad \alpha < \tfrac{1}{2}. \tag{11.67}$$

Thus, for every $0 < \alpha < 1/2$ and every dimension $n \geq 3$, there are smooth examples of nonuniqueness whose density f satisfies $f^{-\alpha} \in L^1$; this condition is weaker than the hypothesis $f^{-1/2} \in L^1$ of Theorem 11.1.2.

Remark 11.9.1 For this example, the positive-density set $\{f_*(t) > 0\}$ has three components: the middle band and the two outer regions. The two solution forms have the same missing direction on each zero level, so $E_{\mathrm{unif}} = \{f_*(t) > 0\}$. The maximum and the minimum of the difference of the two potentials are attained on the two outer components, whose closures are disjoint, in accordance with Theorem 11.1.1. Although the closure of the middle component meets both outer closures, the extremal values do not propagate through the middle component.

Chapter 12
Complex Hessian equations

Let X be a connected compact complex manifold of dimension n, let ω be a smooth positive Hermitian form, and fix $2 \le m < n$. The complex Hessian operator $(\omega + \mathrm{dd}^{\mathrm{c}} u)^m \wedge \omega^{n-m}$ replaces the determinant by an intermediate symmetric polynomial. Its admissible cone allows negative eigenvalues, so the product calculus for plurisubharmonic potentials from Chapter 1 no longer applies directly.

For a continuous admissible weak solution with smooth positive density depending on the potential, the difficulty is to obtain derivative estimates before smoothness is known. Proper exponential equations associate smooth solutions to its smooth admissible approximations. The complex-Hessian estimate is independent of derivatives of the prescribed approximation, so it survives passage to the limit. Uniform convergence defines the continuous mixed products, while obstacle envelopes give the domination principle that identifies the limit with the original solution. A concave uniformly elliptic extension then supplies classical interior regularity. The determinant case is treated in Theorem 10.5.1; the argument here concerns the intermediate Hessian degrees. Uniform stability also constructs solutions for strictly increasing exponents, by contraction between constant barriers.

Bounded admissible potentials require decreasing approximation. The recursion first gives currents with measure coefficients below degree m; local Hessian capacities control multiplication by their discontinuous potentials. Quasicontinuity and weighted convergence make the products symmetric and allow all approximation indices to tend to their limits together. At degree m, the positive product after wedging with ω^{n-m} is a Radon measure.

These weighted limits pass locality and the maximum inequality to bounded potentials. Truncation above the infimum then proves that the Hessian measure of each potential is nonzero on an arbitrary Hermitian background. In global comparison, the maximum inequality leaves a signed total-mass difference. The complex Hessians of the background powers determine when this difference vanishes for every bounded admissible list. On small sublevel sets, a modified comparison estimate absorbs the torsion error on arbitrary Hermitian backgrounds. It yields strict domination, bounded stability for proper equations and smoothness for their solutions with smooth data between constant barriers.

12.1 The admissible cone

For $\lambda \in \mathbb{R}^n$, let $S_j(\lambda)$ be the elementary symmetric polynomial of degree j, put $\sigma_j = S_j/\binom{n}{j}$ and $\sigma_0 = 1$, and set

$$\Gamma_m = \{\lambda : S_j(\lambda) > 0,\ 1 \le j \le m\}.$$

A real $(1,1)$-form belongs to $\Gamma_m(\omega)$ if its eigenvalues relative to ω belong to Γ_m. Write $C_{n,m}$ for the corresponding closed cone of Hermitian matrices. The algebraic assertions below also apply when $m = n$.

We use the classical Gårding facts: the closed spectral cone is convex, contains the nonnegative matrices, and is preserved by adding them; adding a positive matrix puts a closed-cone matrix in its interior. The normalized root $F = \sigma_m^{1/m}$ is concave and increasing there. Polarized products of k forms in $\Gamma_k(\omega)$ with ω^{n-k} are positive, and Maclaurin's inequalities give $\sigma_j^{1/j} \ge \sigma_k^{1/k}$ for $j \le k$. These algebraic facts will serve as inputs to the analytic arguments.

A continuous real function v on X is *admissible* if

$$(\omega + \mathrm{dd^c} v) \wedge \gamma_1 \wedge \cdots \wedge \gamma_{m-1} \wedge \omega^{n-m} \ge 0 \tag{12.1}$$

in distributions for every smooth collection $\gamma_1, \dots, \gamma_{m-1} \in \Gamma_m(\omega)$. For smooth v this is equivalent to the pointwise closed-cone condition; strict admissibility means membership in the open cone. Maxima and convex combinations preserve continuous admissibility. To check the maximum property, fix one smooth positive linear test in (12.1). Locally a smooth solution of its inhomogeneous linear equation reduces the assertion to the maximum property for subsolutions of a smooth elliptic operator.

For a bounded upper semicontinuous function v, admissibility means that every local C^2 upper test q at x satisfies

$$\omega(x) + \mathrm{dd^c} q(x) \in \overline{\Gamma_m(\omega(x))}. \tag{12.2}$$

For continuous v, this agrees with (12.1): Gårding duality reduces both conditions to subsolution inequalities for smooth strictly elliptic linear operators. We use their classical viscosity–distributional equivalence, with the usual subharmonic representative in the bounded class.

The first estimate controls a scalar shift of the cone. It will give lower bounds for every coefficient of the linearized Hessian operator.

Lemma 12.1.1 *For $\lambda \in \Gamma_m$, put*

$$e_m = \frac{\sigma_m(\lambda)}{m\sigma_{m-1}(\lambda)}.$$

Then $\lambda - t\mathbf{1} \in \Gamma_m$ for $0 \le t < e_m$. If $m \ge 2$, the conclusion also holds for $t = e_m$. For $m = 1$, the endpoint lies on the boundary.

Proof The polynomial

$$P(x) = \sigma_m(\lambda + x\mathbf{1}) = \sum_{j=0}^{m} \binom{m}{j} \sigma_j(\lambda) x^{m-j}$$

is a positive multiple of the $(n-m)$th derivative of $\prod_i (x + \lambda_i)$. Hence all its roots are real, by Rolle's theorem. Its coefficients are positive, so all its roots are strictly negative. Write $P(x) = \prod_{i=1}^{m} (x + r_i)$ with $r_i > 0$. Logarithmic differentiation at zero gives

$$\sum_{i=1}^{m} r_i^{-1} = \frac{m\sigma_{m-1}(\lambda)}{\sigma_m(\lambda)} = e_m^{-1}.$$

Thus $\min_i r_i \ge e_m$, with strict inequality if $m \ge 2$. For $x > -\min_i r_i$, every derivative of P is positive: differentiating its product expansion produces sums of products of positive factors. Since

$$P^{(m-j)}(x) = \frac{m!}{j!} \sigma_j(\lambda + x\mathbf{1}), \qquad 1 \le j \le m,$$

all the required symmetric polynomials are positive at $x = -t$. When $m = 1$, the sole root is $-e_1$. □

Lemma 12.1.2 *If $\alpha, \gamma \in \Gamma_m(\omega)$, then*

$$\frac{\alpha^{m-1} \wedge \gamma \wedge \omega^{n-m}}{\omega^n} \frac{\alpha \wedge \omega^{n-1}}{\omega^n} \ge \frac{1}{m!} \frac{\alpha^m \wedge \omega^{n-m}}{\omega^n} \frac{\gamma \wedge \omega^{n-1}}{\omega^n}.$$

The assertion extends to $\gamma \in \overline{\Gamma_m(\omega)}$ by continuity.

Proof Write $\sigma_k = \alpha^k \wedge \omega^{n-k}/\omega^n$, and $M_k = \alpha^{k-1} \wedge \gamma \wedge \omega^{n-k}/\omega^n$. For $1 \le k < m$, the cone shift with index $k+1$ and Gårding positivity give

$$M_{k+1} \ge tM_k \quad \left(0 \le t < \frac{\sigma_{k+1}}{(k+1)\sigma_k}\right).$$

Let t increase to the displayed endpoint. Iterating, starting with $M_1 = \gamma \wedge \omega^{n-1}/\omega^n$, yields

$$M_m \ge \frac{\sigma_m}{m!\sigma_1} M_1.$$

All denominators are positive. Approximating a form in the closed cone by $\gamma + \delta\omega$, $\delta \downarrow 0$, gives the last assertion. □

At a diagonal Hermitian matrix Λ in the open cone, order its eigenvalues as $\lambda_1 \geq \cdots \geq \lambda_n$ and write

$$f = F(\Lambda), \quad F_i = \partial_{\lambda_i} F, \quad S = \operatorname{tr} \Lambda, \quad \mathcal{F} = \sum_i F_i, \quad Q = \sum_i F_i \lambda_i^2.$$

The next inequalities use these derivatives of the normalized root, rather than derivatives of the polynomial S_m.

Lemma 12.1.3 *If M belongs to the closed Hermitian m-cone, then*

$$W := \sum_i F_i M_{i\bar{i}} \geq \frac{f}{m!S} \operatorname{tr} M, \qquad F_i \geq \frac{f}{m!S}, \qquad |M_{1\bar{1}}| \leq \operatorname{tr} M.$$

No simultaneous diagonalization of M and Λ is required.

Proof In the wedge notation of the mixed-trace estimate, differentiation gives $DF_\Lambda(M) = fM_m/\sigma_m$. The estimate $M_m \geq \sigma_m M_1/(m!\sigma_1)$, with $M_1 = \operatorname{tr} M/n$ and $\sigma_1 = S/n$, proves the first inequality. The positive semidefinite rank-one coordinate projections belong to the closed m-cone; taking M to be each projection proves the second inequality. The closed m-cone is contained in the closed 2-cone. Its eigenvalues μ satisfy

$$\operatorname{tr} M \geq 0, \qquad \sum_i \mu_i^2 = (\operatorname{tr} M)^2 - 2S_2(\mu) \leq (\operatorname{tr} M)^2.$$

Thus the operator norm of M is at most its trace, which proves the last inequality. The wedge pairing computes the derivative in the diagonal frame of Λ, regardless of the eigenvectors of M. □

Lemma 12.1.4 *If $0 < f_0 \leq f \leq f_1$, then*

$$Q := \sum_i F_i \lambda_i^2 \geq \frac{f_0}{m} S - \frac{n-m}{m} f_1^2, \qquad \mathcal{F} \geq 1.$$

Proof The derivative of the normalized root is $F_i = fS_{m-1}(\lambda|i)/(mS_m)$. The splitting identity gives

$$Q = \frac{f}{m} S - \frac{(m+1)f}{mS_m} S_{m+1}.$$

For $m = n$, set $S_{n+1} = 0$. If $S_{m+1} \leq 0$, the second term is nonnegative. Otherwise $\lambda \in \Gamma_{m+1}$ and Maclaurin gives $S_{m+1} \leq \binom{n}{m+1} f^{m+1}$. Since $S_m = \binom{n}{m} f^m$, the subtracted term is at most $(n-m)f^2/m$. This proves the first assertion. Summing the derivatives gives $\mathcal{F} = f\sigma_{m-1}/\sigma_m \geq 1$, again by Maclaurin. □

When $m < n$, admissible forms need not be semipositive. Positivity of a mixed Hessian measure therefore does not directly bound every coefficient of its factors.

For degrees below m, deleted-coordinate positivity supplies the required absolute bound: if $S_{j;I}$ means S_j with the coordinates indexed by I omitted, then $S_{j;I}(\lambda) > 0$ for $j + |I| \le m$, by polarized Gårding positivity.

Lemma 12.1.5 *If $0 \le r < m$, $\alpha_1, \dots, \alpha_r \in \Gamma_m(\omega)$, and Ξ is a smooth complementary form, then*

$$|\alpha_1 \wedge \cdots \wedge \alpha_r \wedge \Xi| \le C_{n,m,\Xi}(\alpha_1 + \cdots + \alpha_r)^r \wedge \omega^{n-r}.$$

For $r = 0$ the right-hand side means $C_{n,m,\Xi}\omega^n$.

Proof First take a single form α, diagonal in an ω-unitary frame, with ordered eigenvalues $\lambda \in \Gamma_m$. For $1 \le r < m$, repeated splitting and deleted-coordinate positivity give $S_r(\lambda) \ge \lambda_1 \cdots \lambda_r$. The sum of the last $n - r$ eigenvalues is positive, so each negative eigenvalue has modulus at most $(n - r)\lambda_{r+1}$. Thus every product of r distinct eigenvalues has modulus at most

$$(n - r)^r \lambda_1 \cdots \lambda_r \le (n - r)^r S_r(\lambda).$$

Indeed, replace its negative factors by this bound and its positive factors by the corresponding largest eigenvalues. In the diagonal frame only complementary diagonal coefficients of Ξ contribute to $\alpha^r \wedge \Xi$. This proves $|\alpha^r \wedge \Xi| \le C_{n,m,\Xi}\alpha^r \wedge \omega^{n-r}$.

Apply this bound to the polynomial $(\alpha_1 + t_2\alpha_2 + \cdots + t_r\alpha_r)^r \wedge \Xi$, with $0 \le t_i \le 1$. Its absolute value is bounded by the stated right-hand side, by polarized positivity and monotonicity on the cone. A fixed invertible interpolation matrix on this finite-dimensional polynomial space bounds each coefficient by its supremum on the cube. The coefficient of $t_2 \cdots t_r$ is a fixed positive multiple of $\alpha_1 \wedge \cdots \wedge \alpha_r \wedge \Xi$. This proves the mixed bound. The closed-cone case follows by adding $\varepsilon\omega$ to each form and taking the limit. □

The next coefficient bound also controls a torsion form whose diagonal coefficients can have either sign. It compares each two-coordinate coefficient with the positive coefficients of the associated gradient pairing.

Lemma 12.1.6 *If $\lambda \in \overline{\Gamma_m}$, $1 \le q \le \min\{m-1, n-2\}$, and $i \ne j$, then, with $N = n-2$ and*

$$c_{N,q} = \frac{q(N-q)}{(q+1)(N-q+1)} < 1,$$

one has

$$|S_{q;ij}(\lambda)|^2 \le \frac{S_{q;i}(\lambda) S_{q;j}(\lambda)}{1 - c_{N,q}}.$$

This includes $q = N$, when $c_{N,N} = 0$.

Proof First prove the unnormalized Newton inequality for an arbitrary real list μ of length N. For $1 \le q < N$, put $R(x) = \prod_{a=1}^{N}(x + \mu_a)$ and $G = R^{(N-q-1)}$. Repeated Rolle's theorem makes G a real-rooted polynomial of degree $d = q + 1$. Away from its roots r_a, logarithmic differentiation and Cauchy–Schwarz give

$$G'^2 - GG'' = G^2 \sum_{a=1}^{d} \frac{1}{(x - r_a)^2} \ge \frac{1}{d} G^2 \left(\sum_{a=1}^{d} \frac{1}{x - r_a} \right)^2 = \frac{1}{d} G'^2.$$

Continuity extends this polynomial inequality to every real x. At zero,

$$G = (N-q-1)!\, S_{q+1}(\mu), \quad G' = (N-q)!\, S_q(\mu), \quad G'' = (N-q+1)!\, S_{q-1}(\mu).$$

Consequently $S_{q-1}(\mu) S_{q+1}(\mu) \le c_{N,q} S_q(\mu)^2$. No sign restriction on μ or on these coefficients was used. For $q = N$, its left side is zero and the same assertion holds with $c_{N,N} = 0$.

Apply this to the list with i, j deleted. Put $A = S_{q-1;ij}$, $B = S_{q;ij}$, $C = S_{q+1;ij}$ and $D_i = S_{q;i}$, $D_j = S_{q;j}$. Deleted-coordinate positivity gives $A, D_i, D_j \ge 0$: the required degrees are $q + 1 \le m$. Splitting in the two omitted coordinates gives the exact identity

$$D_i D_j = A S_{q+1}(\lambda) + B^2 - AC.$$

Since $S_{q+1}(\lambda) \ge 0$ and $AC \le c_{N,q} B^2$, this is at least $(1 - c_{N,q}) B^2$. There is no division by A or D_i; all degenerate endpoints are therefore included. Equivalently one may first add $\epsilon \mathbf{1}$ and pass to the closed cone. □

A smooth maximum preserves the cone condition and can be chosen monotone in its smoothing scale as well as in its two arguments.

Lemma 12.1.7 *If smooth uniformly bounded admissible $u_j \downarrow u$ and $v_j \downarrow v$ are given, there are smooth uniformly bounded admissible $w_j \downarrow \max\{u, v\}$. For any chosen $\epsilon_j > 0$ decreasing to zero, they can be chosen to satisfy $w_j = u_j$ on $\{u_j - v_j > \epsilon_j\}$ and $w_j = v_j$ on $\{v_j - u_j > \epsilon_j\}$. For smooth functions f, g on an open subset of X with $\mathrm{dd^c} f, \mathrm{dd^c} g \in \overline{\Gamma_m(\omega)}$, the regularized maximum $M_\epsilon(f, g)$ constructed below satisfies the same unshifted cone condition.*

Proof Choose a nonnegative even smooth probability density ζ supported in $[-1, 1]$, and set

$$r_\epsilon(t) = \int |t - \epsilon s| \zeta(s)\, \mathrm{d}s, \qquad M_\epsilon(x, y) = \tfrac{1}{2}(x + y + r_\epsilon(x - y)).$$

The function r_ϵ is smooth and convex, $|r'_\epsilon| \le 1$, and $r_\epsilon(t) = |t|$ for $|t| \ge \epsilon$. Jensen's inequality and the triangle inequality give

$$\max\{x, y\} \le M_\epsilon(x, y) \le \max\{x, y\} + \epsilon/2.$$

Its partial derivatives in x, y are nonnegative. For fixed t, $r_\epsilon(t)$ is an even convex function of ϵ, since ζ is even. It is therefore nondecreasing for $\epsilon \ge 0$. Consequently $w_j = M_{\epsilon_j}(u_j, v_j)$ decreases pointwise to $\max\{u, v\}$ and has the asserted equalities and bounds.

Put $h_j = u_j - v_j$ and $a_j = (1 + r'_{\epsilon_j}(h_j))/2$. The chain rule gives

$$\omega + \mathrm{dd^c} w_j = a_j(\omega + \mathrm{dd^c} u_j) + (1 - a_j)(\omega + \mathrm{dd^c} v_j) + \tfrac{1}{2} r''_{\epsilon_j}(h_j)\mathrm{d}h_j \wedge \mathrm{d^c} h_j.$$

Here $0 \le a_j \le 1$, and the last form is semipositive. Convexity of the cone and its stability under semipositive addition prove admissibility. For smooth local functions satisfying the unshifted cone condition, omit ω from this chain rule; the same argument proves preservation of that condition. The pointwise maximum is itself admissible: an upper test for it at a point is an upper test for a potential attaining the maximum there. Its canonical representative is thus the indicated pointwise maximum. □

Lemma 12.1.8 *If bounded admissible u, v satisfy $u \le v$ almost everywhere with respect to ω^n, then $u \le v$ everywhere.*

Proof By Lemma 12.1.7, $w = \max\{u, v\}$ is bounded admissible with its indicated canonical representative. Since $w = v$ almost everywhere, they represent the same distribution. The canonical subharmonic representative used in (12.2) is determined by that distribution. Thus $w = v$ pointwise, which is the assertion. □

12.2 Liouville and gradient estimates

The gradient estimate comes from rescaling a sequence at points of large gradient. The background then disappears, leaving a maximal function for a constant Euclidean cone. We first establish the Liouville theorem that rules out such a nonconstant limit.

For this Euclidean argument allow $1 \le m \le n$. Write $H(v) = (v_{i\bar{j}})$. A continuous real function v on a Euclidean domain is admissible for $C_{n,m}$ if

$$\operatorname{tr}(QH(v)) \ge 0 \quad \text{in distributions for every } Q \in C^*_{n,m},$$

where $C^*_{n,m} = \{Q : \operatorname{tr}(QA) \ge 0 \text{ for all } A \in C_{n,m}\}$. For smooth functions this says $H(v) \in C_{n,m}$. Call v maximal if every smooth lower test has Hessian outside the interior of $C_{n,m}$ at the contact point. Admissibility implies subharmonicity and is preserved by nonnegative convolution. The cone polynomial S_m increases under nonnegative matrix addition in the interior.

Lemma 12.2.1 *Local uniform limits of admissible maximal functions are admissible and maximal. Suppose v is admissible and maximal on a bounded open set D, and h is smooth and admissible there. If both are continuous on $\overline{D}$ and $h \le v$ on ∂D, then $h \le v$ on D.*

Proof The distributional inequalities pass to local uniform limits. If a lower test h for the limit at z_0 has Hessian in the interior, subtract $\delta|z - z_0|^2$, for sufficiently small $\delta > 0$, to make the contact strict while retaining interior admissibility near z_0. Interior minimum points for the approximants then tend to z_0. Adding the minimum value produces lower tests for them with Hessian in the interior, contradicting their maximality.

For comparison choose R with $\overline{D} \subset \{|z| \le R\}$. If $h > v$ somewhere, the function $h_\delta = h + \delta(|z|^2 - R^2)$ still exceeds v somewhere for small $\delta > 0$ and is at most v on the boundary. The negative minimum of $v - h_\delta$ is attained inside D. Since $H(h_\delta) = H(h) + \delta I$ belongs to the interior, adding the minimum value gives a forbidden lower test. This argument requires no regularity of the boundary. □

Theorem 12.2.1 *Every bounded globally Lipschitz admissible function on $\mathbb{C}^n$ that is maximal for $C_{n,m}$ is constant.*

Proof For $m = 1$, the distributional subharmonicity and the lower-test condition say that the function is a viscosity solution of the Laplace equation. The elementary equivalence with harmonicity and bounded harmonic Liouville give the conclusion. For $m = n$, admissibility is distributional plurisubharmonicity. The continuous representative is plurisubharmonic, and bounded plurisubharmonic Liouville applies. For a fixed $m \ge 2$, we therefore argue by induction on $n \ge m$.

The reduction in dimension is particularly simple for this cone. For a Hermitian $(n-1)$-by-$(n-1)$ matrix A and $m < n$,

$$S_j(A \oplus 0) = S_j(A), \qquad 1 \le j \le m.$$

Consequently $A \oplus 0$ belongs to $C_{n,m}$, respectively its interior, exactly when A belongs to $C_{n-1,m}$, respectively its interior. For the closed cones, the nonnegative inequalities characterize the closure: the expansion of $S_j(\lambda + \delta \mathbf{1})$ has nonnegative coefficients and a strictly positive δ^j term. If an admissible function is independent of z_n, convolving it and using the block identity shows that the function in the remaining variables is admissible. Extending its lower tests independently of z_n shows that maximality also passes to dimension $n - 1$.

Suppose v is nonconstant. Normalize $\inf v = 0$, $\sup v = 1$, and let L be its Lipschitz constant. Choose a smooth radial nonnegative probability kernel η, supported in the closed unit ball and positive in its interior. Put

$$[f]_r(x) = \int f(x + y)\eta_r(y)\,\mathrm{d}y, \qquad \eta_r(y) = r^{-2n}\eta(y/r), \qquad v_\epsilon = [v]_\epsilon.$$

Both v and v^2 are subharmonic: for the second assertion use $\Delta(v_\epsilon^2) = 2v_\epsilon \Delta v_\epsilon + 2|\nabla v_\epsilon|^2 \geq 0$ and pass to the uniform limit. Their radial averages increase with r, by monotonicity of spherical means. For either $f = v$ or $f = v^2$,

$$|[f]_r(x) - [f]_r(y)| \leq \|f\|_\infty \|\eta_r(\cdot - x) - \eta_r(\cdot - y)\|_{L^1} \leq C\frac{|x - y|}{r}.$$

Thus the limiting average is independent of its center. The submean inequality makes it at least $f(x)$ for every x, and the upper bound is $\sup f = 1$. Hence

$$[v]_r(x) \longrightarrow 1, \qquad [v^2]_r(x) \longrightarrow 1.$$

First suppose there are a fixed $\rho > 0$, numbers $\epsilon_k \downarrow 0$, $r_k \to \infty$, points x_k, and unit complex directions ξ_k, such that

$$[v^2]_{r_k}(x_k) + [v]_\rho(x_k) - 2v(x_k) \geq \frac{4}{3}, \qquad \int_{B(x_k, r_k)} |\partial_{\xi_k} v_{\epsilon_k}|^2\,\mathrm{d}y \longrightarrow 0.$$

Translate and rotate to make x_k the origin and ξ_k the last complex direction. Compactness of uniformly bounded Lipschitz functions and the preceding lemma give a locally uniform limit a that is admissible and maximal. The transformed mollifications have the same limit. Their last derivatives tend to zero in L^2 on every fixed ball, so $\partial_{z_n} a = 0$ in distributions. Since a is real and continuous, it is independent of z_n. The induction hypothesis gives $a = c \in [0, 1]$. In the displayed gap inequality the first average is at most one, while the fixed-radius average and the value at the origin tend to c. This would give $4/3 \leq 1 - c \leq 1$, a contradiction.

If this case does not occur, then for every fixed $\rho > 0$ there is $C_\rho \geq 1$ such that

$$\int_{B(x,r)} |\partial_\xi v_\epsilon|^2\,\mathrm{d}y \geq C_\rho^{-1}$$

for every unit complex direction ξ, whenever $0 < \epsilon < C_\rho^{-1}$, $r > C_\rho$ and $[v^2]_r(x) + [v]_\rho(x) - 2v(x) \geq 4/3$. Indeed, failure for every integer choice $C_\rho = k$ produces

the sequences excluded above. The dependence on the fixed radius ρ is retained. Translate so that $v(0) < 1/12$. Choose ρ with $[v]_\rho(0) > 3/4$, then $r > C_\rho$ with $[v^2]_r(0) > 3/4$. The open set

$$D = \{x : 2v(x) < [v^2]_r(x) + [v]_\rho(x) - 4/3\}$$

contains the origin.

On this set, $[v^2]_r - c|z|^2$ is smooth and admissible for some fixed $c > 0$. To prove this, decompose

$$H([v_\epsilon^2]_r) = [2v_\epsilon H(v_\epsilon)]_r + [2(\partial_i v_\epsilon \overline{\partial_j v_\epsilon})_{ij}]_r = A_\epsilon + B_\epsilon .$$

The matrix A_ϵ belongs to $C_{n,m}$ by convexity and $v_\epsilon \geq 0$. For every complex direction the unweighted energy on $B(x,r)$ is at least C_ρ^{-1}. Since $|\nabla v_\epsilon| \leq L$, a sufficiently thin boundary annulus carries at most half that amount, uniformly in x, ϵ, ξ. On the remaining smaller closed ball η_r has a positive minimum. Therefore $B_\epsilon \geq c_0 I$ on D, with $c_0 > 0$ independent of small ϵ. Choose $0 < c \leq c_0$. Then $A_\epsilon + B_\epsilon - cI \in C_{n,m}$. Uniform convergence of v_ϵ^2 and convolution at the fixed radius give convergence of every derivative to those of $[v^2]_r$, proving the assertion.

The smooth function

$$h = \tfrac{1}{2}\big([v^2]_r - c|z|^2 + [v]_\rho - 4/3\big)$$

is admissible on D. The set $D' = \{v < h\}$ contains the origin, is bounded, and lies in D. Continuity gives $v = h$ on its boundary. The comparison lemma gives $h \leq v$ on D', a contradiction. This completes the induction. □

A trace bound now suffices to bound the gradient. The following statement permits a smooth background different from the metric.

Proposition 12.2.1 *Fix a compact complex manifold X of dimension n, a smooth Hermitian form ω, a smooth real $(1,1)$-form θ, an integer $2 \leq m \leq n$, and constants $M, A, B > 0$. There is a uniform bound for $\sup_X |\partial u|_\omega$ over all smooth real u such that $\theta_u = \theta + \mathrm{dd^c} u \in \Gamma_m(\omega)$ and*

$$|u| \leq M, \qquad \frac{\theta_u^m \wedge \omega^{n-m}}{\omega^n} \leq B, \qquad \operatorname{tr}_\omega \theta_u \leq A\big(1 + \sup_X |\partial u|_\omega^2\big).$$

The bound requires no derivatives of the Hessian density.

Proof In local holomorphic coordinates write $\omega = \mathrm{i} g_{i\bar{j}}\, \mathrm{d}z_i \wedge \mathrm{d}\bar{z}_j$ and $\theta_u = \mathrm{i}(b_{i\bar{j}} + \kappa u_{i\bar{j}})\, \mathrm{d}z_i \wedge \mathrm{d}\bar{z}_j$, where the fixed constant $\kappa > 0$ accounts for the convention for $\mathrm{dd^c}$. For eigenvalues $\lambda \in \Gamma_m$, $m \geq 2$, one has

$$\sum_i \lambda_i^2 = \left(\sum_i \lambda_i\right)^2 - 2S_2(\lambda) < \left(\sum_i \lambda_i\right)^2 .$$

Thus the assumed trace estimate bounds every eigenvalue in absolute value by $A(1 + \sup |\partial u|^2)$.

Suppose contrary to the claim that a sequence u_j has maxima $R_j = \sup |\partial u_j|_\omega \to \infty$, attained at x_j. Pass to $x_j \to x_\infty$ and work in a fixed chart, changing coordinates linearly so that $g(x_\infty) = I$. If y_j is the coordinate of x_j, set

$$v_j(z) = u_j(y_j + z/R_j), \qquad g_j(z) = g(y_j + z/R_j),$$
$$E_j(z) = R_j^{-2} b(y_j + z/R_j) + \kappa H(v_j)(z).$$

These are defined on balls with radii tending to infinity. On each fixed ball $g_j \to I$, the smooth background term tends to zero, and E_j is uniformly bounded by the eigenvalue estimate. In particular $H(v_j)$ and its Euclidean trace are uniformly bounded. Interior estimates for the fixed Euclidean Laplacian give local uniform $W^{2,q}$ bounds for every finite q. A diagonal subsequence converges in C^1 on compact subsets to a bounded globally Lipschitz v, with $|\partial v(0)| = 1$.

The Hermitian matrices $g_j^{-1/2} E_j g_j^{-1/2}$ belong to the interior of $C_{n,m}$ and differ from $\kappa H(v_j)$ by a term tending uniformly to zero on fixed balls. Pairing with any fixed matrix in the dual cone and passing in distributions proves that v is admissible. Its equation is

$$\frac{S_m(g_j^{-1/2} E_j g_j^{-1/2})}{\binom{n}{m}} = R_j^{-2m} \frac{\theta_{u_j}^m \wedge \omega^{n-m}}{\omega^n}(y_j + z/R_j) \le B R_j^{-2m}.$$

We show maximality by lower tests, rather than by an unproved convergence assertion for variable-background Hessian measures. If a smooth lower test ψ at z_0 had $H(\psi)(z_0)$ in the interior, choose a small $\delta > 0$ so that $H(\psi) - \delta I$ remains there near z_0. Strictifying the contact by subtracting $\delta |z - z_0|^2$ gives interior minimum points $z_j \to z_0$ for v_j minus this test. At those points

$$E_j \ge R_j^{-2} b + \kappa(H(\psi) - \delta I).$$

The matrix on the right, measured with g_j, is uniformly inside the cone. Monotonicity of S_m under nonnegative addition gives a fixed positive lower bound for the left side of the preceding equation. This contradicts $B R_j^{-2m} \to 0$. Hence v is maximal. The Liouville theorem makes it constant, contradicting $|\partial v(0)| = 1$. □

On a fixed rescaled ball the metric varies by order R_j^{-1}, whereas the background form enters with factor R_j^{-2}. Thus this argument uses fixed smooth backgrounds and an upper bound for the Hessian density, without derivatives of that density.

12.3 A trace estimate with a prescribed potential

In a coordinate chart write $\omega = (\mathrm{i}/(2\pi))g_{i\bar{j}}\,\mathrm{d}z_i \wedge \mathrm{d}\bar{z}_j$. Covariant derivatives use the Chern connection of g. For a smooth strictly admissible u, put

$$H_{i\bar{j}} = g_{i\bar{j}} + u_{i\bar{j}}, \qquad W = g^{-1}H, \qquad L = \sum_i F_i \nabla_{i\bar{i}}$$

in a unitary frame diagonalizing H. Use $f, \mathcal{F}, S, Q$ from Section 12.1. Since $m \geq 2$, one has $|\lambda_i| < S \leq n\lambda_1$.

We shall estimate equations whose density involves another admissible potential v. In an approximation argument the derivatives of v may diverge. The logarithmic weight below absorbs these derivatives using only uniform closeness to one fixed smooth comparison function.

Lemma 12.3.1 *For $\epsilon > 0$, let $\chi(t) = -(1/12)\log(2\epsilon - t)$ on $|t| \leq \epsilon$. Suppose $q = \chi'(t) \geq 8$. For any $a, b \in \mathbb{C}$,*

$$\chi''(t)|a-b|^2 - (9q^2 + 2q)|a|^2 - q|a| \geq q^2|a|^2 - 1 - 84q^2|b|^2.$$

In particular, let $v, \widetilde{\varphi}$ be smooth real functions with $|v - \widetilde{\varphi}| \leq \epsilon$, and take derivatives in an ω-unitary frame. For a positive diagonal linearized operator with coefficients B_p, setting $t = v - \widetilde{\varphi}$, $a = v_p$, $b = \widetilde{\varphi}_p$ and summing gives an error bounded by $(1 + 84q^2 \sup |\partial\widetilde{\varphi}|^2_\omega)\sum_p B_p$. The condition $q \geq 8$ holds throughout this interval if $\epsilon \leq 1/288$.

Proof Young's inequality gives $|a-b|^2 \geq (7/8)|a|^2 - 7|b|^2$. Since $\chi'' = 12q^2$, the coefficient of $|a|^2$ after subtracting $9q^2$ is $3q^2/2$. Moreover, $2q \leq q^2/4$ and $q|a| \leq q^2|a|^2/4 + 1$. The remaining coefficient is at least q^2, and the error involving b is $84q^2|b|^2$. Finally $q \geq 1/(36\epsilon)$, which proves the last assertion. The weighted version follows by summing the scalar inequality with positive coefficients. □

Lemma 12.3.2 *Suppose $f \ge f_0 > 0$, $C_H, C_G \ge 0$, and q satisfies*

$$q \ge 8, \qquad q \ge \frac{2nm!C_H}{f_0}, \qquad q^2 \ge \frac{4m!C_G}{f_0}.$$

For $0 \le r \le 1/2$, $a, b \in \mathbb{C}^n$ and $M \in C_{n,m}$, put $W_M = \sum_i F_i M_{i\bar{i}}$ and

$$E = q(W_M - \mathcal{F}) - \frac{C_H}{\lambda_1}|M_{1\bar{1}}| - \frac{C_G}{S}\sum_i |a_i|^2 + \sum_i F_i\big(12q^2|a_i - b_i|^2 - (9q^2 + 2q + rq^2)|a_i|^2 - q|a_i|\big).$$

Then

$$E \ge \frac{q}{2}W_M + \frac{q^2}{4}\sum_i F_i|a_i|^2 - (q + 1 + 84q^2 \max_i |b_i|^2)\mathcal{F}.$$

Proof Lemma 12.3.1 gives

$$12q^2|a_i - b_i|^2 - (9q^2 + 2q)|a_i|^2 - q|a_i| \ge q^2|a_i|^2 - 1 - 84q^2|b_i|^2.$$

Subtracting $rq^2|a_i|^2$ leaves at least $q^2|a_i|^2/2$. Since $S \le n\lambda_1$, Lemma 12.1.3 and the hypothesis on q imply

$$\frac{C_H}{\lambda_1}|M_{1\bar{1}}| \le \frac{nC_H}{S}\operatorname{tr} M \le \frac{q}{2}W_M.$$

The lower bound for each F_i similarly gives

$$\frac{C_G}{S}\sum_i |a_i|^2 \le \frac{q^2}{4}\sum_i F_i|a_i|^2.$$

Combining these inequalities yields the assertion. The error depends on the fixed comparison vector b and is not discarded. □

For $\Psi(t) = -2At + (A\tau/2)t^2$, $|t| \le M$ and $\tau M \le 1$, one has $-3A \le \Psi' \le -A$. The two cases for the smallest eigenvalue will reduce to the following numerical estimate.

Proposition 12.3.1 *Fix $a > 0$, $b, d, e \ge 0$ and $0 < \delta < 1$. Let $K \ge 1$ and $0 < f_0 \le f \le f_1$. Suppose the following inequality holds according to the sign of $\lambda_n + \delta\lambda_1$:*

(1) *If $\lambda_n < -\delta\lambda_1$, then $0 \ge aQ/K - bK\mathcal{F} - d\lambda_1\mathcal{F} - e$.*
(2) *If $\lambda_n \ge -\delta\lambda_1$, then $0 \ge aQ/K - bKF_1 - e$.*

Then $S \le CK$ and $\lambda_1 \le CK$, with C depending only on the fixed displayed data and n, m.

Proof In the first case, symmetry and concavity of F imply $F_n \ge F_i$ for every i, so $Q \ge \delta^2\lambda_1^2\mathcal{F}/n$. To see the derivative ordering, apply monotonicity of the gradient

of a concave function to λ and the vector obtained by exchanging its ith and nth coordinates. Divide the assumed inequality by $K\mathcal{F}$, use $\mathcal{F} \geq 1$, and set $t = \lambda_1/K$. It yields $a\delta^2 t^2/n \leq b + dt + e$, which bounds t. Since $S \leq n\lambda_1$, the trace bound follows. In the second case, either $\lambda_1^2 \leq 2bK^2/a$, which gives the same trace bound directly, or $aQ/(2K) \geq bKF_1$. The assumed inequality then gives $Q \leq 2eK/a$. Lemma 12.1.4 bounds S by a multiple of K. Finally the Γ_2 identity gives $\lambda_1 \leq (\sum_i \lambda_i^2)^{1/2} < S$. □

The geometric computation uses a lower support for the largest eigenvalue, as in the second-order argument for the Gauduchon equation. The perturbation affects only this support; derivatives of F remain evaluated at the original matrix W.

Lemma 12.3.3 *At a point with $\lambda_1 > 1$, the largest eigenvalue has a smooth local lower support $\widetilde{\lambda}$, equal to λ_1 at the point, for which*

$$L \log \widetilde{\lambda} \geq \frac{f_{1\bar{1}}}{\lambda_1} + N - \sum_i F_i |Z_i|^2 - C\mathcal{F} - \frac{C}{\lambda_1^2} \sum_i F_i |H_{1\bar{1};i}|,$$

where

$$N = -\frac{D^2 F_W(\nabla_1 W, \nabla_{\bar{1}} W)}{\lambda_1}, \qquad Z_i = \frac{H_{i\bar{1};1}}{\lambda_1}.$$

Here C depends only on the fixed metric. Derivatives of F are evaluated at W.

Proof Choose a smooth unitary frame parallel for the Chern connection at the point and diagonalizing H there. The positive semidefinite tensor B, diagonal in this frame with entries $0, \beta, \dots, \beta$, satisfies $\nabla B = 0$ at the point and $|\nabla^2 B| \leq C\beta$. For $0 < \beta < 1$, the largest eigenvalue of $W - B$ is simple, lies below that of W, and agrees with it at the point. This gives the required smooth support. Only its largest eigenvalue is perturbed; the equation still uses $F(W)$. Differentiating the normalized eigenvector equation gives

$$\widetilde{\lambda}_{;k} = H_{1\bar{1};k}, \qquad \widetilde{\lambda}_{;k\bar{k}} \geq H_{1\bar{1};k\bar{k}} + \sum_{p>1} \frac{|H_{p\bar{1};k}|^2 + |H_{1\bar{p};k}|^2}{\lambda_1 - \lambda_p + \beta} - C\beta.$$

The denominators are at most $(n+1)\lambda_1$. Let $U = \partial\bar{\partial} u$, and take $T^p_{ki} = \Gamma^p_{ki} - \Gamma^p_{ik}$. The first commutations are

$$U_{i\bar{j};k} = U_{k\bar{j};i} - T^p_{ki} U_{p\bar{j}}, \qquad U_{i\bar{j};\bar{k}} = U_{i\bar{k};\bar{j}} - \overline{T^p_{kj}} U_{i\bar{p}}.$$

Apply the first identity, commute one mixed pair of covariant derivatives, and apply the conjugate identity. The result has the form

$$U_{1\bar{1};k\bar{k}} = U_{k\bar{k};1\bar{1}} - 2\,\mathrm{Re} \sum_p U_{k\bar{p};1} \overline{T^p_{k1}} + E_k, \qquad |E_k| \leq C|U|.$$

Indeed the mixed commutator contracts curvature with U, differentiating the first torsion coefficient contracts ∇T with U, and the second use of the first identities produces contractions of two torsion coefficients with U. Thus all the omitted terms

satisfy the displayed bound. Since g is parallel, the same derivative relations apply to H apart from the explicit g terms in the first commutation. At the diagonal point $|U| \le C\lambda_1$. For $p > 1$, rewrite $U_{k\bar{p};1} = U_{1\bar{p};k} + T^j_{k1} U_{j\bar{p}}$. Young's inequality absorbs its third derivative into the positive eigenvalue square, at the cost of $C\lambda_1$. Consequently

$$\widetilde{\lambda}_{;k\bar{k}} \ge H_{k\bar{k};1\bar{1}} - 2\,\mathrm{Re}(H_{k\bar{1};1}\overline{T^1_{k1}}) - C\lambda_1.$$

Differentiate $F(W) = f$ twice and sum this inequality with weights F_k. Write $D_k = H_{1\bar{1};k}$ and $t_k = T^1_{k1}$. The first commutation, using $U_{1\bar{1}} = \lambda_1 - 1$, gives

$$D_k = \lambda_1 Z_k - (\lambda_1 - 1) t_k.$$

The negative logarithmic square and the remaining torsion term therefore satisfy

$$-\frac{|D_k|^2}{\lambda_1^2} - 2\,\mathrm{Re}(Z_k \bar{t}_k) \ge -|Z_k|^2 - C - C\lambda_1^{-2}|D_k|.$$

For example, expanding the left side leaves $-|Z_k|^2 - 2\lambda_1^{-1}\,\mathrm{Re}(Z_k\bar{t}_k) - (1-\lambda_1^{-1})^2|t_k|^2$, and $\lambda_1|Z_k| \le |D_k| + C\lambda_1$. This proves the claim, uniformly for small β. □

Lemma 12.3.4 *Put $s = |\partial u|_g^2$ and $K = 1 + \sup_X s$. For every $\eta > 0$ one has*

$$Ls \ge \sum_{i,k} F_i(|u_{ki}|^2 + |u_{k\bar{i}}|^2) + 2\,\mathrm{Re}\sum_k f_k u_{\bar{k}} - \eta Q - C_\eta K\mathcal{F}.$$

The constant depends only on the metric and η.

Proof Differentiate the squared norm using metric compatibility. Its quadratic part is the displayed sum. Commuting the remaining third derivatives gives

$$u_{ki\bar{i}} = u_{i\bar{i};k} - T^p_{ik} u_{p\bar{i}} + R^p_{i\bar{i}k} u_p, \qquad u_{\bar{k}i\bar{i}} = u_{i\bar{i};\bar{k}} - \overline{T^p_{ik}}\, u_{i\bar{p}}.$$

The first differentiated equation is $\sum_i F_i u_{i\bar{i};k} = f_k$, because the background g is parallel. At the diagonal point the torsion errors are bounded by $C\sqrt{K}\sum_i F_i(|\lambda_i| + 1)$, and the curvature errors by $CK\mathcal{F}$. Use

$$C\sqrt{K} F_i|\lambda_i| \le \eta' F_i \lambda_i^2 + C_{\eta'} K F_i$$

with a sufficiently small η' for the finite sum. This gives the asserted bound. □

Proposition 12.3.2 *Fix $M, B \geq 1$ and a smooth real $h(x,t)$ on a neighborhood of $X \times [-B-1, B+1]$. There is $0 < \varepsilon \leq 1$, depending only on M, B, h, ω, n, m, with the following property. For every smooth real φ with $\|\varphi\|_\infty \leq B$, there is $C < \infty$, depending also on its C^2 norm, such that if smooth real u, v satisfy*

$$W \in \Gamma_m, \qquad I + v_{i\bar{j}} \in \overline{\Gamma_m},$$
$$\|u\|_\infty \leq M, \qquad \|v - \varphi\|_\infty \leq \varepsilon,$$
$$F(W) = \exp\bigl((u + h(x,v))/m\bigr),$$

then

$$\operatorname{tr}_\omega(\omega + \mathrm{dd}^{\mathrm{c}} u) \leq C\bigl(1 + \sup_X |\partial u|_g^2\bigr).$$

The cone condition on v is understood in a unitary frame. The tolerance ε uses no derivatives of φ; the constant C uses no derivatives of v.

Proof For $\varepsilon \leq 1$ the density has fixed bounds $0 < f_0 \leq f \leq f_1$. Its first derivative is

$$f_k = \frac{f}{m}(u_k + h_k(x,v) + h_t(x,v) v_k).$$

The nonnegative u_k contribution can be dropped from the gradient lemma. At a point with $\lambda_1 > 1$, differentiating once more gives

$$f_{1\bar{1}} \geq -C(1 + |\partial v|^2 + |1 + v_{1\bar{1}}|).$$

Here $u_{1\bar{1}} = \lambda_1 - 1 > 0$, the square from differentiating the exponential is nonnegative, and all derivatives of h are bounded on the fixed interval.

Set

$$\Phi(s) = -\tfrac{1}{2}\log(1 - s/(2K)), \qquad \Psi(u) = -2Au + (A\tau/2)u^2,$$
$$\chi(t) = -\tfrac{1}{12}\log(2\varepsilon - t), \qquad \tau = (M+1)^{-1}.$$

Then $(4K)^{-1} \leq \Phi' \leq (2K)^{-1}$, $\Phi'' = 2(\Phi')^2$, $-3A \leq \Psi' \leq -A$, $\Psi'' = A\tau$, and $q = \chi'$ lies between $1/(36\varepsilon)$ and $1/(12\varepsilon)$, with $\chi'' = 12q^2$. Take a maximum of $G = \log\lambda_1 + \Phi(s) + \Psi(u) + \chi(v - \varphi)$ and use the smooth lower support from the eigenvalue lemma. At this point put

$$a_i = v_i, \quad b_i = \varphi_i, \quad P_v = I + v_{i\bar{j}}, \quad W_v = \sum_i F_i (P_v)_{i\bar{i}}, \quad x_i = \Phi' s_i, \quad y_i = \Psi' u_i.$$

The first derivative condition and the torsion identity give

$$H_{1\bar{1};i}/\lambda_1 = -x_i - y_i - q(a_i - b_i), \qquad Z_i = -x_i - y_i - q a_i + e_i, \quad e_i = q b_i + (1 - \lambda_1^{-1}) T^1_{i1}.$$

Thus $|e_i| \leq E_0$, with E_0 independent of A and of derivatives of v.

We make the initial maximum inequality explicit. The gradient lemma and the identity $u_{i\bar{j}} = (\lambda_i - 1)\delta_{ij}$ give, after multiplication by Φ',

$$\Phi' Ls \geq \frac{1}{8K}\sum_{i,k} F_i(|u_{ki}|^2 + |u_{k\bar{\imath}}|^2) + \frac{3}{64K}Q - C\mathcal{F} - \frac{C'_G}{S}\sum_i |a_i|^2.$$

To justify the constants, retain half of the positive quadratic term, use $(\lambda_i - 1)^2 \geq \lambda_i^2/2 - 1$, and choose the torsion parameter to cost at most $Q/(128K)$. The remaining density-gradient error is $C|a|/\sqrt{K}$. Young's inequality bounds it by $C'_G|a|^2/S + cS/K$; choose C'_G large enough that the quadratic coercivity lemma absorbs cS/K by $Q/(128K)$, with a fixed constant error. This leaves $3Q/(64K)$. The linear $H_{1\bar{1};i}$ error in the eigenvalue lemma is estimated using the first derivative condition. Its x_i term costs at most half of the retained quadratic sum and $C\mathcal{F}$. Its y_i term costs at most $\Psi''\sum_i F_i|u_i|^2/4 + \mathcal{F}$ whenever $\lambda_1 \geq L_0(A)$, where $L_0(A)$ is fixed independently of K, v. Its qa_i term costs at most $q\sum_i F_i|a_i|$ when λ_1 exceeds a fixed metric constant; its qb_i term costs $C\mathcal{F}$. If either eigenvalue threshold fails, the required bound follows directly. Otherwise, with fixed C_H, C_G, C_0 independent of A, the second derivative condition gives

$$\begin{aligned} 0 \geq N &- \sum_i F_i|Z_i|^2 + 2\sum_i F_i|x_i|^2 + \tfrac{3}{4}\Psi''\sum_i F_i|u_i|^2 + \frac{Q}{32K} + \Psi'(f - \mathcal{F}) - C_0\mathcal{F} \\ &+ q(W_v - \mathcal{F}) - \frac{C_H}{\lambda_1}|(P_v)_{1\bar{1}}| - \frac{C_G}{S}\sum_i |a_i|^2 + \sum_i F_i\big(12q^2|a_i - b_i|^2 - q|a_i|\big). \end{aligned}$$

The fixed $qL\varphi$ term is included in C_0. Choose ε so the lower bound for q meets all thresholds of the derivative-absorption lemma. These thresholds depend on M, B, h and the metric, and not on derivatives of φ. This choice precedes that of A.

First suppose $\lambda_n < -\delta\lambda_1$. Concavity gives $N \geq 0$, and

$$-|Z_i|^2 + 2|x_i|^2 \geq -6|y_i|^2 - 6q^2|a_i|^2 - 6E_0^2.$$

The derivative-absorption lemma applies after decreasing the right side further by $(3q^2 + 2q)|a_i|^2$. Drop its nonnegative reserves and Ψ'' term. Since $\Psi' f \geq -3Af_1$, this gives

$$0 \geq \frac{Q}{32K} - (54A^2 + C_*)K\mathcal{F} - 3Af_1,$$

where C_* is fixed independently of A, δ.

Now suppose $\lambda_n \geq -\delta\lambda_1$, and let $I = \{i : F_i > \delta^{-1}F_1\}$. For $i \in I$, $\lambda_i < \lambda_1$ and

$$\frac{F_i - F_1}{\lambda_1 - \lambda_i} \geq \frac{(1-\delta)F_i}{(1+\delta)\lambda_1} \geq \frac{(1-2\delta)F_i}{\lambda_1}.$$

The spectral formula for D^2F, including its nonpositive diagonal part, therefore gives $N \geq (1-2\delta)\sum_{i\in I} F_i|Z_i|^2$. This uses the original eigenvalues; repeated eigenvalues do not occur in I. Using $x_i = -Z_i - y_i - qa_i + e_i$ and $|z+w|^2 \geq \delta|z|^2 - \delta|w|^2/(1-\delta)$, one obtains

$$N - \sum_{i\in I} F_i|Z_i|^2 + 2\sum_{i\in I} F_i|x_i|^2 \geq -\frac{4\delta(\Psi')^2}{1-\delta}\sum_{i\in I} F_i|u_i|^2 \\ - rq^2\sum_{i\in I} F_i|a_i|^2 - rE_0^2\mathcal{F}, \qquad r = \frac{8\delta}{1-\delta}.$$

Choose $\delta \leq \min\{1/17, \tau/(72A+\tau)\}$. Then the first coefficient is at most $\Psi''/2$, and $r \leq 1/2$. On the complementary indices the preceding elementary bound gives

$$-\sum_{i\notin I} F_i|Z_i|^2 + 2\sum_{i\notin I} F_i|x_i|^2 \geq -\frac{54A^2 + 6nE_0^2}{\delta} KF_1 - 6q^2\sum_{i\notin I} F_i|a_i|^2.$$

Apply the derivative-absorption lemma, with penalty r on I and zero outside it; adding the unused negative $(9q^2+2q)|a_i|^2$ on I, and $(3q^2+2q)|a_i|^2$ off I, only decreases its input. The constants in its fixed-comparison error and the high-index rE_0^2 error are bounded independently of A, δ. Enlarge C_* to include them. We obtain

$$0 \geq \frac{Q}{32K} - \frac{54A^2 + 6nE_0^2}{\delta} KF_1 + (A - C_*)\mathcal{F} - 3Af_1.$$

Take $A \geq \max\{1, C_* + 1\}$, then fix the displayed δ and the threshold $L_0(A)$. Both case inequalities now satisfy the hypotheses of the conditional eigenvalue proposition, with fixed data. Hence $\lambda_1 \leq CK$ at the maximum point. Finally Φ, Ψ, χ have oscillations bounded independently of K and of derivatives of v. Comparing G at any other point with its maximum gives the same bound for λ_1 everywhere. Since $S \leq n\lambda_1$, this proves the trace estimate. □

Corollary 12.3.1 *Under the hypotheses of the proposition, one has*

$$\sup_X |\partial u|_g + \sup_X |\partial\bar{\partial} u|_g \leq C,$$

with a constant depending on the same fixed data and no derivatives of v.

Proof The Hessian density is $F(W)^m \leq f_1^m$. Apply the trace-to-gradient blowup proposition to the fixed background $\theta = \omega$ and the preceding trace estimate. It gives the uniform gradient bound. The trace is then uniformly bounded, and the Γ_2 identity bounds the absolute value of every eigenvalue of W by its trace. Subtracting the identity matrix gives the complex-Hessian bound. □

The bound controls the complex Hessian. An estimate for all entries of the real Hessian is not needed: the Euclidean Laplacian supplies finite L^p estimates for those derivatives.

12.4 Bounded complex Hessians and elliptic extensions

Uniform complex-Hessian bounds give enough compactness both to pass the nonlinear products to a limit and to make the Hessian root uniformly elliptic. In coordinates use the metric matrix g of the preceding section and write $H(u) = (u_{i\bar{j}})$. Coefficient products with bounded measurable factors will be identified with currents by convolution.

Lemma 12.4.1 *Suppose u_j is smooth,*

$$\sup_j \big(\|u_j\|_\infty + \|\mathrm{dd^c} u_j\|_{L^\infty}\big) < \infty, \qquad u_j \longrightarrow u \quad \text{uniformly on } X.$$

Then $u \in W^{2,p}(X)$ for every $1 < p < \infty$, its distributional complex Hessian has bounded coefficients, and $u_j \to u$ in $C^{1,\alpha}(X)$ for every $0 < \alpha < 1$. The same hypotheses give uniform $W^{2,p}$ bounds for the sequence.

Proof On a coordinate ball the Euclidean Laplacian is $\Delta u_j = 4\sum_i (u_j)_{i\bar{i}}$, so it is uniformly bounded. The interior Laplace estimate on two nested balls gives

$$\|u_j\|_{W^{2,p}(B')} \le C_p\big(\|\Delta u_j\|_{L^p(B)} + \|u_j\|_{L^p(B)}\big).$$

A finite cover gives the global bound. Weak $W^{2,p}$ limits coincide with the uniform limit. The bounded complex Hessians have weak-star limits in L^∞; testing against compactly supported smooth functions identifies them with $H(u)$. Choose p with $1 - 2n/p > \alpha$. The compact Sobolev embedding into $C^{1,\alpha}$ gives convergence of subsequences. Every such limit is u, hence the whole sequence converges. This estimates the full real Hessian in every finite L^p space, without asserting that it is bounded. □

Lemma 12.4.2 *For $1 \le a \le k \le n$, suppose u_j^a and u^a satisfy the preceding lemma. Let θ_a be fixed smooth real $(1,1)$-forms. Then*

$$\bigwedge_{a=1}^{k} (\theta_a + \mathrm{dd^c} u_j^a) \longrightarrow \bigwedge_{a=1}^{k} (\theta_a + \mathrm{dd^c} u^a) \quad \text{as currents.}$$

The current on the right is the product of the almost-everywhere coefficients. No closedness or positivity of the θ_a is required. For each compactly supported smooth complementary test form η, the difference of its pairings is bounded by $C_\eta \max_a \|u_j^a - u^a\|_\infty$.

Proof Set $D_j^a = \mathrm{dd^c} u_j^a$ and $D^a = \mathrm{dd^c} u^a$. On a smaller coordinate ball, convolution gives smooth u_ϵ^a whose complex Hessians are uniformly bounded and converge to $H(u^a)$ in every finite L^p space. Their coefficient products consequently converge in finite L^p spaces. In particular the products of the D^a are closed currents, since their smooth approximants are closed.

Expand the smooth background factors and telescope each remaining product. Every difference has the form

$$\mathrm{dd^c}(u_j^a - u^a) \wedge T_j,$$

where T_j is a product of D_j^b and D^b with $b \neq a$. It has uniformly bounded coefficients and is closed. Local convolution, followed by strong convergence of its finite coefficient products, justifies integration by parts:

$$\left\langle \mathrm{dd^c}(u_j^a - u^a) \wedge T_j, \xi \right\rangle = \int (u_j^a - u^a)\, T_j \wedge \mathrm{dd^c}\xi.$$

Here ξ includes the chosen smooth background factors and the test form, so their derivatives are retained. The right-hand side has the asserted uniform bound. A finite partition of unity proves the claim on X. This argument also proves that the coefficient product is the distributional limit; it does not identify a separately defined bounded Hessian operator for all nonsmooth admissible functions. □

Lemma 12.4.3 *For $f_0 > 0$ and $L > 0$, assume the set*

$$K = \{A \in C_{n,m} : \operatorname{tr} A \le L,\ \sigma_m(A) \ge f_0^m\}$$

is nonempty. It is a compact subset of the interior, and there are $\vartheta, \Theta > 0$, depending only on n, m, f_0, L, such that

$$\vartheta I \le DF_A \le \Theta I \qquad (A \in K).$$

The function on all Hermitian matrices defined by

$$\widehat{F}(B) = \inf_{A \in K} \big(F(A) + \operatorname{tr}(DF_A(B - A))\big)$$

is concave, agrees with F on K, and satisfies, for $P \ge 0$,

$$\vartheta \operatorname{tr} P \le \widehat{F}(B + P) - \widehat{F}(B) \le \Theta \operatorname{tr} P.$$

Proof In the closed 2-cone,

$$\sum_i \lambda_i^2 = (\operatorname{tr} A)^2 - 2S_2(A) \le L^2.$$

Thus K is bounded and closed. Maclaurin gives $\sigma_j(A) \ge \sigma_m(A)^{j/m} \ge f_0^j$ for $j \le m$, so every matrix in K is in the interior. In a unitary eigenframe,

$$F_i = \frac{F^{1-m} S_{m-1}(\lambda|i)}{m\binom{n}{m}}, \qquad \frac{f_0}{m!L} \le F_i \le \frac{L^{m-1}}{n f_0^{m-1}}.$$

The lower bound is Lemma 12.1.3; the upper bound uses $|\lambda_i| \le L$ in the polynomial numerator and its positivity. These bounds give possible values of ϑ and Θ. Concavity places each tangent plane above F on the cone; the plane at B gives equality when $B \in K$. An infimum of affine functions is concave. Each plane increases under $P \ge 0$ by a number between the two displayed trace bounds; taking infima preserves these bounds. The same estimates give global Lipschitz continuity of $\widehat{F}$. □

To interpret this as a real elliptic operator, let $C(R)$ be the complex Hessian of the real quadratic function $q(x) = \frac{1}{2}x^{\mathsf{T}}Rx$, where $x \in \mathbb{R}^{2n}$. For $R \ge 0$, one has $C(R) \ge 0$ and $\operatorname{tr} C(R) = \operatorname{tr} R/4$. If $\mu I \le g(x) \le MI$, then

$$\mathcal{G}(x,R) = \widehat{F}\big(I + g(x)^{-1/2}C(R)g(x)^{-1/2}\big)$$

is uniformly elliptic on real symmetric matrices, with constants $\vartheta/(4M)$ and $\Theta/(4\mu)$. Its dependence on x satisfies on compact coordinate balls

$$|\mathcal{G}(x,R) - \mathcal{G}(y,R)| \le C|x-y|(1 + \|R\|).$$

These follow respectively from the trace bound and the smooth dependence of the positive matrix square root of the fixed metric.

We use the classical interior Evans–Krylov–Caffarelli estimate for a concave operator on all real symmetric matrices with fixed positive ellipticity constants and coefficient oscillation bounded by $C|x-y|^{\gamma}(1 + \|R\|)$, where $\gamma > 0$. A Hölder right-hand side then gives an interior $C^{2,\beta}$ estimate, for some $\beta > 0$. This estimate applies also to continuous viscosity solutions. The real extension just constructed satisfies these conditions. Once its solution is $C^{2,\beta}$ and the attained complex Hessians remain in a compact subset of the open cone, the original smooth Hessian operator and Schauder estimates give the higher derivatives.

We next identify the limit of the proper auxiliary equations that will be used for regularity.

Proposition 12.4.1 *Suppose $v_j \to \varphi$ uniformly on X, $h(x,t)$ is smooth on a fixed bounded interval containing their values, and smooth admissible u_j satisfy*

$$(\omega + \mathrm{dd^c}u_j)^m \wedge \omega^{n-m} = e^{u_j + h(x,v_j)}\omega^n.$$

Assume $u_j \to u$ uniformly and the complex Hessians of u_j are uniformly bounded. Then $\omega + \mathrm{dd^c}u$ is admissible almost everywhere and its coefficient product satisfies

$$(\omega + \mathrm{dd^c}u)^m \wedge \omega^{n-m} = e^{u + h(x,\varphi)}\omega^n.$$

On every coordinate ball u also solves the corresponding uniformly elliptic concave extension in the viscosity sense.

Proof The first lemma gives $u \in W^{2,p}$ for every finite p and a bounded complex Hessian. The matrices $A_j = I + g^{-1/2}H(u_j)g^{-1/2}$ converge weakly in L^2 to the analogous matrix A for u. Mazur's lemma gives convex combinations of tails converging strongly in L^2, hence almost everywhere along a subsequence. The pointwise

closed cone is convex, so $A \in C_{n,m}$ almost everywhere. The product lemma passes the equation to the limit as currents, since its right-hand side converges uniformly. Equality of the bounded densities then gives the equation almost everywhere.

The right-hand sides are bounded above and away from zero. The complex Hessian bound gives a uniform upper bound L for $\operatorname{tr} A_j$. Choose $f_0 > 0$ below all their normalized roots. Thus every A_j, and almost every A, belongs to the compact set K of the preceding lemma. Every u_j is a classical solution of

$$\mathcal{G}(x, D^2 u_j) = r_j(x), \qquad r_j(x) = e^{(u_j + h(x, v_j))/m}.$$

For completeness, if a smooth test q touches u from above at an interior point x_0, add a small positive quartic term to make the local contact strict. Local maximum points of $u_j - q$ tend to x_0. At these points $D^2 u_j \le D^2 q$, and ellipticity gives $\mathcal{G}(x, D^2 q) \ge r_j(x)$. Pass to the limit, then remove the quartic term. A test from below gives the reverse inequality. The extension is defined on every real Hessian, so no admissibility of a lower test has been assumed. This proves the viscosity statement.□

12.5 Proper equations and admissible approximation

For a smooth potential write $H_m(w) = (\omega + \mathrm{dd^c} w)^m \wedge \omega^{n-m}$. The positive exponential coefficient controls additive constants by the maximum principle. The resulting smooth equations will also construct admissible approximations of bounded potentials, before any continuous Hessian product is defined.

Lemma 12.5.1 *For every $a > 0$ and smooth real H on X, there is a unique smooth strictly admissible solution of*

$$H_m(w) = e^{aw + H} \omega^n.$$

It satisfies

$$-\frac{\max_X H}{a} \le w \le -\frac{\min_X H}{a}.$$

Proof At a maximum of w, the admissible form $\omega + \mathrm{dd^c} w$ is at most ω, hence $e^{aw+H} \le 1$ there. At a minimum it is at least ω, and the reverse inequality holds. These give the bounds. For two solutions, a positive maximum of their difference would imply $H_m(w_1) \le H_m(w_2)$ there, contradicting the exponential factor. This proves uniqueness.

First take $a = 1$ and use the path $H_m(w_t) = e^{w_t + tH} \omega^n$, starting with $w_0 = 0$. The trace estimate of Proposition 12.3.2 applies with prescribed potential $v = 0$, fixed smooth comparison 0, and $h(x, v) = tH(x)$; its constants are uniform for $t \in [0, 1]$. Proposition 12.2.1 then gives a uniform gradient and complex-Hessian bound. Lemma 12.4.1 gives uniform $W^{2,p}$ and hence $C^{1,\alpha}$ bounds, for any fixed $\alpha < 1$. Consequently $r_t = e^{(w_t + tH)/m}$ has a uniform Hölder bound.

The extension of Lemma 12.4.3 is uniformly elliptic and concave on all real Hessians, with coefficient oscillation bounded by $C|x-y|(1+\|R\|)$. The analytic estimate recalled in Section 12.4 therefore gives uniform $C^{2,\beta}$ bounds on a finite cover. The original smooth Hessian operator is uniformly elliptic near the attained compact cone set. Differentiating and applying Schauder estimates gives bounds for every higher derivative.

The linearization of $\log(H_m(w)/\omega^n) - w - tH$ is $L_w - 1$, where

$$L_w\xi = \frac{m\mathrm{dd^c}\xi \wedge (\omega + \mathrm{dd^c}w)^{m-1} \wedge \omega^{n-m}}{H_m(w)}.$$

Its principal coefficients are positive definite. The maximum principle gives zero kernel; smooth elliptic Fredholm theory gives surjectivity and Schauder inversion. The implicit-function theorem proves openness. The uniform estimates prove closedness, so the path reaches $t = 1$. For general a, use the metric $a\omega$ and potential $\widehat{w} = aw$. Both sides of its coefficient-one equation acquire the same factor a^n, so it is exactly the stated equation after division by that factor. □

An ordinary smooth approximation need not be admissible. To obtain an admissible one, choose a smooth obstacle above the continuous potential and penalize the solution's distance from that obstacle.

Lemma 12.5.2 *Every continuous admissible φ on X is the uniform limit of smooth strictly admissible functions.*

Proof Fix a smooth $h \geq \varphi$ and a constant

$$b > \max\{1, \|H_m(h)/\omega^n\|_\infty\}.$$

For each positive integer N solve, by the preceding lemma,

$$H_m(w_N) = be^{N(w_N - h)}\omega^n.$$

At a positive maximum of $w_N - h$, the form $\omega + \mathrm{dd^c}h$ lies above the strictly admissible form $\omega + \mathrm{dd^c}w_N$, hence is admissible there. Monotonicity would give $be^{N(w_N-h)} \leq H_m(h)/\omega^n < b$, a contradiction. Thus $w_N \leq h$. The preceding zero-order estimate also gives

$$\|w_N\|_\infty \leq M_N := \|h\|_\infty + \frac{\log b}{N}.$$

Let x_N maximize $\varphi - (1+N^{-1})w_N$. The smooth positive form $T_N = (\omega + \mathrm{dd^c}w_N)^{m-1} \wedge \omega^{n-m}$ defines a strictly elliptic linear operator. Admissibility gives $(\omega + \mathrm{dd^c}\varphi) \wedge T_N \geq 0$ in distributions. Its linear maximum principle, applied to the upper test $(1+N^{-1})w_N$ plus the maximum value, gives at x_N

$$0 \leq \left(\omega + (1+N^{-1})\mathrm{dd^c}w_N\right) \wedge T_N.$$

This application is to a continuous distributional subsolution of a smooth strictly elliptic operator. It does not assume a second derivative of φ. Writing $d_N = H_m(w_N)/\omega^n$, polarized Gårding positivity yields

$$(N+1)d_N \geq \omega \wedge T_N/\omega^n \geq d_N^{(m-1)/m}.$$

Therefore, at this maximum point,

$$w_N - h \geq -E_N, \qquad E_N = \frac{m\log(N+1) + \log b}{N}.$$

Since $\varphi \leq h$, the maximum of $\varphi - (1+N^{-1})w_N$ is at most $E_N + M_N/N$. It follows on all of X that

$$\varphi - E_N - 2M_N/N \leq w_N \leq h.$$

Given $\delta > 0$, choose an ordinary smooth majorant $\varphi \leq h \leq \varphi + \delta$, and then N so large that $E_N + 2M_N/N \leq \delta$. The resulting w_N is strictly admissible and within δ of φ. Let $\delta \downarrow 0$. No monotonicity of the chosen approximants is needed. □

12.5.1 Decreasing approximation of bounded potentials

Upper semicontinuity supplies smooth obstacles decreasing to a bounded potential. The same penalty equation gives admissible functions between the potential and each obstacle, up to an error tending to zero. Choosing successive obstacles below the preceding smooth approximation makes the admissible approximations decrease as well.

Lemma 12.5.3 *Every bounded upper semicontinuous real function u on X is the pointwise decreasing limit of smooth functions $h_j > u$.*

Proof Fix a Riemannian distance d on X and put

$$c_j(x) = \sup_{y\in X}\{u(y) - jd(x,y)\}.$$

Each c_j is Lipschitz, $c_j \geq u$, and $c_{j+1} \leq c_j$. The supremum is attained. If y_j attains it at a fixed x, then $jd(x,y_j) \leq \sup_X u - u(x)$, so $y_j \to x$. Upper semicontinuity gives $\limsup_j c_j(x) \leq u(x)$, and hence $c_j \downarrow u$ pointwise.

Set $\delta_j = 4^{-j}$. Smooth approximation of continuous functions on a compact manifold gives $s_j \in C^\infty(X)$ with $\|s_j - c_j\|_\infty \leq \delta_j/4$. Take $h_j = s_j + \delta_j$. Then

$$u + \tfrac{3}{4}\delta_j \leq h_j \leq c_j + \tfrac{5}{4}\delta_j, \qquad h_{j+1} \leq c_j + \tfrac{5}{16}\delta_j < c_j + \tfrac{3}{4}\delta_j \leq h_j.$$

The bounds also imply $h_j(x) \to u(x)$ at every point. □

Lemma 12.5.4 *Let u be bounded admissible and $h \geq u$ smooth. Choose*

$$b > \max\{1, \|H_m(h)/\omega^n\|_\infty\}.$$

For each positive integer N, let w_N be the smooth strictly admissible solution of

$$H_m(w_N) = be^{N(w_N - h)}\omega^n.$$

With

$$M_N = \|h\|_\infty + \frac{\log b}{N}, \qquad E_N = \frac{m\log(N+1) + \log b}{N},$$

one has $\|w_N\|_\infty \leq M_N$ and

$$u - E_N - 2M_N/N \leq w_N \leq h.$$

Proof Existence follows from Lemma 12.5.1. The maximum comparison with h in the proof of Lemma 12.5.2 gives $w_N \leq h$; it involves only the smooth obstacle and solution. The zero-order bound from Lemma 12.5.1 gives $\|w_N\|_\infty \leq M_N$.

The upper semicontinuous function $u - (1 + N^{-1})w_N$ attains its maximum at some x_N. The smooth function $(1 + N^{-1})w_N$ plus this maximum is an upper test for u there. Put

$$T_N = (\omega + \mathrm{dd}^c w_N)^{m-1} \wedge \omega^{n-m}, \qquad d_N = H_m(w_N)/\omega^n > 0.$$

Condition (12.2) and polarized positivity yield, at x_N,

$$(N+1)d_N \geq \omega \wedge T_N/\omega^n \geq d_N^{(m-1)/m}.$$

Consequently $d_N \geq (N+1)^{-m}$ and $w_N - h \geq -E_N$ there. Using $u \leq h$, the maximum is at most $E_N + M_N/N$. On all of X this gives

$$u \leq (1 + N^{-1})w_N + E_N + M_N/N \leq w_N + E_N + 2M_N/N.$$

Theorem 12.5.1 *Every bounded admissible potential u on X is the pointwise decreasing limit of smooth strictly admissible potentials. The sequence may be chosen uniformly bounded.*

Proof Choose smooth $h_k \downarrow u$ by Lemma 12.5.3 and put $\varepsilon_j = 8^{-j}$. We construct smooth strictly admissible u_j with $u_j \geq u + \varepsilon_j$. For $j = 1$, take $k_1 = 1$. At a subsequent step choose $k_j \geq \max\{j, k_{j-1} + 1\}$ so large that

$$h_{k_j} < u_{j-1} - \tfrac{1}{2}\varepsilon_{j-1} \quad \text{on } X.$$

Such an index exists: the open sets $\{h_k < u_{j-1} - \varepsilon_{j-1}/2\}$ increase with k and cover X, since $h_k \downarrow u \leq u_{j-1} - \varepsilon_{j-1}$. Compactness gives a single index for all of X.

For this fixed obstacle h_{k_j} choose b_j as in Lemma 12.5.4, and then choose N_j so large that its error $E_{N_j} + 2M_{N_j}/N_j$ is at most ε_j. The resulting smooth solution w_j

satisfies

$$u - \varepsilon_j \le w_j \le h_{k_j}.$$

Put $u_j = w_j + 2\varepsilon_j$. Adding a constant preserves strict admissibility, and $u_j \ge u + \varepsilon_j$. For $j \ge 2$,

$$u_j \le h_{k_j} + 2\varepsilon_j < u_{j-1} - \tfrac{1}{2}\varepsilon_{j-1} + 2\varepsilon_j = u_{j-1} - \tfrac{1}{4}\varepsilon_{j-1}.$$

Finally, $u \le u_j \le h_{k_j} + 2\varepsilon_j$ and $k_j \ge j$ give pointwise convergence to u. The bounds $\inf_X u \le u_j \le \sup_X u_1$ give a common uniform bound. □

For continuous u, Dini's theorem makes these decreasing approximations converge uniformly on X. This is the convergence used for the continuous mixed products in the next section.

12.6 Continuous products, envelopes and domination

Uniform admissible approximation allows us to define the mixed Hessian products. Their local bounds retain the derivatives of the Hermitian background; closedness of the background is not required.

Proposition 12.6.1 *For continuous admissible $u_1, \dots, u_k$, $1 \le k \le m$, the current*

$$(\omega + \mathrm{dd^c} u_1) \wedge \cdots \wedge (\omega + \mathrm{dd^c} u_k) \wedge \omega^{n-m}$$

is well defined as the limit of uniform smooth admissible approximations. It is positive, local, and continuous when its potentials converge uniformly. Its local masses are bounded in terms of uniform bounds on the potentials. In particular $H_m(u)$ is a positive Radon measure.

Proof Lemmas 12.5.1 and 12.5.2 provide the smooth approximations without using any continuous Hessian product or domination input. For a smooth admissible u put $\sigma = \omega + \mathrm{dd^c} u$. Since $\mathrm{d}\sigma = \mathrm{d}\omega$, the coefficients of $\mathrm{dd^c}(\chi \sigma^{r-1} \wedge \omega^{n-r})$ are sums of smooth test factors paired with powers σ^q, $q \le r-1$, where χ is a fixed cutoff. The absolute-form lemma and integration by parts give the Chern–Levine–Nirenberg bound by induction on $r \le m$:

$$\int_K \sigma^r \wedge \omega^{n-r} \le C_{K,U,\omega}(1 + \|u\|_{L^\infty(U)})^r.$$

At the induction step write $\sigma^r = \omega \wedge \sigma^{r-1} + \mathrm{dd^c} u \wedge \sigma^{r-1}$, integrate the second term against χ, and move $\mathrm{dd^c}$ to $\chi \sigma^{r-1} \omega^{n-r}$. The resulting powers have degrees $r-1, r-2, r-3$, with negative powers absent, and the induction applies on nested slightly larger compact sets. Mixed masses reduce to the single potential average, by positivity of the expansion of its power. Positive mixed currents have total variation controlled by these trace masses.

To prove independence, telescope the difference between two smooth mixed products whose potentials have a common uniform bound. Each term paired with a fixed smooth complementary test is

$$\int \mathrm{dd^c}(u_a - v_a) \wedge T \wedge \eta = \int (u_a - v_a)\mathrm{dd^c}(T \wedge \eta),$$

where T is a product of the remaining admissible factors and ω^{n-m}. The identity $\mathrm{d}(\omega + \mathrm{dd^c}u) = \mathrm{d}\omega$ and its $\mathrm{d^c}$ analogue show that derivatives of T introduce only fixed metric derivatives; every term has at most $k - 1 < m$ admissible factors. The absolute mixed-form bound and the mass estimate just proved bound the variation of $\mathrm{dd^c}(T \wedge \eta)$ uniformly. Consequently the pairing difference is at most $C_\eta \max_a \|u_a - v_a\|_\infty$. The same construction with an arbitrary complementary smooth test also defines the signed products of fewer than m factors without the factor ω^{n-m}: their variation is bounded by the absolute-form lemma. These products justify the metric-derivative terms above. This proves that all approximations have the same limit and that the products are continuous in the uniform topology. Positivity passes from the smooth mixed products. Using a test supported in an open set on which two limiting potentials coincide proves locality by the same estimate on a smaller neighborhood of its support. □

Write $H_m(u)$ for the measure with every potential equal to u. Locality and uniform continuity of these products give comparison on a contact set.

Lemma 12.6.1 *If $u \le v$ are continuous admissible functions and the remaining $m - 1$ factors are fixed continuous admissible functions, then on $\{u = v\}$ the mixed measure with first factor $\omega + \mathrm{dd^c}u$ is at most the one with first factor $\omega + \mathrm{dd^c}v$. In particular $\mathbf{1}_{\{u=v\}} H_m(u) \le \mathbf{1}_{\{u=v\}} H_m(v)$.*

Proof Write $M(w)$ for the mixed measure with first potential w. Positivity and locality give, for $t > 0$,

$$M(\max(v, u + t)) \ge \mathbf{1}_{\{v>u+t\}} M(v) + \mathbf{1}_{\{u\ge v\}} M(u).$$

The first indicators increase to $\mathbf{1}_{\{v>u\}}$ as $t \downarrow 0$, and the potentials on the left converge uniformly to v. Integrate against nonnegative continuous tests and pass to the limit. Subtract the first restricted measure to obtain the claimed contact inequality. Replacing one factor at a time proves the pure-power claim and the analogous contact inequalities for all mixed powers. □

For a continuous real obstacle h, define $P(h)$ to be the supremum of continuous admissible functions bounded above by h. Constants make the family nonempty. The penalty construction also proves that this supremum is continuous and its Hessian measure lies on the contact set.

Lemma 12.6.2 *The function $P(h)$ is continuous and admissible, and $H_m(P(h))$ is supported on $\{P(h) = h\}$. Moreover $\|P(h_1) - P(h_2)\|_\infty \le \|h_1 - h_2\|_\infty$.*

Proof For smooth h, use the penalty solutions w_N in Lemma 12.5.2. Its maximum argument applies to every continuous admissible competitor $v \le h$, with an error depending on h and N, and not on v. Taking their supremum gives

$$P(h) - E_N - 2M_N/N \le w_N \le P(h),$$

where the error tends to zero. Thus $P(h)$ is their uniform limit and is continuous and admissible. On every compact subset of $\{P(h) < h\}$ the penalty densities $be^{N(w_N-h)}$ tend uniformly to zero. Product continuity implies the contact support assertion. Adding constants to competitors gives the stated Lipschitz bound. Approximate a continuous h uniformly by smooth obstacles. Their envelopes converge uniformly to $P(h)$, proving continuity and admissibility. Any compact subset of $\{P(h) < h\}$ also lies outside the contact sets of all sufficiently close smooth obstacles; product continuity gives the support assertion for h. □

The obstacle also bounds discontinuous competitors. Their upper-test admissibility suffices for the penalty estimate, so allowing them does not change the continuous envelope of a smooth obstacle.

Proposition 12.6.2 *For every smooth real obstacle h, the envelope $P(h)$ equals the pointwise supremum of all bounded admissible functions below h.*

Proof The solutions w_N of Lemma 12.5.4 are continuous admissible competitors, so $w_N \le P(h)$. For each bounded admissible $u \le h$, the same lemma gives

$$u \le w_N + E_N + 2M_N/N \le P(h) + E_N + 2M_N/N.$$

Let $N \to \infty$ for this fixed obstacle and fixed b. Thus $P(h)$ dominates every bounded competitor. Since $P(h)$ itself is a bounded competitor, it equals their supremum. □

The trace test in (12.1) gives $L_\omega u \ge -n$, where $L_\omega u = n\mathrm{dd}^{\mathrm{c}}u \wedge \omega^{n-1}/\omega^n$. We use the classical normalized Green estimate

$$\int_X (\sup_X u - u)\omega^n \le C_\omega \tag{12.3}$$

for continuous admissible u. The stationary probability of L_ω has a smooth positive density equivalent to ω^n. The positive measure $L_\omega u + n$ has stationary mass n, so the Green-kernel estimate gives this bound. It is a linear elliptic input, and does not assert compactness for a nonlinear Hessian measure.

To use envelopes in domination, we must first exclude a potential with zero total Hessian mass.

Lemma 12.6.3 *Every continuous admissible u satisfies $\int_X H_m(u) > 0$.*

Proof Suppose this integral is zero. For $s > 0$ put $w = \max(u, \min_X u + s)$ and $U = \{u < \min_X u + s\}$. The open set U is nonempty, $0 \le w - u \le s$, and $w = u$ outside it. Set $\sigma_u = \omega + \mathrm{dd}^{\mathrm{c}}u$, $\sigma_w = \omega + \mathrm{dd}^{\mathrm{c}}w$, and $\mu_q = \sigma_u^q \wedge \sigma_w^{m-q} \wedge \omega^{n-m}$. The

contact lemma gives $\mathbf{1}_{X\setminus U}\mu_q \geq \mathbf{1}_{X\setminus U}\mu_m$, for $0 \leq q \leq m$. For $q < m$ the telescoping identity is

$$\mu_q - \mu_m = \mathrm{dd^c}(w-u)\wedge T_q, \qquad T_q = \sigma_u^q \wedge \sum_{r=0}^{m-q-1} \sigma_w^r \wedge \sigma_u^{m-q-1-r} \wedge \omega^{n-m}.$$

Integration by parts on X therefore gives

$$\int_U (\mu_q - \mu_m) \leq \int_X (\mu_q - \mu_m) = \int_X (w-u)\mathrm{dd^c}T_q.$$

This identity follows first for smooth approximants and then by uniform product continuity. The derivatives of T_q contain only fixed metric derivatives and products of at most $m-1$ admissible factors, so the absolute-form lemma makes $\mathrm{dd^c}T_q$ a measure of uniformly controlled variation. Uniform convergence also justifies its continuous weight. On U, locality gives $\sigma_w = \omega$ and thus

$$|\mathrm{dd^c}T_q| \leq C\sum_{r=0}^{m-1}\mu_r.$$

The constant depends only on the metric and m, n, and not on u or s. Consequently

$$\sum_{q=0}^{m}\int_U \mu_q \leq (m+1)\int_U H_m(u) + Cms\sum_{r=0}^{m-1}\int_U \mu_r.$$

For sufficiently small s, absorption and $H_m(u) = 0$ force all these nonnegative integrals to vanish. But $\mu_0 = \omega^n$ on the nonempty open set U, a contradiction. □

The envelope of a stretched difference now converts vanishing of a restricted measure into an order relation. The linear bound (12.3) prevents these envelopes from tending to $-\infty$ on an open set.

Proposition 12.6.3 *If continuous admissible u, v satisfy $\mathbf{1}_{\{u<v\}}H_m(u) = 0$, then $u \geq v$.*

Proof Replace v by $\max(u, v)$, so $u \leq v$. For $b > 1$ put $p_b = P(bu - (b-1)v)$ and $z_b = b^{-1}p_b + (1-b^{-1})v \leq u$. On the contact set $C_b = \{p_b = bu - (b-1)v\}$ one has $z_b = u$; the contact inequality and polarized positivity give

$$\mathbf{1}_{C_b}b^{-m}H_m(p_b) \leq \mathbf{1}_{C_b}H_m(z_b) \leq \mathbf{1}_{C_b}H_m(u).$$

The envelope measure is supported on C_b and has positive mass. It vanishes on $C_b \cap \{u < v\}$ by the hypothesis, so some point of $C_b \cap \{u = v\}$ exists. Hence $\sup_X p_b \geq \inf_X v$, while $p_b \leq u$. The estimate (12.3) is consequently uniform for p_b. On the open set $E_a = \{u < v - a\}$, for $a > 0$, one has $p_b \leq v - ba$, and therefore

$$C_\omega \geq \int_X (\sup_X p_b - p_b)\omega^n \geq (ba - \operatorname{osc}_X v)\int_{E_a} \omega^n.$$

Letting $b \to \infty$ gives zero volume for E_a. Since it is open it is empty, and $a \downarrow 0$ gives $u \geq v$. □

Proposition 12.6.4 *If continuous admissible u, v satisfy*

$$\mathbf{1}_{\{u<v\}} H_m(u) \leq c\mathbf{1}_{\{u<v\}} H_m(v), \qquad 0 \leq c < 1,$$

then $u \geq v$.

Proof Choose $b > 1$ so that $(1 - b^{-1})^m > c$, and put $p = P(bu - (b-1)v)$ and $z = b^{-1}p + (1 - b^{-1})v \leq u$. On $C = \{p = bu - (b-1)v\}$ the contact comparison gives

$$\mathbf{1}_C\big(b^{-m}H_m(p) + (1 - b^{-1})^m H_m(v)\big) \leq \mathbf{1}_C H_m(u).$$

Restricting to $\{u < v\}$ and using the hypothesis shows that $H_m(p)$ vanishes on $C \cap \{u < v\}$. Its support lies in C, where $p < v$ is equivalent to $u < v$. Thus $H_m(p)$ vanishes on $\{p < v\}$. The preceding domination proposition gives $p \geq v$. Since $p \leq bu - (b-1)v$, it follows that $u \geq v$. □

Strict domination yields the comparison needed for the proper equations.

Lemma 12.6.4 *For continuous admissible u, v and $a > 0$, if*

$$e^{-av} H_m(v) \geq e^{-au} H_m(u),$$

then $u \geq v$.

Proof Fix $\delta > 0$. On $\{u < v - \delta\}$, the assumed inequality gives

$$H_m(u) \leq e^{a(u-v)} H_m(v) \leq e^{-a\delta} H_m(v - \delta).$$

The constant $e^{-a\delta}$ is strictly smaller than one, so Proposition 12.6.4 applied to u and $v - \delta$ gives $u \geq v - \delta$. Letting $\delta \downarrow 0$ proves the assertion. □

12.7 Continuous equations and regularity

The proper equation is stable in the uniform norm, so its smooth solutions extend to continuous data. This also identifies the limit of the auxiliary equations with a prescribed continuous weak solution.

Proposition 12.7.1 *Let $a > 0$ and let smooth H_j converge uniformly to a continuous H. The smooth solutions of $H_m(w_j) = e^{aw_j+H_j}\omega^n$ converge uniformly to the unique continuous admissible solution of $H_m(w) = e^{aw+H}\omega^n$. For two continuous data H_1, H_2, the corresponding solutions satisfy*

$$\|w_1 - w_2\|_\infty \le a^{-1}\|H_1 - H_2\|_\infty.$$

They also satisfy $-\max_X H/a \le w \le -\min_X H/a$.

Proof Smooth solutions exist by Lemma 12.5.1. At a maximum of $w_1 - w_2$, monotonicity of the smooth Hessian operator gives $e^{aw_1+H_1} \le e^{aw_2+H_2}$. Hence $a(w_1 - w_2) \le H_2 - H_1$ there. Exchanging the functions gives the stated norm estimate for smooth data. Thus a uniformly convergent sequence of smooth data gives a uniformly Cauchy sequence of solutions. Its limit is admissible by the linear distributional inequalities, and Proposition 12.6.1 passes the equation to the limit. The bounds follow from those for the smooth solutions. Taking limits in the smooth norm estimate proves it for continuous data. Finally, Lemma 12.6.4 in both directions gives uniqueness among continuous admissible solutions. □

For smooth positive densities depending on the potential, the estimate of Section 12.3 gives complex-Hessian bounds independent of derivatives of the prescribed approximation. The elliptic extension then upgrades the continuous solution to a classical one.

Theorem 12.7.1 *If φ is continuous and admissible on X, $f(x,t)$ is smooth on a neighborhood of its bounded range, and*

$$H_m(\varphi) = e^{f(x,\varphi)}\omega^n,$$

then φ is smooth.

Proof Choose smooth admissible $v_j \to \varphi$ uniformly, by Lemma 12.5.2. Their values lie in a fixed compact interval on which f is smooth. Put $h(x,t) = -t + f(x,t)$ and solve

$$H_m(u_j) = e^{u_j+h(x,v_j)}\omega^n.$$

The preceding stability proposition shows that u_j converges uniformly to a continuous admissible u satisfying

$$e^{-u}H_m(u) = e^{-\varphi+f(x,\varphi)}\omega^n = e^{-\varphi}H_m(\varphi).$$

Lemma 12.6.4, applied in both directions, gives $u = \varphi$.

The zero-order bounds for u_j are uniform. Fix M bounding them and choose $B > \|\varphi\|_\infty + 1$. Extend h smoothly away from a neighborhood of the range of φ to $X \times [-B-1, B+1]$; this does not change the equations for large j. The tolerance ε in Proposition 12.3.2 depends on these bounds and on h, without derivatives of the smooth comparison function. Choose a fixed smooth $\widetilde{\varphi}$ with $\|\widetilde{\varphi} - \varphi\|_\infty < \varepsilon/2$ and $\|\widetilde{\varphi}\|_\infty \le B$. For large j, $\|v_j - \widetilde{\varphi}\|_\infty < \varepsilon$. Corollary 12.3.1 then gives uniform gradient

and complex-Hessian bounds for u_j, independent of derivatives of v_j. Lemma 12.4.1 yields $\varphi \in W^{2,p}$ for every finite p, and $\varphi \in C^{1,\alpha}$ for every $\alpha < 1$.

Proposition 12.4.1 makes φ a continuous viscosity solution of the concave uniformly elliptic extension, with right-hand side $e^{f(x,\varphi)/m}$. This right-hand side is Hölder. The analytic estimate in Section 12.4 therefore gives $\varphi \in C^{2,\beta}$, for some $\beta > 0$. The operator agrees with the original Hessian root on the attained compact cone set; the now classical equation thus has smooth dependence on x, φ and its complex Hessian, and is uniformly elliptic there. Difference quotients and interior Schauder estimates give $C^{3,\beta}$; iteration proves smoothness. The estimate applies directly to the viscosity limit. □

The proper equation can now be solved when its exponent depends smoothly on the unknown potential, provided that constant barriers bound the desired range and the dependence is strictly increasing.

Theorem 12.7.2 *Let $A < B$ and let f be smooth on a neighborhood of $X \times [A, B]$. Suppose that, for every $x \in X$,*

$$f(x, A) \le 0 \le f(x, B), \qquad 0 < \kappa \le \partial_t f(x, t) \le L \quad (A \le t \le B).$$

There is a unique continuous admissible solution with values in $[A, B]$ of

$$H_m(w) = e^{f(x,w)}\omega^n.$$

This solution is smooth and strictly admissible.

Proof Choose $a \ge L$ and let $C = \{v \in C(X) : A \le v \le B\}$, a complete subset of $C(X)$ in the uniform norm. For $v \in C$ put $H_v(x) = f(x, v(x)) - av(x)$ and let $T(v)$ be the continuous proper solution with exponent $aT(v) + H_v$, furnished by Proposition 12.7.1. The function $f(x, t) - at$ is nonincreasing in t, so

$$-aB \le f(x, B) - aB \le H_v(x) \le f(x, A) - aA \le -aA.$$

The zero-order bounds in that proposition give $A \le T(v) \le B$. The mean-value theorem also gives

$$\|H_v - H_z\|_\infty \le (a - \kappa)\|v - z\|_\infty, \qquad \|T(v) - T(z)\|_\infty \le (1 - \kappa/a)\|v - z\|_\infty.$$

Since $0 \le 1 - \kappa/a < 1$, the contraction theorem gives a unique fixed point $w \in C$. It is admissible because it equals $T(w)$, and its equation is exactly the stated equation. Every continuous admissible solution in this interval is a fixed point, by uniqueness of the continuous proper equation with its prescribed H_w. This proves uniqueness in the stated class. Theorem 12.7.1 makes w smooth. Its form lies in the closed m-cone and has positive mth symmetric polynomial; Maclaurin's inequalities then put it in the open cone. Thus it is strictly admissible. □

12.8 Bounded potentials and recursive Hessian currents

The decreasing approximation of bounded admissible potentials supplies limits that uniform approximation cannot reach. A bounded potential can multiply a current with measure coefficients, so one can apply $\mathrm{dd^c}$ to the resulting current. Repeating this operation requires bounds on every coefficient, rather than only on the trace of a positive mixed measure. The absolute-form estimate provides these bounds below degree m; at degree m, positivity is obtained after wedging with ω^{n-m}.

All bounded potentials have their canonical upper semicontinuous representatives from (12.2). Their pointwise values will be used when multiplying measure coefficients. For a real current T of order zero, write $\|T\|_K$ for the sum of the total variations of its coefficients on a compact coordinate set K. Fix $K \Subset U$ in a coordinate chart. Different fixed coordinate frames give equivalent local bounds.

Lemma 12.8.1 *If u is bounded admissible, then $\mathrm{dd^c}u$ has signed Radon measure coefficients. For $K \Subset U$ contained in a coordinate chart,*

$$\|\mathrm{dd^c}u\|_K \le C_{K,U,\omega}(1 + \|u\|_{L^\infty(X)}).$$

Proof Choose smooth strictly admissible $u_j \downarrow u$ by Theorem 12.5.1, and put $\sigma_j = \omega + \mathrm{dd^c}u_j$. After discarding finitely many terms, $\|u_j\|_\infty \le \|u\|_\infty + 1$. Indeed, the increasing open sets $\{u_j < \sup_X u + 1\}$ cover X, and compactness gives a single index whose open set is all of X; the lower bound follows from $u_j \ge u$.

The closed m-cone lies in the closed 2-cone. In an ω-unitary frame, its eigenvalues satisfy

$$\sum_i \lambda_i^2 \le (\operatorname{tr}\sigma_j)^2, \qquad \operatorname{tr}\sigma_j \ge 0.$$

Thus every coefficient of σ_j is bounded by its trace. The degree-one Chern–Levine–Nirenberg estimate in Proposition 12.6.1, applied to these smooth functions, bounds the integral of that trace on K by $C(1 + \|u\|_\infty)$. Subtracting the fixed smooth ω gives the same bound for the coefficient variations of $\mathrm{dd^c}u_j$. Bounded convergence gives $u_j \to u$ in local L^1, and therefore $\mathrm{dd^c}u_j \to \mathrm{dd^c}u$ in distributions. The uniform coefficient bounds show that this limit has measure coefficients with the asserted bound. □

Set $D_0 = 1$. For an ordered list $u_1, \dots, u_p$ of bounded admissible potentials, define recursively

$$D_p(u_1, \dots, u_p) = \mathrm{dd^c}\big(u_p D_{p-1}(u_1, \dots, u_{p-1})\big). \tag{12.4}$$

The next result justifies the bounded multiplication at every step up to $p = m$.

Proposition 12.8.1 *For $1 \le p < m$, the recursion defines a real closed current of order zero and bidegree (p,p). If $M = \max_a \|u_a\|_{L^\infty(X)}$, then*

$$\|D_p(u_1,\dots,u_p)\|_K \le C_{K,U,\omega,p}(1+M)^p.$$

For $p = m$, it defines a real closed distributional current. For any smooth admissible sequences $u_a^{j_a} \downarrow u_a$ with a common uniform bound, one has

$$D_p(u_1,\dots,u_p) = \lim_{j_p\to\infty} \cdots \lim_{j_1\to\infty} \mathrm{dd^c} u_1^{j_1} \wedge \cdots \wedge \mathrm{dd^c} u_p^{j_p} \tag{12.5}$$

in distributions. The index j_1 tends to infinity first. Below degree m, all these limits have locally uniformly bounded coefficient variations.

Proof The case $p = 1$ is the preceding lemma. Suppose the assertions hold through degree $p-1 < m$. Since u_p is bounded Borel and D_{p-1} has measure coefficients, their product is well defined. Applying $\mathrm{dd^c}$ gives a real current that is both d- and $\mathrm{d^c}$-closed.

For a fixed smooth complementary test form η, dominated convergence against the fixed signed measures gives

$$\begin{aligned}\langle D_p,\eta\rangle &= \langle u_p D_{p-1}, \mathrm{dd^c}\eta\rangle \\ &= \lim_{j_p\to\infty} \langle u_p^{j_p} D_{p-1}, \mathrm{dd^c}\eta\rangle.\end{aligned}$$

With j_p fixed, the inductive iterated limit for D_{p-1} can be paired with the smooth form $u_p^{j_p}\,\mathrm{dd^c}\eta$. Integration by parts for the smooth closed factors identifies the resulting pairing with the smooth product on the right of (12.5). This proves that identity also when $p = m$.

For $p < m$, expand the smooth product using $\mathrm{dd^c} u_a^{j_a} = \sigma_a^{j_a} - \omega$. A term with q admissible factors, $0 \le q \le p$, has the form

$$\sigma_{a_1}^{j_{a_1}} \wedge \cdots \wedge \sigma_{a_q}^{j_{a_q}} \wedge \omega^{p-q}.$$

Every such q is strictly less than m. Apply Lemma 12.1.5 to each coefficient test, and then the smooth mass estimate from Proposition 12.6.1 to the potential sum. The term $q = 0$ is the fixed smooth form ω^p. For $q \ge 1$, the sum of its admissible forms is $q(\omega + \mathrm{dd^c}\bar u)$, where $\bar u$ is their average and $\|\bar u\|_\infty \le M + 1$. The result is a coefficient variation bound $C(1+M)^p$, after choosing the approximations with norm at most $M+1$ as in the preceding proof. For arbitrary uniformly bounded approximations the same argument uses their common bound. The bounds survive each distributional limit, proving that D_p has order zero and the stated estimate. This completes the induction. No coefficient bound for the unwedged degree-m current is used or asserted. □

For a subset $I = \{i_1 < \cdots < i_q\} \subset \{1, \ldots, p\}$, write $D_I = D_q(u_{i_1}, \ldots, u_{i_q})$, with $D_\varnothing = 1$. Define the shifted current and its mixed positive current by

$$R_p(u_1, \ldots, u_p) = \sum_{I \subset \{1,\ldots,p\}} \omega^{p-|I|} \wedge D_I, \qquad Q_p = R_p \wedge \omega^{n-m}. \tag{12.6}$$

Below degree m, R_p has measure coefficients. At degree m it is initially a distributional current. Its positive wedge Q_m is nevertheless a measure.

Put $M = \max_a \|u_a\|_{L^\infty(X)}$.

Theorem 12.8.1 *For $1 \le p \le m$, Q_p is a positive current of order zero, and*

$$\int_K Q_p \wedge \omega^{m-p} \le C_{K,U,\omega,p}(1 + M)^p.$$

It is the iterated limit, in the order of (12.5), of

$$(\omega + \mathrm{dd^c} u_1^{j_1}) \wedge \cdots \wedge (\omega + \mathrm{dd^c} u_p^{j_p}) \wedge \omega^{n-m}.$$

In particular Q_m is a positive Radon measure. These currents are local in the canonical potentials and independent of the chosen approximations for the fixed ordering. When all potentials are continuous, Q_p equals the continuous mixed product of Proposition 12.6.1.

Proof Expand the smooth shifted product over its subsets. Applying (12.5) to each subset, in its inherited ordering, gives (12.6). The absent indices have no effect on a subset's limit.

Each smooth product is positive: pairing with a decomposable strongly positive complementary test appends $m - p$ nonnegative rank-one $(1,1)$-forms, and polarized Gårding positivity applies. The smooth mixed mass bound is uniform in all indices. Distributional limits preserve positivity and the local trace bound at every step. Positive currents have order zero, so this gives the assertions for Q_p, including the top-degree measure.

The recursion uses only bounded multiplication of canonical values and local distributional differentiation. It is therefore local. Its definition contains no approximation choices, so the proved limit is independent of those choices while the ordering is fixed. For continuous potentials, the approximations converge uniformly by Dini's theorem. The telescoping estimate in Proposition 12.6.1 is uniform in all remaining indices and shows that their iterated limit is the same continuous mixed product. This also proves permutation invariance in the continuous case. □

The shifted currents are not closed. Their derivatives can be stated without multiplying a discontinuous function by a distribution of positive order. This is the torsion identity needed before considering integration by parts with bounded weights.

Proposition 12.8.2 *Write $R^{\widehat{a}}_{p-1}$ for the shifted current obtained by omitting u_a, in the inherited order, and use two hats for two omissions. Put $R_0 = 1$. For $1 \le p \le m$,*

$$\begin{aligned} \mathrm{d}R_p &= \mathrm{d}\omega \wedge \sum_{a=1}^{p} R^{\widehat{a}}_{p-1}, \\ \mathrm{d}^{\mathrm{c}}R_p &= \mathrm{d}^{\mathrm{c}}\omega \wedge \sum_{a=1}^{p} R^{\widehat{a}}_{p-1}, \\ \mathrm{d}\mathrm{d}^{\mathrm{c}}R_p &= \mathrm{d}\mathrm{d}^{\mathrm{c}}\omega \wedge \sum_{a=1}^{p} R^{\widehat{a}}_{p-1} + 2\,\mathrm{d}\omega \wedge \mathrm{d}^{\mathrm{c}}\omega \wedge \sum_{a<b} R^{\widehat{a}\widehat{b}}_{p-2}. \end{aligned}$$

The last sum is absent for $p = 1$. All currents on the right have order zero. If all but at most one potential are smooth, R_p is independent of the ordering and is the ordinary product of the smooth factors with $\omega + \mathrm{d}\mathrm{d}^{\mathrm{c}}u$.

Proof Every D_I is both d- and d^{c}-closed. Differentiating (12.6) therefore gives

$$\mathrm{d}R_p = \mathrm{d}\omega \wedge \sum_{I} (p - |I|)\omega^{p-|I|-1} \wedge D_I,$$

with zero terms omitted. The coefficient $p - |I|$ counts the omitted indices outside I, which proves the first formula; the second is identical with d^{c} in place of d. Apply d to the second formula. Each pair of omitted indices occurs twice, and $-\mathrm{d}^{\mathrm{c}}\omega \wedge \mathrm{d}\omega = \mathrm{d}\omega \wedge \mathrm{d}^{\mathrm{c}}\omega$ because both forms have odd degree three. This gives the displayed $\mathrm{d}\mathrm{d}^{\mathrm{c}}$ formula, with every background derivative retained.

If all but one potential are smooth, applying $\mathrm{d}\mathrm{d}^{\mathrm{c}}$ to the bounded potential times a smooth closed product gives its $\mathrm{d}\mathrm{d}^{\mathrm{c}}$ wedged with that product. At later smooth steps, closedness again makes the recursion ordinary smooth multiplication. This is independent of the position of the bounded potential, and the subset expansion gives the last assertion. □

Local capacity arguments naturally concern functions whose unshifted Hessian lies in the cone. On a coordinate ball U, call a bounded canonical function f *m-subharmonic relative to ω* if

$$\mathrm{d}\mathrm{d}^{\mathrm{c}}f \wedge \gamma_1 \wedge \cdots \wedge \gamma_{m-1} \wedge \omega^{n-m} \ge 0$$

for all smooth $\gamma_i \in \Gamma_m(\omega)$. Equivalently, its local upper tests q satisfy $\mathrm{d}\mathrm{d}^{\mathrm{c}}q \in \overline{\Gamma_m(\omega)}$. The same Hermitian form ω is used here and in the chapter's shifted admissibility.

Lemma 12.8.2 *Let U be a coordinate ball compactly contained in a holomorphic chart. There is a smooth strictly plurisubharmonic ρ on a neighborhood of $\overline{U}$ such that $\mathrm{dd^c}\rho \geq 2\omega$ and, for every bounded admissible u on X, $u + \rho$ is m-subharmonic relative to ω on U. Adding ρ to the approximations in Theorem 12.5.1 gives uniformly bounded smooth decreasing approximations in this local class.*

Proof Take $\rho = C|z|^2$ in the chart. On the fixed compact set $\overline{U}$, a sufficiently large C gives $\mathrm{dd^c}\rho \geq 2\omega$. An upper test q for $u + \rho$ at x gives the upper test $q - \rho$ for u there. Hence

$$\mathrm{dd^c}q = (\omega + \mathrm{dd^c}(q - \rho)) + (\mathrm{dd^c}\rho - \omega) \in \overline{\Gamma_m(\omega)},$$

since the second summand is positive and the cone is preserved by adding nonnegative forms. Smooth addition preserves the canonical representative. The same identity applies pointwise to every smooth admissible approximation. Adding a fixed smooth function preserves pointwise decrease and convergence, and its bounded norm on $\overline{U}$ preserves the common local bound. □

The correction is a local inclusion of classes. It leaves the metric in the cone tests unchanged. Although $\tau = \mathrm{dd^c}\rho$ is closed, $\tau - \omega$ has derivative $-\mathrm{d}\omega$, so the background terms in the preceding torsion identity remain present. In particular, $\omega + \mathrm{dd^c}u = \mathrm{dd^c}(u + \rho) + (\omega - \tau)$. Comparison of the unshifted Hessians of the corrected functions must therefore account for this smooth remainder.

Example 12.8.1 On the unit ball in $\mathbb{C}^3$, put $\beta_j = \mathrm{dd^c}|z_j|^2$, $\beta = \sum_{j=1}^3 \beta_j$ and

$$u = -\tfrac{1}{2}\sum_{j=1}^{3} |z_j|^2, \qquad v = -\tfrac{4}{5}|z_1|^2.$$

Both $\beta + \mathrm{dd^c}u$ and $\beta + \mathrm{dd^c}v$ are strictly positive, but

$$(\beta + \mathrm{dd^c}v)^2 \wedge \beta > (\beta + \mathrm{dd^c}u)^2 \wedge \beta, \qquad (\mathrm{dd^c}v)^2 \wedge \beta < (\mathrm{dd^c}u)^2 \wedge \beta.$$

Thus shifted Hessian order does not imply unshifted Hessian order, even for smooth potentials with positive perturbed forms.

Proof The eigenvalues of the two perturbed forms relative to β are $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ and $(\frac{1}{5}, 1, 1)$. For a diagonal form with relative eigenvalues $\lambda_1, \lambda_2, \lambda_3$, its second Hessian is $(\lambda_1\lambda_2 + \lambda_1\lambda_3 + \lambda_2\lambda_3)\beta^3/3$. Consequently the shifted measures of u, v are $\frac{1}{4}\beta^3$ and $\frac{7}{15}\beta^3$, while their unshifted expressions are $\frac{1}{4}\beta^3$ and 0. Their unshifted traces are negative, so neither original function belongs to the local unshifted class. Adding $\sum_j |z_j|^2$ gives an exact correction in this constant closed background. An exact correction $\mathrm{dd^c}\rho = \omega$ is impossible where $\mathrm{d}\omega \neq 0$. □

The iterated limit fixes the order of the potentials. Symmetry and simultaneous convergence require control of discontinuous weights against varying coefficient measures. The next section supplies the first-Hessian estimate for Theorem 12.9.1; the local Hessian capacities in Section 12.10 give the control in the remaining degrees.

12.9 Sobolev capacity and two Hessian factors

To multiply a varying coefficient measure by a bounded potential, weak convergence of the measures is not enough. We first control the sets on which a potential can be discontinuous. The linear trace of an admissible form supplies this control through Sobolev capacity. Its Gauduchon multiplier must be chosen in the conformal class of ω, since an admissible form need not be positive in every tangent direction.

Choose $\rho > 0$ by Theorem 4.1.1 and put

$$T = \rho\omega^{n-1}, \qquad \mathrm{d}\mathrm{d}^{\mathrm{c}}T = 0, \qquad A = \int_X \omega \wedge T > 0.$$

Write $H^1(X) = W^{1,2}(X, \mathbb{R})$ and use the equivalent Sobolev norm

$$\|f\|_{H^1}^2 = \int_X f^2\omega^n + \int_X \mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}}f \wedge T.$$

For an open set $G \subset X$ define

$$\mathrm{Cap}_1(G) = \inf\{\|f\|_{H^1}^2 : f \in H^1(X),\ f \geq 1 \text{ almost everywhere on } G\},$$

and for an arbitrary set E take the infimum over open $G \supset E$. Thus this capacity is defined by Sobolev energy; it is distinct from an m-Hessian capacity. Truncation allows $0 \leq f \leq 1$ in the infimum for open sets.

Lemma 12.9.1 *The capacity* Cap_1 *is countably subadditive. For a smooth real* f *and* $a > 0$*,*

$$\mathrm{Cap}_1(\{|f| > a\}) \leq a^{-2}\|f\|_{H^1}^2.$$

If a positive Radon measure μ *satisfies* $|\int_X \phi \,\mathrm{d}\mu| \leq C\|\phi\|_{H^1}$ *for every smooth real* ϕ*, then for every Borel set* E*,*

$$\mu(E) \leq C\,\mathrm{Cap}_1(E)^{1/2}.$$

Proof For open G_i choose Sobolev functions $0 \leq f_i \leq 1$ equal to one almost everywhere on G_i, with a summably small excess in their squared norms over the capacity infima. The Sobolev chain rule gives

$$\|\max_{i \leq N} f_i\|_{H^1}^2 \leq \sum_{i \leq N} \|f_i\|_{H^1}^2.$$

Indeed, almost everywhere the gradient of the maximum is the gradient of an active function, and the squared value is bounded by the sum of the squared values. If the sum is finite, these maxima converge in L^2, are bounded in H^1, and have a weak H^1 limit equal to one almost everywhere on $\bigcup_i G_i$. Lower semicontinuity proves subadditivity for open sets. Taking open supersets proves it for arbitrary sets. If the sum is infinite there is nothing to prove. The level-set estimate follows by testing with $\min\{1, |f|/a\}$ and the same Sobolev chain rule.

Fix a compact $K \subset G$ and a Sobolev competitor $0 \le f \le 1$ for the open set G. Positive local mollification and a partition of unity give smooth nonnegative $f_\epsilon \to f$ in H^1 that satisfy $f_\epsilon \ge 1$ on K for small ϵ: every convolution ball meeting K then lies in G, where $f = 1$ almost everywhere. The assumed estimate gives $\mu(K) \le C \lim_\epsilon \|f_\epsilon\|_{H^1} = C\|f\|_{H^1}$. Take the infimum over f and then the supremum over compact $K \subset G$ to obtain the estimate for G. Outer regularity and open supersets give it for every Borel E. □

Lemma 12.9.2 *Every bounded admissible u belongs to $H^1(X)$. Its trace*

$$\mu_u = (\omega + \mathrm{dd^c} u) \wedge T$$

is a positive Radon measure of total mass A. If $\|u\|_\infty \le M$, then

$$\|u\|_{H^1} \le C(1 + M), \qquad \mu_u(E) \le C(1 + M)\,\mathrm{Cap}_1(E)^{1/2}$$

for every Borel E. On each fixed relatively compact coordinate chart, the total variation of every coefficient of $\mathrm{dd^c} u$ is also bounded on E by $C(1 + M)\,\mathrm{Cap}_1(E)^{1/2}$.

Proof First let u be smooth admissible. The first-cone inequality gives $\mu_u \ge 0$, since T is conformal to ω^{n-1}, and $\mathrm{dd^c} T = 0$ gives $\mu_u(X) = A$. Applying distributional Stokes to $\mathrm{dd^c}(u^2)$ yields the energy identity

$$\int_X \mathrm{d}u \wedge \mathrm{d^c} u \wedge T = -\int_X u\,\mathrm{dd^c} u \wedge T = -\int_X u\,\mathrm{d}\mu_u + \int_X u\omega \wedge T \le 2MA.$$

Together with the L^2 bound this controls $\|u\|_{H^1}$. For bounded admissible u, choose smooth admissible $u_j \downarrow u$ by Theorem 12.5.1, discard a finite initial segment, and take $\|u_j\|_\infty \le M + 1$ as in Lemma 12.8.1. Bounded convergence gives strong L^2 convergence. The energy bound gives weak H^1 compactness, and every weak cluster point agrees with u in L^2; thus the entire sequence converges weakly to u in H^1. This proves the Sobolev bound. The trace measures converge weakly to μ_u, preserving positivity and total mass.

For any smooth real ϕ, the first-order Stokes identity is

$$\int_X \phi\,\mathrm{dd^c} u \wedge T = -\int_X \mathrm{d}\phi \wedge \mathrm{d^c} u \wedge T + \int_X \phi\,\mathrm{d^c} u \wedge \mathrm{d}T.$$

It remains valid for $u \in H^1$ by smooth Sobolev approximation. Both terms are bounded by $C\|u\|_{H^1}\|\phi\|_{H^1}$; the background term $\int \phi\omega \wedge T$ is bounded by $C\|\phi\|_{H^1}$. The preceding capacity lemma gives the bound for μ_u. In particular the derivative $\mathrm{d}T$ has not been discarded.

For a smooth admissible approximant, write the eigenvalues of $\omega + \mathrm{dd^c} u_j$ in an ω-unitary frame as λ_i. Since $m \ge 2$,

$$\sum_i \lambda_i^2 \le \left(\sum_i \lambda_i\right)^2, \qquad \sum_i \lambda_i \ge 0.$$

Consequently every coefficient of this form is dominated by its trace. On a fixed coordinate chart this bounds the coefficient variations of $\mathrm{dd^c} u_j$ by $C(\mu_{u_j} + \omega^n)$. Passing to the weak measure limits of Lemma 12.8.1 gives the same domination by $C(\mu_u + \omega^n)$. Finally $\int_E \omega^n \le \mathrm{Cap}_1(E)$ and $\mathrm{Cap}_1(E) \le \|1\|^2_{H^1}$ absorb the smooth term into the claimed square-root estimate. □

Lemma 12.9.3 *Every bounded canonical admissible potential is continuous on the complement of an open set of arbitrarily small* Cap_1. *The same open set can be chosen for any countable family of such potentials.*

Proof Choose smooth admissible $u_j \downarrow u$. By the preceding lemma these functions converge weakly to u in H^1. Mazur's lemma gives finite convex combinations w_N of terms with $j \ge N$ such that

$$\|w_N - u\|_{H^1} \le 8^{-N}.$$

Because $u \le w_N \le u_N$, they converge pointwise to the canonical function u, not just to an unspecified almost-everywhere representative. Put

$$G_{N_0} = \bigcup_{N \ge N_0} \{|w_{N+1} - w_N| > 2^{-N}\}.$$

The capacity tools imply

$$\mathrm{Cap}_1(G_{N_0}) \le \sum_{N \ge N_0} 4^N \|w_{N+1} - w_N\|^2_{H^1} \le C \sum_{N \ge N_0} 16^{-N} \longrightarrow 0.$$

Outside G_{N_0}, the successive differences form a uniformly summable series. Thus w_N converge uniformly there and their limit u is continuous on that closed set. For a countable family, choose the exceptional open sets with capacities less than $\epsilon 2^{-i}$ and take their union. Countable subadditivity proves the last assertion. □

Proposition 12.9.1 *Suppose $u_j \downarrow u$ and $v_j \downarrow v$ are bounded canonical admissible potentials with a common uniform bound. Then*

$$v_j \mathrm{dd^c} u_j \longrightarrow v \mathrm{dd^c} u$$

weakly as currents with signed measure coefficients. The same conclusion holds for $v_j \mu_{u_j} \to v \mu_u$.

Proof Bounded convergence gives $u_j \to u$ in L^1. Their complex Hessians therefore converge in distributions. The preceding coefficient bounds are uniform, so this is weak convergence of each signed coefficient measure against continuous compactly supported tests. The trace measures also converge weakly. Every one of these measures has total variation bounded by $C_M \,\mathrm{Cap}_1(E)^{1/2}$ on a Borel set E.

Fix $\epsilon > 0$. Quasicontinuity supplies an open G with $\mathrm{Cap}_1(G) < \epsilon$ on whose complement v and every v_j are continuous. Dini's theorem on the compact set $X \setminus G$ gives uniform convergence there. Extend $v|_{X \setminus G}$ to a continuous function F on X with

the same uniform bound, by Tietze's theorem. For any one of the signed coefficient measures $\nu_j \to \nu$ and a fixed continuous compactly supported test ψ, subtract $F\nu_j$ and $F\nu$. The resulting error is at most

$$C_{M,\psi}\big(\|\nu_j - \nu\|_{X\setminus G} + \epsilon^{1/2}\big).$$

The term with F converges by weak measure convergence. First let $j \to \infty$ and then $\epsilon \downarrow 0$. This proves the assertion for the Hessian coefficients and for the positive trace measures. □

Theorem 12.9.1 *For two bounded admissible potentials u, v, the recursive current $D_2(u,v) = \mathrm{dd^c}(v\mathrm{dd^c}u)$ is symmetric in its arguments. If $u_j \downarrow u$ and $v_j \downarrow v$ are bounded admissible sequences with a common uniform bound, then*

$$D_2(u_j, v_j) \longrightarrow D_2(u,v)$$

in distributions. Their shifted positive currents

$$Q_2(u,v) = \big(\omega^2 + \omega \wedge \mathrm{dd^c}u + \omega \wedge \mathrm{dd^c}v + D_2(u,v)\big) \wedge \omega^{n-m}$$

converge weakly as positive currents. For $m = 2$ these are positive Radon measures. For $m > 2$, the unwedged D_2 also converges weakly as a current with measure coefficients.

Proof For smooth admissible approximations $u_k \downarrow u$ and $v_k \downarrow v$, the weighted convergence proposition gives

$$\mathrm{dd^c}(v_k \mathrm{dd^c}u_k) \longrightarrow \mathrm{dd^c}(v\mathrm{dd^c}u).$$

The smooth current on the left is $\mathrm{dd^c}v_k \wedge \mathrm{dd^c}u_k$ and is symmetric. Applying the same argument in the opposite order proves $D_2(u,v) = D_2(v,u)$. For the bounded sequences in the statement, weighted convergence followed by $\mathrm{dd^c}$ gives the asserted simultaneous distributional limit.

The displayed subset expansion is the current of Theorem 12.8.1 with $p = 2$. Its lower-degree terms converge weakly, so its whole distributional limit is $Q_2(u,v)$. Positivity and the uniform local mass bounds turn this into weak convergence of currents of order zero. When $m > 2$, the same conclusion for D_2 follows from the uniform coefficient bounds below degree m in Proposition 12.8.1. □

The capacity estimate depends on using a first Hessian. A product of two Hessians can already charge a set of zero Sobolev capacity.

Lemma 12.9.4 *Let E be a compact subset of a smooth real submanifold of codimension two contained in a coordinate chart. Then* $\mathrm{Cap}_1(E) = 0$.

Proof It suffices to treat a compact subset of a submanifold chart, since finitely many such subsets cover E and the capacity is subadditive. Choose real coordinates (s,t) there, with $t \in \mathbb{R}^2$ and the submanifold given by $t = 0$. Choose $0 \le \eta \le 1$ smooth,

supported in this chart and equal to one near the compact subset. Put $r = |t|$. For $0 < \epsilon < 1/2$ define

$$h_\epsilon(r) = \begin{cases} 1, & 0 \le r \le \epsilon^2, \\ \dfrac{\log(\epsilon/r)}{\log(1/\epsilon)}, & \epsilon^2 < r < \epsilon, \\ 0, & r \ge \epsilon. \end{cases}$$

The Sobolev function $f_\epsilon = \eta h_\epsilon$ equals one on an open neighborhood of that subset. On the fixed compact coordinate set the Sobolev norm is equivalent to the Euclidean one. Integration in the two normal variables gives

$$\|f_\epsilon\|_{H^1}^2 \le C\left(\epsilon^2 + \int_{\epsilon^2}^{\epsilon} \frac{\mathrm{d}r}{r\log(1/\epsilon)^2}\right) = C\left(\epsilon^2 + \frac{1}{\log(1/\epsilon)}\right) \longrightarrow 0.$$

The derivatives of η contribute at most $C\epsilon^2$. Taking the infimum over open neighborhoods proves the assertion. □

Example 12.9.1 There are bounded continuous ω-plurisubharmonic potentials u, v and a compact Borel set E such that

$$\operatorname{Cap}_1(E) = 0, \qquad \int_E Q_2(u, v) \wedge \omega^{m-2} > 0.$$

Consequently the first-Hessian capacity estimate does not extend to this positive two-factor measure, even within the continuous ω-plurisubharmonic subclass.

Proof Choose holomorphic coordinates $z_j = x_j + \mathrm{i}y_j$ and a smooth nonnegative cutoff χ supported in the chart and equal to one on a smaller coordinate box. Extend

$$u = a\chi|x_1|, \qquad v = a\chi|x_2|$$

by zero outside the chart. These functions are globally continuous and bounded. To check their curvature, replace $|x_j|$ by $g_\delta(x_j) = (x_j^2 + \delta^2)^{1/2}$, with $0 < \delta \le 1$. The Hessian of χg_δ has the nonnegative term $\chi \mathrm{dd}^{\mathrm{c}} g_\delta$; all its remaining terms are uniformly bounded forms, since g_δ and g_δ' are uniformly bounded on the fixed support. Thus $\mathrm{dd}^{\mathrm{c}}(\chi g_\delta) \ge -C\omega$ with C independent of δ. Choosing $a > 0$ sufficiently small gives $\omega + \mathrm{dd}^{\mathrm{c}}(a\chi g_\delta) \ge \omega/2$ for both coordinates. Their decreasing limits u, v are therefore ω-plurisubharmonic and admissible.

On the box where $\chi = 1$, set $\alpha_j = \frac{\mathrm{i}}{4\pi}\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j$. The book's normalization gives

$$\mathrm{dd}^{\mathrm{c}} g_\delta(x_j) = \tfrac{1}{2} g_\delta''(x_j)\alpha_j, \qquad g_\delta''(x_j) = \frac{\delta^2}{(x_j^2 + \delta^2)^{3/2}} \longrightarrow 2\delta_{\{x_j = 0\}}.$$

The measures $g_\delta''(t)\,\mathrm{d}t$ have mass two, while their mass outside any fixed neighborhood of zero tends to zero. The two smooth factors depend on distinct real variables, so their product is an approximate identity in (x_1, x_2) and converges to the tensor-product measure. By Theorem 12.9.1, locally

$$D_2(u,v) = a^2 \delta_{\{x_1=0\}} \delta_{\{x_2=0\}} \alpha_1 \wedge \alpha_2.$$

Choose E to be a compact piece of $\{x_1 = x_2 = 0\}$ inside this box with nonempty relative interior. The preceding lemma gives $\mathrm{Cap}_1(E) = 0$. On this box, the positive measure $D_2(u,v) \wedge \omega^{n-2}$ has strictly positive mass on E, since ω is strictly positive. The smooth term ω^n and the two single-Hessian terms in the expansion

$$Q_2(u,v) \wedge \omega^{m-2} = \omega^n + \omega^{n-1} \wedge (\mathrm{dd^c} u + \mathrm{dd^c} v) + D_2(u,v) \wedge \omega^{n-2}$$

have zero mass on E: each single-Hessian term is absolutely continuous in the other normal real variable. Hence the asserted mass is strictly positive. A bound by $C\,\mathrm{Cap}_1(F)^b$ for all Borel F, with any $b > 0$, would contradict this choice of E. □

The preceding Sobolev-capacity estimate therefore cannot be iterated to control higher-degree coefficient measures. A local Hessian capacity supplies that control in the next section.

12.10 Local capacities and decreasing products

The codimension-two example shows why Sobolev capacity cannot control a product of Hessians. Local capacities built from smooth Hessian measures give the stronger control needed for the recursive currents. Their quasicontinuity estimate comes from an energy variation in which the derivatives of the background remain present.

Work on a coordinate ball U with compact closure in a holomorphic chart, with the restriction of ω. For a smooth function in the local unshifted class of Lemma 12.8.2, put

$$\Lambda_s(f) = (\mathrm{dd^c} f)^s \wedge \omega^{n-s}, \qquad 0 \le s \le m,$$

where $\Lambda_0(f) = \omega^n$. The local mass and gradient estimates needed for the capacity use ordinary smooth products.

Lemma 12.10.1 *Fix $K \Subset U$ and $M < \infty$. For smooth local m-subharmonic $f_1, \dots, f_q$ with $|f_i| \le M$, $0 \le q \le m$, their mixed trace has mass at most a constant depending only on K, U, ω, m, M. If also f is smooth in this class and $|f| \le M$, then, for $q \le m-1$,*

$$\int_K \mathrm{d}f \wedge \mathrm{d^c} f \wedge \mathrm{dd^c} f_1 \wedge \cdots \wedge \mathrm{dd^c} f_q \wedge \omega^{n-q-1} \le C.$$

Proof For one potential and a nonnegative compactly supported cutoff χ, closedness of $\mathrm{dd^c} f$ gives

$$\int \chi (\mathrm{dd^c} f)^q \omega^{n-q} = \int f (\mathrm{dd^c} f)^{q-1} \mathrm{dd^c}(\chi \omega^{n-q}).$$

For $q \ge 1$, the absolute-form estimate Lemma 12.1.5 applies at degree $q-1 < m$. Nested cutoffs and induction, starting with volume, therefore bound the left side by

CM^q; replacing M by $1 + M$ includes $M = 0$. For mixed factors, positivity of every term in the expansion of $(\sum_i \mathrm{dd^c} f_i)^q \omega^{n-q}$ bounds the mixed trace by a fixed multiple of the single trace for $\sum_i f_i$. This proves the first assertion, including its degree-zero convention.

Replace f by $f + M$, so that $0 \le f \le 2M$ without changing its gradient or Hessian. The identity

$$\mathrm{dd^c}(f^2) = 2f\,\mathrm{dd^c} f + 2\mathrm{d}f \wedge \mathrm{d^c} f$$

also shows that f^2 belongs to the local cone. Wedge with the remaining q Hessians and ω^{n-q-1}. The first term on the right is nonnegative, and the mixed mass estimate applied to f^2 and the other potentials bounds the second term. The degree used is $q + 1 \le m$. A cutoff equal to one on K gives the stated local estimate. □

Definition 12.10.1 For Borel $E \subset U$ define the smooth capacity

$$c_s(E) = \sup\left\{ \int_E \Lambda_s(a) : a \in C^\infty(U),\ -1 \le a \le 0, \mathrm{dd^c} a \in \overline{\Gamma_m(\omega)} \right\},$$

for $0 \le s \le m$. Its outer-open version is

$$c_s^*(E) = \inf\{c_s(G) : E \subset G \subset U,\ G \text{ open}\}.$$

A function on a compact $K \Subset U$ is quasicontinuous for this capacity if, for every $\epsilon > 0$, it is continuous on $K \setminus G$ for some open $G \subset U$ with $c_s(G) < \epsilon$.

In particular $c_0(E) = \int_E \omega^n$. Each c_s is monotone, countably subadditive and continuous under increasing unions. For the last assertion, the supremum over competitors commutes with the increasing supremum over sets. Local smooth mass bounds make it finite on compact subsets. The outer capacity c_s^* is monotone and countably subadditive and agrees with c_s on open sets.

The capacities control mixed traces for smooth local m-subharmonic functions $f_1, \dots, f_q$ with a common bound. Choose a fixed smooth strictly plurisubharmonic b with $\mathrm{dd^c} b \ge \omega$ on U. For $q \le s$, choose constants B and $L \ge 1$ so that $(f_1 + \cdots + f_q + b - B)/L$ lies in $[-1, 0]$. Both constants depend only on the common bound and the fixed data. Positivity of the smooth binomial expansion gives

$$(\mathrm{dd^c} f_1 + \cdots + \mathrm{dd^c} f_q)^q \omega^{n-q} \le C\Lambda_s\big((\textstyle\sum_i f_i + b - B)/L\big). \tag{12.7}$$

For $q = 0$ the left side is ω^n; the same argument applies. Indeed, replacing any of the $s - q$ factors $\mathrm{dd^c} b$ by ω subtracts a nonnegative mixed trace. Thus every such mixed trace, and every coefficient of a smooth product of $q < m$ Hessians, is dominated on Borel sets by Cc_s. The latter assertion follows from the absolute mixed-form estimate.

Lemma 12.10.2 *Let $0 \le q \le m-1$ and let S be a smooth real $(1,1)$-form in $\overline{\Gamma_m(\omega)}$ pointwise. Put $T = S^q \omega^{n-q-2}$. For smooth real f and nonnegative Borel weights a, supported on a fixed compact set,*

$$\left| \int a \, \mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}} \omega \wedge T \right| \le C \left(\int a \, \mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}} f \wedge \omega \wedge T \right)^{1/2} \left(\int a \, \omega^2 \wedge T \right)^{1/2}.$$

The corresponding inequality with $\mathrm{d}^{\mathrm{c}} f \wedge \mathrm{d}\omega$ holds as well. For a mixed product of q cone forms in place of S^q, it suffices to sum these bounds over the finitely many subset sums of its factors.

Proof For $q \le m-2$, diagonalize S in an ω-unitary frame. Every diagonal coefficient of $S^q \omega^{n-q-2}$ is a positive multiple of $S_{q;ij}(\lambda)$ for two omitted coordinates. This is nonnegative by deleted-coordinate positivity, because $q+2 \le m$. The form is a nonnegative sum of simple positive coordinate forms.

For one such simple form, only the remaining complex two-plane contributes to a complementary wedge. The coefficients of $\mathrm{d}^{\mathrm{c}}\omega$ are uniformly bounded in unitary frames on the fixed compact set. Its wedge with $\mathrm{d}f$ is consequently bounded by a constant times the gradient norm on that plane. The wedges with ω^2 and with $\mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}} f \wedge \omega$ give, up to fixed positive constants, one and the square of that norm. Pointwise Cauchy–Schwarz over the simple summands, followed by integral Cauchy–Schwarz with weight a, proves the estimate. Conjugation gives the other estimate.

For $q = m-1$, at one point choose an ω-unitary coframe e_i that diagonalizes S. Put $\epsilon_i = \mathrm{i} e_i \wedge \bar{e}_i$ and $\Omega = \epsilon_1 \cdots \epsilon_n$, so that $\omega = \sum_i \epsilon_i$ and $S = \sum_i \lambda_i \epsilon_i$. Writing $B_{ij} = S_{q;ij}(\lambda)$ and $D_i = S_{q;i}(\lambda)$, ordinary wedge expansion gives

$$S^q \omega^{n-q-2} = q!(n-q-2)! \sum_{i<j} B_{ij} \prod_{k \notin \{i,j\}} \epsilon_k.$$

Only the remaining two-plane contributes to its wedge with $\mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}}\omega$. If $\partial f = \sum_i f_i e_i$, its absolute density relative to Ω is bounded by

$$C \sum_{i<j} (|f_i| + |f_j|) |B_{ij}|.$$

The constant bounds the tensor coefficients of $\mathrm{d}^{\mathrm{c}}\omega$ in all unitary frames on the fixed compact set. Diagonalization is only pointwise; no derivative of this moving frame is taken.

Lemma 12.1.6 and finite Cauchy–Schwarz bound this sum by

$$C \sum_i |f_i| \sqrt{D_i} \sum_j \sqrt{D_j} \le C \left(\sum_i |f_i|^2 D_i \right)^{1/2} \left(\sum_i D_i \right)^{1/2}.$$

Here $\sum_i D_i = (n-q)S_q(\lambda)$. Moreover

$$S^q\omega^{n-q} = q!(n-q)!S_q(\lambda)\Omega,$$
$$\mathrm{d}f \wedge \mathrm{d}^{\mathrm{c}} f \wedge S^q\omega^{n-q-1} = \kappa q!(n-q-1)! \sum_i |f_i|^2 D_i\,\Omega,$$

where $\kappa = 1/(2\pi)$ by the book's d^{c} normalization. These two densities are nonnegative. Thus the pointwise torsion density is bounded by a constant times their geometric mean. Multiplication by a and integral Cauchy–Schwarz give the assertion, including the cases where either density vanishes. The other wedge is conjugate up to a fixed sign, which does not affect its absolute value. For $q \geq 1$, use the exact polarization identity

$$q!\,\alpha_1 \wedge \cdots \wedge \alpha_q = \sum_{J \subset \{1,\ldots,q\}} (-1)^{q-|J|} \left(\sum_{i\in J} \alpha_i\right)^q .$$

Every nonempty subset sum remains in the cone. Applying the single power estimate to each term and taking absolute values proves the mixed assertion. At $q = 0$ use the single term $S^0 = 1$. No Cauchy–Schwarz assertion for an arbitrary weakly positive $(n-2, n-2)$-form is needed. □

Lemma 12.10.3 *Let f_j be uniformly bounded smooth local m-subharmonic functions with $f_j \downarrow f$, and fix a smaller concentric ball $V \Subset U$. There are uniformly bounded smooth local functions $v_j \downarrow v$ which equal f_j on a neighborhood of $\overline{V}$ and equal one fixed strictly plurisubharmonic ψ on one fixed boundary collar. Moreover $v = f$ near $\overline{V}$ and $v = \psi$ on that collar.*

Proof Write $U = \{|z| < R\}$ and $|f_j| \leq M$. Take $\psi = A(|z|^2 - R^2) + b$, with $b > M + 2$ and then A so large that $\psi < -M - 2$ on a neighborhood of $\overline{V}$. It exceeds $M + 2$ on a fixed sufficiently thin boundary collar.

Use the regularized maximum M_ϵ constructed in Lemma 12.1.7. Choose $0 < \epsilon_j \downarrow 0$ with $\epsilon_j < 1$, and put $v_j = M_{\epsilon_j}(f_j, \psi)$. The lemma preserves the local unshifted cone condition. Its two monotonicities give $v_j \downarrow \max(f, \psi) = v$, and the fixed gaps give the two asserted regions of exact equality. The bounds

$$\max(f_j, \psi) \leq v_j \leq \max(f_j, \psi) + \epsilon_j/2$$

give a common bound. In particular all differences $v_k - v_j$ have support in one fixed compact subset of U. □

Proposition 12.10.1 *For the localized sequence in the preceding lemma and* $0 \le s \le m$,

$$c_s\{v_k - v > \delta\} \longrightarrow 0 \qquad (\delta > 0).$$

Consequently a uniformly bounded smooth decreasing local sequence has a quasi-continuous pointwise limit on every compact subset of U, *for each* c_s^* *as well as* c_s, $0 \le s \le m$.

Proof The assertion for $s = 0$ follows by bounded convergence for volume. Induct on s, assuming it for $s-1$, and put $q = s-1$ and $\theta = \omega^{n-s}$. For $j \ge k$ let $h = v_k - v_j \ge 0$. The support of h lies in one fixed compact set $K_0 \Subset U$. Smooth capacity domination and the induction hypothesis give, uniformly over all bounded local smooth mixed potentials,

$$\int h\, \mathrm{dd^c} g_1 \cdots \mathrm{dd^c} g_q \omega^{n-q} \longrightarrow 0 \quad (k \to \infty). \tag{12.8}$$

To see this, split at $h = \delta$. On $\{h \le \delta\}$ the mass bound gives $C\delta$. On the remaining set use $h \le v_k - v$, the capacity bound and the induction hypothesis. Let k tend to infinity before $\delta \downarrow 0$. For $q = 0$ this is the volume estimate. Constants are uniform in $j \ge k$ and all potentials with the fixed common bound.

Consider the real smooth energy

$$E_s(w) = \int_U w(\mathrm{dd^c} w)^s \theta, \qquad w_t = v_j + th, \quad 0 \le t \le 1.$$

The energies $E_s(v_j)$ are bounded: on the fixed collar the integrand is fixed, and the remaining compact set has a uniform smooth mass bound. Since h vanishes near the boundary, integration by parts and closedness of $\mathrm{dd^c} w_t$ give the exact identity

$$\begin{aligned} \frac{\mathrm{d}}{\mathrm{d}t} E_s(w_t) &= (s+1) \int h(\mathrm{dd^c} w_t)^s \theta \\ &\quad + s \int h(\mathrm{dd^c} w_t)^q \left(\mathrm{d}w_t \wedge \mathrm{d^c}\theta - \mathrm{d^c} w_t \wedge \mathrm{d}\theta + w_t \mathrm{dd^c}\theta\right). \end{aligned} \tag{12.9}$$

Here

$$\begin{aligned} \mathrm{d}\theta &= (n-s)\mathrm{d}\omega \wedge \omega^{n-s-1}, \\ \mathrm{dd^c}\theta &= (n-s)\mathrm{dd^c}\omega \wedge \omega^{n-s-1} \\ &\quad + (n-s)(n-s-1)\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge \omega^{n-s-2}, \end{aligned}$$

and the analogous $\mathrm{d^c}$ formula holds. A zero scalar coefficient means that its term is absent. The two first-order terms in (12.9) tend uniformly to zero by Lemma 12.10.2, the uniform local gradient bound, and (12.8). The last term has the same property by the absolute-form estimate at degree $q < m$. More explicitly, the first torsion integral is bounded by

$$C\left(\int h\, \mathrm{d}w_t \wedge \mathrm{d^c} w_t \wedge (\mathrm{dd^c} w_t)^q \omega^{n-q-1}\right)^{1/2} \left(\int h(\mathrm{dd^c} w_t)^q \omega^{n-q}\right)^{1/2}.$$

The first factor is bounded since h has a common bound and Lemma 12.10.1 applies; the second tends to zero by (12.8). Conjugation handles the other first-order term. Thus, with $e_k \downarrow 0$ after taking a tail supremum,

$$E_s(v_k) - E_s(v_j) = (s+1)\Delta_{kj} + r_{kj}, \quad \Delta_{kj} = \int_0^1 \int h\Lambda_s(w_t)\,\mathrm{d}t \geq 0, \quad |r_{kj}| \leq e_k.$$

It follows that $E_s(v_j) \leq E_s(v_k) + e_k$ for $j \geq k$. Taking a subsequence k approaching the liminf shows that the bounded energy sequence converges. Hence $\Delta_{kj} \to 0$ uniformly for $j \geq k$. Positivity of the binomial expansion $\Lambda_s(w_t) \geq (1-t)^s \Lambda_s(v_j)$ then gives

$$\int h\Lambda_s(v_j) \longrightarrow 0 \quad \text{uniformly for } j \geq k. \tag{12.10}$$

It remains to replace each Hessian factor by a capacity competitor. For any smooth $-1 \leq a \leq 0$ in the local cone, put

$$I_\ell = \int h(\mathrm{dd^c} v_j)^\ell (\mathrm{dd^c} a)^{s-\ell}\theta, \qquad \eta_\ell = (\mathrm{dd^c} v_j)^\ell (\mathrm{dd^c} a)^{s-\ell-1}, \quad 0 \leq \ell < s.$$

First-order Stokes, with every metric derivative retained, gives

$$I_\ell = -\int \mathrm{d}h \wedge \mathrm{d^c} a \wedge \eta_\ell\theta + \int h\,\mathrm{d^c} a \wedge \eta_\ell \mathrm{d}\theta.$$

The second term is $o(1)$ uniformly in a and $j \geq k$. Use finite polarization in Lemma 12.10.2; each subset sum has a uniform local gradient bound and its lower trace is controlled by (12.8).

The form $\eta_\ell\theta$ is positive of bidegree $(n-1, n-1)$: a complementary nonnegative rank-one form completes a polarized product of $s \leq m$ cone forms. Its associated Hermitian gradient pairing is nonnegative, so Cauchy–Schwarz and the uniform gradient bound for a give

$$I_\ell \leq C F_\ell(h)^{1/2} + o(1), \qquad F_\ell(h) = \int \mathrm{d}h \wedge \mathrm{d^c} h \wedge \eta_\ell\theta.$$

Another exact first-order Stokes identity gives

$$F_\ell(h) = I_{\ell+1} - \int h\mathrm{dd^c} v_k \wedge \eta_\ell\theta + \int h\,\mathrm{d^c} h \wedge \eta_\ell \mathrm{d}\theta \leq I_{\ell+1} + o(1).$$

The dropped term is nonnegative. For the last term the same polarized torsion estimate applies: its first gradient factor is uniformly bounded because $h = v_k - v_j$, and its second factor tends to zero by (12.8); here $h^2 \leq Ch$ and the gradient energy of the difference is at most twice the sum of those of v_k and v_j for every positive single-power gradient pairing. Starting with (12.10) at I_s, finite backward induction gives $I_0 \to 0$ uniformly in a and $j \geq k$.

Chebyshev's inequality now yields $c_s\{v_k - v_j > \delta\} \le \delta^{-1} \sup_a I_0$. These sets increase to $\{v_k - v > \delta\}$ as $j \to \infty$. Continuity of c_s under increasing unions proves the induction.

For any one $0 \le s \le m$, choose k_N so that the open sets $G_N = \{v_{k_N} - v > 2^{-N}\}$ satisfy $c_s(G_N) < \epsilon 2^{-N}$, $N \ge 1$. They are open because v is upper semicontinuous and v_{k_N} is smooth. On $U \setminus \bigcup_N G_N$ these smooth functions converge uniformly to the pointwise limit v. Hence v is continuous there. The union has capacity less than ϵ. Boundary localization transfers this conclusion to f on each smaller compact set. Open sets have the same outer capacity, which also proves the assertion for c_s^*. □

Lemma 12.10.4 *Every bounded admissible potential on X is locally quasicontinuous for each smooth capacity c_s^*, $0 \le s \le m$. For $0 \le p < m$, each coefficient measure ν of the ordered D_p satisfies*

$$|\nu|(E) \le C c_{m-1}^*(E), \qquad E \subset K \Subset U,$$

uniformly when its global potentials have one common bound. The assertion at $p = 0$ means the volume coefficient of $D_0 = 1$.

Proof The global decreasing approximation and Lemma 12.8.2 provide bounded smooth local approximations to $u + \rho$. The preceding proposition makes its canonical pointwise limit quasicontinuous. Subtracting the smooth ρ preserves quasicontinuity.

For smooth approximations write $\mathrm{dd^c} u_i = \mathrm{dd^c}(u_i + \rho) - \mathrm{dd^c}\rho$ and expand the product. Each term has $q \le p < m$ local cone factors and fixed smooth complementary factors. The absolute-form estimate and (12.7), with $s = m - 1$, bound each coefficient variation by $C c_{m-1}$ on Borel sets. The constants depend only on the common bound and local data.

Take the iterated limits of Proposition 12.8.1 on a slightly larger compact neighborhood of K. Lower semicontinuity of signed measure variation on open sets preserves these estimates at each limit. For any open $G \supset E$, intersect with a fixed open neighborhood of K having compact closure in U; this gives $|\nu|(E) \le C c_{m-1}(G)$. Taking the infimum proves the outer estimate. No simultaneous rough product or rough diagonal polynomial expansion is used. □

Lemma 12.10.5 *Fix $0 \le s \le m$ and the outer smooth capacity c_s^* on U. Let signed Radon measures $\nu_j \to \nu$ weakly have uniformly bounded local variations, with all variations dominated on compact subsets by $C c_s^*$. Suppose, for $1 \le i \le \ell$, that bounded Borel functions $b_i^j \downarrow b_i$ have one common bound and every member of these countable families is locally quasicontinuous for this capacity. For any continuous real F on a compact box containing their ranges,*

$$F(b_1^j, \dots, b_\ell^j)\nu_j \longrightarrow F(b_1, \dots, b_\ell)\nu$$

weakly as signed Radon measures.

Proof Fix $\phi \in C_c(U)$ and a compact $K \Subset U$ containing its support. Allocate summable exceptional capacities to all the functions. Their open union G has

$c_s(G) < \epsilon$, and every function is continuous on the compact set $A = K \setminus G$. Dini's theorem gives $b_i^j \to b_i$ uniformly on A for each i. Uniform continuity of F on the compact box therefore gives $f_j \to f$ uniformly on A, where $f_j = F(b_1^j, \dots, b_\ell^j)$ and $f = F(b_1, \dots, b_\ell)$. Put $M = \|F\|_\infty$. Extend $f|_A$ to a continuous g on U with $|g| \le M$; if A is empty, take $g = 0$. Then

$$\left| \int \phi f_j \, \mathrm{d}\nu_j - \int \phi f \, \mathrm{d}\nu \right| \le \|\phi\|_\infty \|f_j - f\|_A |\nu_j|(K) + \left| \int \phi g \, \mathrm{d}(\nu_j - \nu) \right| + 2M\|\phi\|_\infty \big(|\nu_j|(K \cap G) + |\nu|(K \cap G) \big).$$

For fixed G, the first two terms tend to zero. The last term is at most $4MC\|\phi\|_\infty \epsilon$. Let ϵ tend to zero. Weak convergence is applied to ϕg on the whole measure. □

Theorem 12.10.1 *For uniformly bounded admissible potentials $u_i^j \downarrow u_i$ on X, the currents $D_p(u_1^j, \dots, u_p^j)$ converge to $D_p(u_1, \dots, u_p)$ in distributions for $p \le m$, and weakly with measure coefficients for $p < m$. These currents are symmetric in their potentials. For $p < m$ the coefficient convergence also holds after multiplication by a uniformly bounded decreasing admissible weight. The positive shifted currents Q_p converge weakly for $p \le m$; Q_m converges as a positive Radon measure. At degree m, the convergence assertion for D_m is distributional.*

Proof Work on a compact coordinate test set. Degree zero is constant. Suppose the result holds for D_{p-1}, which has measure coefficients since $p - 1 < m$. The preceding two lemmas, applied coefficientwise with weight u_p^j, give convergence of $u_p^j D_{p-1}(u_1^j, \dots, u_{p-1}^j)$. Applying dd^c proves distributional convergence at degree p. For $p < m$, the uniform coefficient bounds in Proposition 12.8.1 upgrade this to weak convergence of measures, by smooth approximation of compactly supported continuous tests. The same weighted lemma gives the additional weighted conclusion.

For each fixed list choose simultaneous smooth decreasing global approximations. Their smooth raw Hessian wedges are symmetric. The convergence just proved identifies their limit with D_p in any ordering, proving symmetry without an exchange of previously unproved iterated limits.

The subset expansion for R_p uses fixed smooth powers of ω, so its distributional convergence and symmetry follow from those of D_I. Its wedge Q_p is positive with uniform local masses by Theorem 12.8.1. Distributional convergence and these mass bounds imply weak convergence as an order-zero positive current, including the Radon measure conclusion at $p = m$. A partition of unity on a finite coordinate cover proves the global assertions. □

The coefficient bound for raw currents uses only c_{m-1}. For the positive shifted products, c_m also controls their trace at top degree. This allows an additional bounded weight in every Hessian degree.

Lemma 12.10.6 *On $K \Subset U$, the positive shifted currents $Q_p(u_1, \dots, u_p)$, $1 \le p \le m$, for globally bounded admissible potentials have trace and coefficient variations bounded on Borel $E \subset K$ by $Cc_m^*(E)$. The constants are uniform when all potentials have a common bound.*

Proof First take smooth potentials, put $\sigma_i = \omega + \mathrm{dd}^{\mathrm{c}} u_i$, and choose the fixed local correction $\tau = \mathrm{dd}^{\mathrm{c}}\rho \ge 2\omega$. Then $\beta_i = \mathrm{dd}^{\mathrm{c}}(u_i + \rho) = \sigma_i + (\tau - \omega)$ lies in the same local cone. Since $\tau - \omega \ge 0$, mixed positivity gives

$$0 \le \int_E Q_p \wedge \omega^{m-p} \le \int_E \beta_1 \cdots \beta_p \omega^{n-p} \le C c_m(E), \qquad E \subset K.$$

Here $Q_p \wedge \omega^{m-p} = \sigma_1 \cdots \sigma_p \omega^{n-p}$. The last bound follows from smooth mixed-trace domination at $s = m$ for the bounded corrected potentials and a normalized bounded sum with a fixed strictly plurisubharmonic function. Positivity of Q_p bounds each of its coefficient variations on the compact coordinate set by a fixed multiple of its trace measure.

For bounded potentials choose the smooth decreasing global approximations already established in the chapter. The joint convergence in Theorem 12.10.1 identifies their positive-current limit with the previously constructed Q_p. On a compact neighborhood of K inside U, lower semicontinuity on open sets preserves trace and coefficient variation estimates. For an arbitrary open $G \supset E$ intersect with a fixed relatively compact neighborhood of K before taking this limit; its capacity is at most $c_m(G)$. Therefore every such trace or variation measure μ satisfies $\mu(E) \le C c_m(G)$. Infimize over G to obtain the asserted outer-open bound. The constants of the smooth estimates are independent of the approximation index. The argument does not multiply a rough current of positive order or use an unproved rough diagonal polynomial expansion. □

Theorem 12.10.2 *Suppose $a_j \downarrow a$ and $u_i^j \downarrow u_i$ are bounded canonical global admissible potentials with common bounds. Then, for $1 \le p \le m$,*

$$a_j Q_p(u_1^j, \dots, u_p^j) \longrightarrow a Q_p(u_1, \dots, u_p)$$

weakly as currents with measure coefficients. At $p = m$ this is weak convergence of weighted Radon measures.

Proof Work on a compact coordinate test set. By Theorem 12.10.1, every coefficient measure of the positive shifted currents converges weakly and has a uniform local variation bound. Lemma 12.10.6 strengthens this to domination by Cc_m^* on Borel sets. Lemma 12.10.4 makes the canonical weights a_j and a quasicontinuous for this capacity. Apply Lemma 12.10.5 with $s = m$ to each coefficient, and then use a finite partition of unity. At $p = m$, Q_m is a positive Radon measure, so this also gives the stated weighted measure convergence. □

12.11 Locality and maxima of bounded potentials

Where one bounded admissible potential is strictly larger than another, the maximum has the same positive Hessian current as the larger potential. These strict comparison sets need not be open. Quasicontinuity gives cutoffs whose products with the approximating currents converge, allowing smooth locality to pass to these sets.

Proposition 12.11.1 *Let u, v be bounded admissible, put $w = \max\{u, v\}$, and fix $1 \le p \le m$. For any bounded admissible $t_2, \dots, t_p$,*

$$\mathbf{1}_{\{u>v\}} Q_p(w, t_2, \dots, t_p) = \mathbf{1}_{\{u>v\}} Q_p(u, t_2, \dots, t_p).$$

The equality is coefficientwise as currents with measure coefficients. The corresponding equality on $\{v > u\}$ follows by exchanging u, v.

Proof Choose smooth uniformly bounded decreasing approximations of all the potentials by Theorem 12.5.1. Construct w_j by Lemma 12.1.7. Work on one compact coordinate test set. Fix $\delta > 0$ and a smooth $\chi_\delta : \mathbb{R} \to [0, 1]$ that vanishes for $s \le \delta/2$ and equals one for $s \ge \delta$. For j large enough that $\epsilon_j < \delta/2$, ordinary smooth locality gives

$$\chi_\delta(u_j - v_j) Q_p(w_j, t_2^j, \dots, t_p^j) = \chi_\delta(u_j - v_j) Q_p(u_j, t_2^j, \dots, t_p^j).$$

Indeed, wherever the weight is nonzero, $w_j = u_j$ on an open neighborhood. The equality elsewhere follows from its zero weight.

Both sequences of positive currents converge by Theorem 12.10.1; every coefficient variation is uniformly dominated by Cc_m^* by Lemma 12.10.6. The potentials and their limits are quasicontinuous by Lemma 12.10.4. Apply Lemma 12.10.5 with $s = m$ and $F(x, y) = \chi_\delta(x - y)$ to the real and imaginary parts of each coefficient. Passing to the limit gives the same identity with $u, v, w, t_2, \dots, t_p$. Choose the cutoffs so that $\chi_\delta(s) \to \mathbf{1}_{\{s>0\}}$ pointwise as $\delta \downarrow 0$. Dominated convergence against the fixed finite coefficient variations on the test set gives the asserted restriction. A partition of unity proves it globally. □

On the contact set, a positive constant shift gives a strict comparison before the limit is taken. Decreasing the shift then recovers that set by dominated convergence for a fixed measure.

Theorem 12.11.1 *Let u, v be bounded admissible. Fix $1 \le r \le m$ and bounded admissible $z_1, \dots, z_{m-r}$. Define the positive Radon measure*

$$\mu_r(t) = Q_m(\underbrace{t, \dots, t}_{r}, z_1, \dots, z_{m-r}).$$

For $w = \max\{u, v\}$,

$$\mu_r(w) \ge \mathbf{1}_{\{u \ge v\}} \mu_r(u) + \mathbf{1}_{\{u < v\}} \mu_r(v).$$

The inequality with u, v exchanged also holds.

Proof Symmetry and Proposition 12.11.1, applied to the r slots, give $\mu_r(w) = \mu_r(v)$ on $\{u < v\}$ and $\mu_r(w) = \mu_r(u)$ on $\{u > v\}$. To include the contact set, put $w_\epsilon = \max\{u + \epsilon, v\}$. Strict locality and invariance under addition of constants give

$$\mu_r(w_\epsilon) \ge \mathbf{1}_{\{u+\epsilon > v\}} \mu_r(u).$$

The invariance follows from the smooth products and their joint decreasing limits. As $\epsilon \downarrow 0$, $w_\epsilon \downarrow w$, so the left side converges weakly to $\mu_r(w)$. Against any nonnegative continuous compactly supported test function, the right side converges by dominated convergence for the fixed measure $\mu_r(u)$ to $\mathbf{1}_{\{u \ge v\}} \mu_r(u)$. This proves the measure inequality on the contact set as well as on $\{u > v\}$. On its disjoint complement $\{u < v\}$, the already proved equality supplies $\mu_r(v)$. Restricting the positive measures to these two Borel sets and adding gives the assertion. Exchanging u, v gives its other form. □

Convex rescaling also supplies a positive background term in the measure.

Lemma 12.11.1 *For bounded admissible v, $0 \le \alpha \le 1$ and a real constant b, the function $v_\alpha = \alpha v + b$ is bounded admissible and*

$$H_m(v_\alpha) \ge \alpha^m H_m(v) + (1 - \alpha)^m \omega^n.$$

Proof Take smooth decreasing uniformly bounded admissible $v_j \downarrow v$. Cone convexity makes $\alpha v_j + b$ admissible because

$$\omega + \mathrm{dd}^{\mathrm{c}}(\alpha v_j + b) = \alpha(\omega + \mathrm{dd}^{\mathrm{c}} v_j) + (1 - \alpha)\omega.$$

For $\alpha > 0$, an upper test q for $\alpha v + b$ gives the upper test $(q - b)/\alpha$ for v. The same convex combination of forms therefore proves admissibility of the limit. For $\alpha = 0$ the potential is constant. The pointwise decreasing limit has the displayed canonical affine values. Expand the smooth top product. Every mixed term is positive by polarized Gårding positivity. Keeping the two extreme terms gives

$$H_m(\alpha v_j + b) \ge \alpha^m H_m(v_j) + (1 - \alpha)^m \omega^n.$$

Joint decreasing convergence from Theorem 12.10.1 passes this inequality against each nonnegative continuous test to the asserted inequality of positive Radon measures. □

The weighted limits also pass integration by parts against metric derivatives. A truncation just above the infimum then excludes zero Hessian mass for a bounded potential.

Lemma 12.11.2 *Put $k = m - 1$ and $\ell = n - m$. For bounded admissible $t_1, \dots, t_k$, let $T = R_k(t_1, \dots, t_k) \wedge \omega^\ell$. Then $\mathrm{dd^c} T$ is a signed Radon measure. If bounded admissible $t_i^j \downarrow t_i$ have a common bound, these measures converge weakly, also after multiplication by any continuous function of finitely many uniformly bounded decreasing admissible potentials.*

Proof The subset definition and the torsion formulas in Proposition 12.8.2 give, in distributions,

$$\begin{aligned}\mathrm{dd^c} T = \mathrm{dd^c}\omega \wedge \left(\sum_{a=1}^{k} R_{k-1}^{\widehat{a}} \omega^\ell + \ell R_k \omega^{\ell-1} \right) \\ + 2\,\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge \sum_{a<b} R_{k-2}^{\widehat{a}\widehat{b}} \omega^\ell \\ + 2\ell\,\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge \sum_{a=1}^{k} R_{k-1}^{\widehat{a}} \omega^{\ell-1} \\ + \ell(\ell-1)\,\mathrm{d}\omega \wedge \mathrm{d^c}\omega \wedge R_k \omega^{\ell-2}.\end{aligned}$$

The sum with two hats is absent when $k = 1$, and the last term is absent when $\ell = 1$. Every factor R_r has degree $r \le k < m$, so its coefficients are signed measures. Expanding each R_r over subsets expresses the displayed measure as fixed smooth forms wedged with raw currents D_p of degrees $p \le m - 1$. Lemma 12.10.4 therefore bounds its variation locally by $C c^*_{m-1}$, uniformly under common bounds on the potentials. Joint convergence follows from Theorem 12.10.1 applied to this expansion. All the canonical weights are quasicontinuous for c^*_{m-1}. Lemma 12.10.5, with $s = m - 1$, thus proves the weighted assertion coefficientwise on a finite coordinate cover. A partition of unity gives it on X. The term involving $R_k \mathrm{dd^c}(\omega^\ell)$ retains degree $m - 1$; the argument requires no coefficient estimate in degree m. □

Proposition 12.11.2 *Every bounded admissible potential u has*

$$\int_X H_m(u) > 0.$$

No differential identities for powers of ω are required.

Proof Suppose instead that $H_m(u) = 0$. Fix $s > 0$, set $c = \inf_X u + s$, and put $w = \max\{u, c\}$. The upper semicontinuity of u makes $U = \{u < c\}$ open, and the definition of the infimum makes it nonempty. Moreover $0 \le w - u \le s$ and this difference is zero outside U. The maximum is bounded admissible with its canonical pointwise values by Lemma 12.1.7.

For $0 \le q \le m$, define the positive Radon measures

$$\mu_q = Q_m(\underbrace{u, \dots, u}_{q}, \underbrace{w, \dots, w}_{m-q}).$$

Thus $\mu_m = H_m(u) = 0$. For $q < m$, let T_q be the sum of $m - q$ currents with $q + r$ slots equal to u and $m - q - 1 - r$ slots equal to w, for $0 \le r < m - q$, each of degree $m - 1$ and wedged with ω^{n-m}. In smooth notation this is

$$T_q = \sum_{r=0}^{m-q-1} (\omega + \mathrm{dd^c} u)^{q+r} (\omega + \mathrm{dd^c} w)^{m-q-1-r} \omega^{n-m}.$$

Here each displayed product denotes the symmetric shifted current R_{m-1} of (12.6), wedged with ω^{n-m}.

Choose smooth bounded admissible $u_j \downarrow u$ and the regularized maxima $w_j = M_{\epsilon_j}(u_j, c) \downarrow w$, where $\epsilon_j \downarrow 0$, as in Lemma 12.1.7. Both lists have a common bound. The smooth polynomial identity and Stokes' theorem on the compact manifold give

$$\int_X (\mu_q^j - \mu_m^j) = \int_X (w_j - u_j) \mathrm{dd^c} T_q^j.$$

Joint decreasing convergence passes the left side to its limit. The preceding lemma, with $F(x, y) = y - x$ and the decreasing lists u_j, w_j, passes the right side to its limit. Hence

$$\int_X \mu_q = \int_X (w - u) \mathrm{dd^c} T_q.$$

The difference of the two decreasing sequences need not itself decrease; the continuous two-variable weight is essential here.

On the open set U, the potential w is constant. Locality of the raw recursion therefore sets every factor $\mathrm{dd^c} w$ to zero there, so that its shifted factors become ω. The formula in the preceding lemma expresses $\mathrm{dd^c} T_q|_U$ as finitely many smooth metric-derivative forms wedged with powers of $\omega + \mathrm{dd^c} u$ of degrees at most $m - 1$. Use smooth admissible approximations to u and the constant c in these local expressions; their limits are the same restricted currents. For those smooth approximations, the absolute mixed-form estimate Lemma 12.1.5 bounds each such term by a constant times the corresponding positive trace, and therefore by $C \sum_{r=0}^{m-1} \mu_r$ on U after taking joint limits. More explicitly, a term with r factors is bounded by $C(\omega + \mathrm{dd^c} u)^r \omega^{n-r}$; this is $C\mu_r$ on U. Against compactly supported nonnegative tests in U, weak convergence and lower semicontinuity of total variation preserve the estimate. Exhaustion gives the measure inequality

$$\mathbf{1}_U |\mathrm{dd^c} T_q| \le C \sum_{r=0}^{m-1} \mathbf{1}_U \mu_r.$$

Here C depends only on ω, m, n, not on u or s; a fixed finite coordinate cover bounds all the smooth metric coefficients.

Since $w - u$ vanishes outside U, positivity gives

$$\int_U \mu_q \le \int_X \mu_q \le Cs \sum_{r=0}^{m-1} \int_U \mu_r \qquad (0 \le q < m).$$

Summing these m inequalities and choosing $s > 0$ with $mCs < 1$ forces $\sum_{r=0}^{m-1} \int_U \mu_r = 0$. But locality gives $\mu_0 = \omega^n$ on the nonempty open set U, whose volume is positive. This contradiction proves the result. □

12.12 Hessian mass and global comparison

The maximum inequality compares measures on complementary Borel sets. Integrating it leaves a difference of total masses. The recursive currents express this difference through the complex Hessians of the background powers, extending the mass calculation of Chapter 2 to bounded admissible potentials. Their vanishing characterizes the unmodified comparison principle. When they do not vanish, a small sublevel set limits the change made by the maximum; the resulting torsion error can still be absorbed after rescaling the upper potential.

For bounded admissible $t_1, \dots, t_m$, put

$$\mathcal{M}_m(t_1, \dots, t_m) = \int_X Q_m(t_1, \dots, t_m), \qquad H_m(t) = Q_m(t, \dots, t).$$

Here $H_m(t)$ is a finite positive Radon measure and $\mathcal{M}_m$ is the total mass of a mixed positive measure, by Theorem 12.8.1. For a nonempty subset $I = \{i_1 < \cdots < i_q\} \subset \{1, \dots, m\}$, put $i(I) = i_q$ and $I^- = I \setminus \{i_q\}$. Use D_{I^-} for the recursive current with those ordered inputs, with $D_\varnothing = 1$.

Lemma 12.12.1 *For every bounded admissible list,*

$$\mathcal{M}_m(t_1,\dots,t_m) = \int_X \omega^n + \sum_{\varnothing\neq I\subset\{1,\dots,m\}} \int_X t_{i(I)} D_{I^-} \wedge \mathrm{dd}^{\mathrm{c}}(\omega^{n-|I|}). \tag{12.11}$$

Every integral on the right is an integral of bounded canonical values against signed measure coefficients.

Proof Expand Q_m using (12.6). The term for I pairs D_I with the smooth form $\omega^{n-|I|}$. By (12.4),

$$\langle D_I, \omega^{n-|I|}\rangle = \langle t_{i(I)} D_{I^-}, \mathrm{dd}^{\mathrm{c}}(\omega^{n-|I|})\rangle.$$

Since $|I^-| \le m-1$, Proposition 12.8.1 gives measure coefficients for D_{I^-}; their bounded product with $t_{i(I)}$ is well defined. Thus the displayed pairing is exactly the integral in the sum, and is finite on compact X. The empty subset contributes $\int_X \omega^n$. □

Let μ_r be the repeated-slot mixed measure from Theorem 12.11.1, for fixed r and $z_1,\dots,z_{m-r}$. The total-mass difference below therefore has the explicit expression (12.11) for the two indicated lists.

Proposition 12.12.1 *If u, v are bounded admissible and $w = \max\{u,v\}$, then*

$$\int_{\{u<v\}} \mathrm{d}\mu_r(v) \le \int_{\{u<v\}} \mathrm{d}\mu_r(u) + \int_X \mathrm{d}\mu_r(w) - \int_X \mathrm{d}\mu_r(u).$$

Proof Set $E = \{u < v\}$. The contact-set version of Theorem 12.11.1 gives

$$\mu_r(w) \ge \mathbf{1}_{X\setminus E}\mu_r(u) + \mathbf{1}_E \mu_r(v).$$

All these measures are finite and positive. Integrating on X and using $\mu_r(u)(X\setminus E) = \mu_r(u)(X) - \mu_r(u)(E)$ gives exactly the assertion. No boundary or closed-background hypothesis enters this calculation. □

The unmodified global comparison principle holds precisely when the powers occurring in this mass formula are dd^{c}-closed. Only the powers $n-m,\dots,n-1$ occur at Hessian degree m.

Theorem 12.12.1 *The following conditions are equivalent:*

(1) $\mathrm{dd}^{\mathrm{c}}(\omega^{n-q}) = 0$ *for every* $1 \le q \le m$;
(2) $\int_X H_m(u)$ *is independent of the smooth admissible potential* u;
(3) $\mathcal{M}_m(t_1, \dots, t_m) = \int_X \omega^n$ *for every bounded admissible list;*
(4) *every pair of bounded admissible* u, v *satisfies*

$$\int_{\{u<v\}} H_m(v) \le \int_{\{u<v\}} H_m(u).$$

Under these conditions, for every $1 \le r \le m$ *and every fixed bounded admissible list* $z_1, \dots, z_{m-r}$, *one also has*

$$\int_{\{u<v\}} \mathrm{d}\mu_r(v) \le \int_{\{u<v\}} \mathrm{d}\mu_r(u).$$

Proof The first condition implies the third by (12.11). The third implies the second by taking all inputs equal to a smooth potential.

To prove that the second implies the first, fix any smooth real f. For all sufficiently small real t of either sign, $\omega + t\mathrm{dd}^{\mathrm{c}} f$ is positive, so tf is strictly admissible. The polynomial

$$\int_X (\omega + t\mathrm{dd}^{\mathrm{c}} f)^m \wedge \omega^{n-m} = \sum_{q=0}^{m} \binom{m}{q} t^q \int_X (\mathrm{dd}^{\mathrm{c}} f)^q \wedge \omega^{n-q}$$

is constant on an interval. Consequently every coefficient with $q \ge 1$ vanishes. Polarizing that coefficient by replacing f with $\sum_{a=1}^{q} s_a f_a$ gives

$$\int_X \mathrm{dd}^{\mathrm{c}} f_1 \wedge \cdots \wedge \mathrm{dd}^{\mathrm{c}} f_q \wedge \omega^{n-q} = 0$$

for all smooth real f_a. Integration by parts in the first factor, using Lemma 2.1.1, gives

$$\int_X f_1 \mathrm{dd}^{\mathrm{c}} f_2 \wedge \cdots \wedge \mathrm{dd}^{\mathrm{c}} f_q \wedge \mathrm{dd}^{\mathrm{c}}(\omega^{n-q}) = 0.$$

Since f_1 is arbitrary, the smooth top-degree form paired with it vanishes pointwise. At each point the other complex Hessians can be prescribed by real quadratic functions times a cutoff. Complexifying this multilinear identity gives all coordinate $(q-1, q-1)$-forms, as in the proof of Theorem 2.2.2. They detect every coefficient of $\mathrm{dd}^{\mathrm{c}}(\omega^{n-q})$, so that form vanishes. When $q = 1$, there are no other Hessians and the same conclusion follows directly from the arbitrariness of f_1.

Under the third condition, $\mu_r(w)$ and $\mu_r(u)$ have the same total mass. Proposition 12.12.1 proves the mixed comparison assertion, and $r = m$ gives the fourth condition. Finally, suppose the fourth condition holds and fix smooth admissible u, v. Choose C so large that $u < v + C$ everywhere. Constant invariance gives

$H_m(v+C) = H_m(v)$, so comparison gives $\int_X H_m(v) \le \int_X H_m(u)$. Exchanging u, v gives equality, which is the second condition. □

The same varying background that obstructs Monge–Ampère comparison also obstructs comparison at each intermediate Hessian degree.

Example 12.12.1 Let $X = (\mathbb{C}/(\mathbb{Z}+\mathrm{i}\mathbb{Z}))^n$, with $z_j = x_j + \mathrm{i}y_j$, and put

$$\beta_j = \frac{\mathrm{i}}{2\pi}\,\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j, \qquad b = 2 + \cos(2\pi x_1), \qquad \omega = \beta_1 + b\beta_2 + \sum_{j=3}^{n} \beta_j.$$

For $|t| < \pi^{-2}$ the potential $u_t = t\cos(2\pi x_1)$ is smooth strictly admissible, and, with $B_n = \int_X \beta_1 \wedge \cdots \wedge \beta_n$,

$$\int_X H_m(u_t) = n!\left(2 - \frac{m\pi^2 t}{2n}\right) B_n.$$

Thus every $-\pi^{-2} < t < 0$, together with a constant $C > |t|$, gives a pair $u = 0$, $v = u_t + C$ that violates the unmodified global comparison inequality.

Proof As in Example 2.3.1, $\mathrm{dd^c}u_t = -\pi^2 t\cos(2\pi x_1)\beta_1$. The coefficient of β_1 in $\omega + \mathrm{dd^c}u_t$ is strictly positive in the stated range, and all the other coefficients are positive. Since $(\mathrm{dd^c}u_t)^2 = 0$, expansion gives

$$H_m(u_t) = \omega^n + m\mathrm{dd^c}u_t \wedge \omega^{n-1} = n!b\left(1 - \frac{m}{n}\pi^2 t\cos(2\pi x_1)\right)\beta_1 \wedge \cdots \wedge \beta_n.$$

The period averages of b and $b\cos(2\pi x_1)$ are respectively 2 and $1/2$, proving the mass formula. For $t < 0$ this mass is strictly larger than $\int_X H_m(0) = 2n!B_n$. Meanwhile $C > |t|$ gives $\{0 < u_t + C\} = X$, so the comparison inequality for this pair would assert the opposite ordering of these masses. □

12.12.1 Modified comparison

On a sublevel set just above the infimum of a difference, the maximum changes the lower potential by at most a prescribed small number. Integration by parts then expresses the mass defect through this small difference and a torsion measure. Mixed lower-degree traces control its variation. Rescaling the upper potential adds a positive background term that relates these traces to the top Hessian measure.

For bounded admissible u, V, use the notation

$$\sigma_u = \omega + \mathrm{dd^c}u, \qquad M_{p,q} = \sigma_u^p \sigma_V^q \omega^{n-p-q} \quad (0 \le p+q \le m).$$

These expressions denote the positive mixed measure Q_m with p slots equal to u, q slots equal to V and the remaining slots equal to the constant zero. In particular $M_{0,0} = \omega^n$.

For $p+q \le m-1$, put

$$T_{p,q} = \sigma_u^p \sigma_V^q \omega^{n-p-q-1}.$$

This denotes R_{m-1} with the same nonconstant slots and zero in its other slots, wedged with ω^{n-m}.

Lemma 12.12.2 *Let u, V be bounded admissible, b a real constant and $s > 0$. Suppose $0 \le \max\{u, V+b\} - u \le s$. Set $E = \{u < V+b\}$ and $b_{p,q} = M_{p,q}(E)$. There is a constant C, depending only on X, ω, m, n, such that*

$$b_{p,q+1} \le b_{p+1,q} + Cs \sum_{a+d \le p+q} b_{a,d} \qquad (p+q \le m-1).$$

For $q = 0$, the error can instead be bounded by $Cs(b_{p,0} + b_{p-1,0} + b_{p-2,0})$, with negative indices zero.

Proof First estimate the torsion of $T_{p,q}$, writing $r = p+q$. For smooth admissible potentials, the product rule expresses $\mathrm{dd^c} T_{p,q}$ as a sum of fixed smooth metric forms wedged with products of σ_u, σ_V of degrees $r, r-1, r-2$. The terms of degree r come from differentiating the background power; they cannot be discarded. Indeed, $\mathrm{d}\sigma_u = \mathrm{d}\sigma_V = \mathrm{d}\omega$, $\mathrm{d^c}\sigma_u = \mathrm{d^c}\sigma_V = \mathrm{d^c}\omega$ and $\mathrm{dd^c}\sigma_u = \mathrm{dd^c}\sigma_V = \mathrm{dd^c}\omega$. Every term therefore contains either $\mathrm{dd^c}\omega$ or $\mathrm{d}\omega \wedge \mathrm{d^c}\omega$, with its product-rule multiplicity and the appropriate remaining background power. Terms with negative numbers of factors are absent.

All variable degrees are at most $r < m$. Apply Lemma 12.1.5 to each term. Expanding the resulting positive power of the sum of its variable factors gives the pointwise bound

$$|\mathrm{dd^c} T_{p,q}| \le C \sum_{a+d \le r} M_{a,d}.$$

For $q = 0$ every variable factor is σ_u, so the sharper bound is $C(M_{p,0} + M_{p-1,0} + M_{p-2,0})$. The constant bounds fixed metric coefficients on a finite coordinate cover and the finitely many multiplicities; it is independent of the potentials and their bounds.

Choose uniformly bounded smooth decreasing approximations to u, V. By Lemma 12.11.2, the torsion measures converge weakly; by Theorem 12.10.1, all positive measures in these bounds also converge weakly. Against nonnegative continuous tests, lower semicontinuity of total variation preserves both bounds. They are consequently inequalities of measures and may be restricted to the Borel set E.

Put $w = \max\{u, V+b\}$ and $h = w - u$. The mixed maximum theorem Theorem 12.11.1, with one moving slot and the fixed slots defining $T_{p,q}$, gives

$$(\omega + \mathrm{dd^c} w) T_{p,q} \ge \mathbf{1}_E \sigma_V T_{p,q} + \mathbf{1}_{X \setminus E} \sigma_u T_{p,q}.$$

All products here are the corresponding positive mixed measures. After integration, this implies

$$b_{p,q+1} \le b_{p+1,q} + \int_X \big((\omega + \mathrm{dd^c} w) - \sigma_u\big) T_{p,q}.$$

Regularized maxima of the smooth decreasing approximations give a uniformly bounded decreasing smooth list $w_j \downarrow w$. Stokes' theorem on compact X gives for these lists

$$\int_X \big((\omega + \mathrm{dd^c} w_j) - \sigma_{u_j}\big) T^j_{p,q} = \int_X (w_j - u_j) \mathrm{dd^c} T^j_{p,q}.$$

Joint decreasing convergence passes the positive mixed measures on the left to their limits. The continuous two-variable weight $F(x, y) = y - x$ in Lemma 12.11.2 passes the right side to $\int_X h \mathrm{dd^c} T_{p,q}$. No monotonicity of $w_j - u_j$ is needed. Since h is zero outside E and $0 \le h \le s$,

$$\int_X h \mathrm{dd^c} T_{p,q} \le s |\mathrm{dd^c} T_{p,q}|(E).$$

The torsion bounds prove both assertions. The argument never passes a varying measure to a weak limit after restriction to E. □

Theorem 12.12.2 *There is $C \ge 1$, depending only on X, ω, m, n, with the following property. For bounded admissible u, v and $0 < \alpha < 1$, put $\eta = 1 - \alpha$, $V = \alpha v$ and $S = \inf_X(u - V)$. For $0 < s < \eta^3/C$, let $E_s = \{u < V + S + s\}$. Then*

$$\int_{E_s} H_m(V) \le \left(1 + \frac{Cs}{\eta^m}\right) \int_{E_s} H_m(u).$$

No differential identity for a power of ω is assumed.

Proof Use the mixed measures above on E_s, writing $b_{p,q} = M_{p,q}(E_s)$ and $a_k = b_{k,0}$. The definition of S gives $0 \le \max\{u, V + S + s\} - u \le s$, so Lemma 12.12.2 applies. Repeatedly moving a V slot to a u slot gives, for $p + q = r$,

$$b_{p,q} \le a_r + C_1 s \sum_{d=0}^{r-1} A_d, \qquad A_d = \max_{a+b=d} b_{a,b}, \qquad 1 \le r \le m.$$

Here there are at most m moves, and the multiplicity $d + 1$ in the lower-degree sum is absorbed in C_1. For $0 < s \le 1$, induction on r shows

$$A_r \le a_r + K_r s \sum_{k<r} a_k.$$

In fact $A_0 = a_0$, and one may take $K_r = C_1(1 + \sum_{1 \le d < r} K_d)$: insert the earlier bounds in the displayed recurrence and use $s^2 \le s$. Thus, for a constant C_2 depending only on the setting,

$$b_{0,m} \le a_m + C_2 s \sum_{k<m} a_k.$$

It remains to control the lower diagonal masses by a_m. The identity $\sigma_V = \alpha \sigma_v + \eta\omega$ and mixed positivity give $b_{k,1} \ge \eta a_k$; this identity and inequality pass from smooth

approximations by joint convergence. The diagonal assertion of Lemma 12.12.2 gives

$$\eta a_k \le a_{k+1} + C_3 s(a_k + a_{k-1} + a_{k-2}) \qquad (0 \le k < m),$$

with $a_{-1} = a_{-2} = 0$. Set $B_k = \eta^{m-k} a_k$ for $0 \le k \le m$, and set $B_{-1} = B_{-2} = 0$. Multiplying by η^{m-k-1} and using $0 < \eta < 1$ gives

$$B_k \le B_{k+1} + \delta(B_k + B_{k-1} + B_{k-2}), \qquad \delta = C_3 s \eta^{-3}.$$

For $M = \max_{0 \le k < m} B_k$, summing from any $j < m$ through $m - 1$ gives $B_j \le B_m + 3m\delta M$. If $s < \eta^3/(6mC_3)$, it follows that $M \le 2B_m$. Consequently

$$a_k \le 2\eta^{-(m-k)} a_m \quad (k < m), \qquad \sum_{k<m} a_k \le 2m\eta^{-m} a_m.$$

Choose $C \ge \max\{1, 6mC_3, 2mC_2\}$. Then the asserted range for s supplies every preceding restriction, and substitution in the bound for $b_{0,m}$ proves the theorem. No division by a_m occurs, so zero top mass on E_s is included. □

12.12.2 Domination and proper equations

The weak modified comparison estimate makes strict domination possible on an arbitrary Hermitian background. A convex rescaling supplies a positive volume term, while choosing a sufficiently small sublevel set absorbs the torsion error. Canonical representatives detect its positive volume even when the set is not open.

Theorem 12.12.3 *Let u, v be bounded admissible. If, for some $0 \le c < 1$,*

$$\mathbf{1}_{\{u<v\}} H_m(u) \le c \mathbf{1}_{\{u<v\}} H_m(v),$$

then $u \ge v$ everywhere, on an arbitrary Hermitian background. In particular, $H_m(u)(\{u < v\}) = 0$ implies $u \ge v$.

Proof Add the same constant to u, v so that $v \ge 1$. This preserves the measure hypothesis and the desired conclusion. Choose $0 < \alpha < 1$ with $\alpha^m > c$ and put $V = \alpha v$, $\eta = 1 - \alpha$. Suppose $S = \inf_X(u - V) < 0$. For $0 < s < -S$, the set $E_s = \{u < V + S + s\}$ is contained in $\{u < V\}$ and hence in $\{u < v\}$. It has positive volume. Indeed, if its volume were zero, then $u \ge V + S + s$ almost everywhere. Both functions are bounded admissible with their canonical representatives, so Lemma 12.1.8 would give this order everywhere, contradicting the definition of S. The argument does not require E_s to be open or the infimum to be attained.

Choose also $s < \eta^3/C$, where C is from Theorem 12.12.2. By Lemma 12.11.1 and the measure hypothesis,

$$\begin{aligned}\alpha^m H_m(v)(E_s) + \eta^m \int_{E_s} \omega^n &\le H_m(V)(E_s)\\ &\le (1 + Cs\eta^{-m}) H_m(u)(E_s)\\ &\le c(1 + Cs\eta^{-m}) H_m(v)(E_s).\end{aligned}$$

If $c > 0$, take s still smaller so that $c(1 + Cs\eta^{-m}) < \alpha^m$. If $c = 0$, this strict inequality already holds. All measures are finite and positive, so the display forces the positive-volume term to be zero, a contradiction. Hence $S \ge 0$ and $u \ge \alpha v$. Let α increase to one, with $\alpha^m > c$. Since v is bounded, $\alpha v \to v$ uniformly, and therefore $u \ge v$. The final assertion is $c = 0$. □

Corollary 12.12.1 *Fix $a > 0$. If bounded admissible u, v satisfy*

$$e^{-av} H_m(v) \ge e^{-au} H_m(u),$$

then $u \ge v$. Consequently, for any fixed finite positive Radon measure ν, the equation $H_m(u) = e^{au}\nu$ has at most one bounded admissible solution.

Proof For $\delta > 0$, put $E_\delta = \{u < v - \delta\}$. Multiplying the assumed measure inequality by the positive bounded Borel function e^{au} gives on E_δ

$$H_m(u) \le e^{a(u-v)} H_m(v) \le e^{-a\delta} H_m(v - \delta).$$

The last identity uses invariance under constants. Since $e^{-a\delta} < 1$, Theorem 12.12.3 applied to $u, v - \delta$ gives $u \ge v - \delta$ everywhere. Letting $\delta \downarrow 0$ gives $u \ge v$. Two solutions of the stated equation have equal weighted measures $e^{-au} H_m(u) = \nu$. Applying the order assertion in both directions proves uniqueness. □

A strictly increasing exponent also controls changes in logarithmic data for a fixed Radon right-hand measure.

Proposition 12.12.2 *Let $A < B$ and f be smooth near $X \times [A, B]$, with $\partial_t f \geq \kappa > 0$ there, and let ν be a finite positive Radon measure. Suppose bounded admissible u, v have values in $[A, B]$ and satisfy*

$$H_m(u) = e^{f(x,u)+h_1}\nu, \qquad H_m(v) = e^{f(x,v)+h_2}\nu,$$

where h_1, h_2 are bounded Borel functions. Then

$$\|u - v\|_\infty \leq \kappa^{-1}\|h_1 - h_2\|_{L^\infty(\nu)}.$$

Proof Put $K = \|h_1 - h_2\|_{L^\infty(\nu)}$ and fix $s > K/\kappa$. On $E_s = \{v + s < u\}$, the actual values u, v lie in $[A, B]$, so $f(x, u) - f(x, v) \geq \kappa s$. The equations and the essential bound on $h_2 - h_1$ therefore give, as restricted measures,

$$\mathbf{1}_{E_s} H_m(v + s) = \mathbf{1}_{E_s} H_m(v) \leq e^{K-\kappa s}\mathbf{1}_{E_s} H_m(u).$$

The constant is smaller than one. Applying Theorem 12.12.3 to $v + s, u$ gives $u \leq v + s$ pointwise. Let $s \downarrow K/\kappa$ and exchange u, v to obtain the norm bound. The exponent is evaluated only at u, v; the shifted comparison potential need not take its values in $[A, B]$. □

Corollary 12.12.2 *Under the hypotheses of Theorem 12.7.2, every bounded admissible solution with values in $[A, B]$ is its smooth solution. In particular, for every $a > 0$ and smooth real H, the equation $H_m(u) = e^{au+H}\omega^n$ has exactly one bounded admissible solution, and that solution is smooth and strictly admissible.*

Proof For a continuous admissible potential, smooth decreasing admissible approximations converge uniformly on compact X by Dini's theorem. Thus Theorem 12.10.1 and Proposition 12.6.1 define the same Hessian measure on the continuous class. The smooth solution of Theorem 12.7.2 therefore solves the bounded equation as well. Apply Proposition 12.12.2 with $\nu = \omega^n$ and $h_1 = h_2 = 0$ to identify any other bounded solution in $[A, B]$ with it. For the final assertion, smooth existence is already Lemma 12.5.1, and Corollary 12.12.1 with $\nu = e^H\omega^n$ gives uniqueness among all bounded solutions. □

Part III
Relative singularities and equations

Chapter 13
Envelopes and volumes of singularities

Throughout this chapter, X is a connected compact complex manifold of dimension $n \geq 1$, with an auxiliary Hermitian metric ω and a smooth positive volume form $\mathrm{d}V$, and θ denotes a smooth real $(1,1)$-form on X whose positivity is specified in each section.

In a closed background, the non-pluripolar Monge–Ampère mass of a potential depends only on its singularity type; this is what makes mass a tool for comparing singularities. In a nonclosed background, a bounded change of the potential can change the mass, and a singularity type may contain potentials of different, even infinite, masses. This chapter opens the part of the book on relative singularities and the equations they govern, and introduces two kinds of invariants that take this into account.

The first records the variation of mass: the lower and upper volumes $\underline{\mathrm{vol}}_\theta(u)$ and $\overline{\mathrm{vol}}_\theta(u)$ of a potential u are the infimum and the supremum of the masses of all potentials of the same singularity type. The second replaces a mass condition by a condition on envelopes. Fix a reference potential φ. Stretching a potential u away from φ by a factor $b \geq 1$ gives the obstacle $bu - (b-1)\varphi$, which is more singular than u where u lies below φ. The *relative envelope class* $\mathcal{E}_\varphi$ consists of the potentials u at least as singular as φ for which every such stretched obstacle lies above some θ-plurisubharmonic function. This class is convex and stable under finite rooftops, its members have the same singularity envelope as φ, and its definition involves no mass.

The main tool is the contact property of envelopes: the Monge–Ampère measure of an envelope is carried by the set where it touches its obstacle. Together with ordered contact, it gives the domination principle for bounded potentials in a semipositive background and bounds the measures of rooftop envelopes. For envelopes of logarithmic growth on $\mathbb{C}^n$, which correspond to envelopes on $\mathbb{P}^n$, we also examine how the contact of the regularized envelope with its obstacle depends on the growth allowance.

In a semipositive big background, the contact property also produces positive mass. Let φ be a model reference, that is, a fixed point of the singularity envelope that admits a competitor in a smaller background. Every member u of $\mathcal{E}_\varphi$ then has a competitor in a background $a\theta$ with $0 < a < 1$, and an envelope in the remaining

big background $(1-a)\theta$ has positive mass, which it transfers to u on the contact set. The argument uses only that each bounded potential has positive mass, so it applies even when the infimum of these masses is zero. Conversely, if the Hermitian metric ω does not have the bounded mass property of Definition 6.5.1, the relative envelope class of the zero potential contains potentials of infinite mass. Envelope conditions and mass bounds are therefore different requirements, and this distinction is essential for the equations with prescribed singularities in the next chapter.

We use the following notation from Chapter 1. For quasi-plurisubharmonic functions u, v, we write $u \preceq v$ if $u \leq v + C$ for a constant C, and $u \sim v$ if $u \preceq v$ and $v \preceq u$; the equivalence class of u is its *singularity type* (Definition 1.12.1). For an obstacle f, the envelope $P_\theta(f)$ is the upper semicontinuous regularization of the supremum of all $v \in \mathrm{PSH}(X,\theta)$ with $v \leq f$ quasi-everywhere; it may be identically $-\infty$, and then it does not belong to $\mathrm{PSH}(X,\theta)$. For $u, v \in \mathrm{PSH}(X,\theta)$, the rooftop envelope is $P_\theta(u,v) = P_\theta(\min(u,v))$, and $V_\theta = P_\theta(0)$ is the potential with minimal singularities; see Section 1.19. The singularity envelope $P_\theta[u]$, its variant $P_{\theta,F}[u]$ with a smooth obstacle F, and envelope fixed points, that is, potentials with $P_\theta[u] = u$, are defined in Definition 1.19.1. We write $\theta_u = \theta + \mathrm{dd^c} u$ and $\omega_u = \omega + \mathrm{dd^c} u$. For $u \in \mathrm{PSH}(X,\theta)$, $\mathrm{MA}_\theta(u)$ denotes the extended Monge–Ampère measure $\mathrm{MA}^{\mathrm{ext}}_\theta(u)$ of Theorem 6.1.1. It is the Bedford–Taylor measure $(\theta + \mathrm{dd^c} u)^n$ when u is bounded, it puts no mass on pluripolar sets, and its total mass, the *extended mass* of u, may be infinite.

13.1 Contact sets

The Monge–Ampère measure of an envelope is concentrated on the contact set, where the envelope meets its obstacle. For a smooth obstacle and a Hermitian background, the envelope is the uniform limit of solutions of exponential equations whose densities tend to zero wherever the envelope stays strictly below the obstacle. Continuity of bounded products then carries this property to quasi-continuous obstacles, first bounded ones, through monotone approximation, and then general ones, through truncation.

Proposition 13.1.1 *Let $f \in C^\infty(X,\mathbb{R})$. For $\beta > 0$, denote by u_β the smooth strictly ω-plurisubharmonic solution of*

$$\omega_{u_\beta}^n = \mathrm{e}^{\beta(u_\beta - f)}\omega^n.$$

As $\beta \longrightarrow +\infty$, these solutions converge uniformly to $p = P_\omega(f)$. Moreover,

$$\mathbf{1}_{\{p<f\}}\omega_p^n = 0.$$

Proof The solutions exist by Theorem 9.6.1. Choose $A \geq 0$ with $\mathrm{dd^c} f \leq A\omega$. At a maximum point of $u_\beta - f$, the second derivative test gives

$$\omega_{u_\beta} \le \omega + \mathrm{dd}^{\mathrm{c}} f \le (1 + A)\omega.$$

Evaluating the equation at this point, we obtain

$$u_\beta \le f + \frac{C_f}{\beta}, \qquad C_f = n \log(1 + A).$$

Thus $u_\beta - C_f/\beta$ is a competitor for $P_\omega(f)$, and $u_\beta \le p + C_f/\beta$.

For the lower bound, note that p is continuous by Proposition 1.19.1, and choose smooth strictly ω-plurisubharmonic functions $v_j \downarrow p$ by Theorem 1.11.1; by Dini's theorem the convergence is uniform. For any $\delta > 0$, choose j so that

$$p \le v_j \le p + \delta/2.$$

Then $v_j - \delta \le f$, since $p \le f$. Since $\omega_{v_j} > 0$ and X is compact, there is $c_j > 0$ such that $\omega_{v_j}^n \ge c_j \omega^n$. Put $C_j = \max(0, -\log c_j)$. The function

$$w_{j,\beta} = v_j - \delta - C_j/\beta$$

satisfies

$$\omega_{w_{j,\beta}}^n = \omega_{v_j}^n \ge \mathrm{e}^{-C_j} \omega^n \ge \mathrm{e}^{\beta(w_{j,\beta} - f)} \omega^n.$$

Exponential comparison, Corollary 10.2.2 with $\lambda = \beta$, gives $w_{j,\beta} \le u_\beta$. Consequently

$$p - \delta - C_j/\beta \le u_\beta \le p + C_f/\beta.$$

Letting first $\beta \to \infty$ with j fixed, so that no lower bound for c_j uniform in j is needed, and then $\delta \downarrow 0$, we obtain uniform convergence. Bounded Bedford–Taylor continuity then gives weak convergence of the measures.

On a compact subset of the open set $\{p < f\}$, uniform convergence gives $u_\beta - f \le -\epsilon$ for some $\epsilon > 0$ and all large β. There the measures $\omega_{u_\beta}^n$ have densities at most $\mathrm{e}^{-\beta\epsilon}$ with respect to ω^n. Testing against continuous functions with compact support in $\{p < f\}$ and passing to the limit gives $\omega_p^n = 0$ on this open set. □

Proposition 13.1.2 *If f is bounded and lower semicontinuous, then $P_\omega(f)$ is bounded, lies below f quasi-everywhere, and its Monge–Ampère measure is concentrated on $\{P_\omega(f) = f\}$.*

Proof Suppose first that f is continuous. Choose smooth functions $f_j \to f$ uniformly. The Lipschitz bound for envelopes in Proposition 1.19.1 gives $p_j = P_\omega(f_j) \to p = P_\omega(f)$ uniformly. Every compact subset of the open set $\{p < f\}$ has a neighborhood on which $p_j < f_j$ for all large j. The preceding proposition and convergence of bounded products then give $\omega_p^n = 0$ on $\{p < f\}$.

For lower semicontinuous f, choose continuous functions $f_j \uparrow f$ with common upper and lower bounds. For example, for a fixed distance d inducing the topology of X, one may take

$$f_j(x) = \inf_{y \in X} \bigl(f(y) + j d(x, y)\bigr).$$

These functions are Lipschitz and increase to f: if convergence failed at x, approximate minimizers y would approach x, contradicting lower semicontinuity of f at x.

The functions $p_j = P_\omega(f_j)$ increase and stay bounded, so the regularized limit $p_\infty = (\lim_j p_j)^*$ is a bounded ω-plurisubharmonic function. It agrees with $\lim_j p_j$ outside a pluripolar set, and since each p_j lies below $f_j \le f$ outside a pluripolar set, we obtain $p_\infty \le f$ quasi-everywhere. Thus $p_\infty \le P_\omega(f)$.

For fixed k, the set $\{p_\infty < f_k\}$ is open, since p_∞ is upper semicontinuous and f_k is continuous. If $j \ge k$, then $p_j \le p_\infty < f_k \le f_j$ there, so the continuous case gives $\omega_{p_j}^n = 0$ on that open set. Bedford–Taylor continuity along increasing sequences applies after adding a fixed smooth local function whose Hessian dominates ω and expanding with respect to the resulting smooth form. Together with the lower semicontinuity of the mass of open sets under weak convergence, it yields

$$\omega_{p_\infty}^n(\{p_\infty < f_k\}) = 0.$$

Taking the union over k gives zero measure on $\{p_\infty < f\}$, hence also on $\{p_\infty < P_\omega(f)\}$ outside a pluripolar set, since $P_\omega(f) \le f$ quasi-everywhere. Bounded measures of this kind do not charge pluripolar sets, so the domination principle, Theorem 10.2.2, gives $p_\infty \ge P_\omega(f)$. The two functions are therefore equal, and the assertion follows. □

Theorem 13.1.1 *Let $\theta \ge 0$ be smooth and let f be bounded and quasi-continuous. Then $p = P_\theta(f)$ is bounded, $p \le f$ quasi-everywhere, and*

$$\mathbf{1}_{\{p<f\}}\mathrm{MA}_\theta(p) = 0.$$

Proof First suppose that $\theta = \omega$ is Hermitian. Choose bounded lower semicontinuous functions $f_j \downarrow f$ quasi-everywhere, with common bounds, as in Lemma 1.8.5. The bounded functions $p_j = P_\omega(f_j)$ decrease to p. Indeed, their limit is a competitor for p, since it lies below f quasi-everywhere, and the reverse inequality follows from monotonicity.

For fixed k, put $H_k = \min\{1, (f - p_k)_+\}$, a bounded quasi-continuous function. Where $H_k > 0$ and $j \ge k$, we have $p_j \le p_k < f \le f_j$ outside a pluripolar set. The lower semicontinuous case therefore gives

$$\int_X H_k\, \omega_{p_j}^n = 0.$$

The convergence of bounded products against quasi-continuous weights in Section 1.8 gives $\int_X H_k\, \omega_p^n = 0$. Since the sets $\{p_k < f\}$ increase to $\{p < f\}$, this proves the assertion for Hermitian θ.

For general semipositive θ, set $\theta_j = \theta + j^{-1}\omega$. The functions $p_j = P_{\theta_j}(f)$ have the common bounds $\inf_X f \le p_j \le \sup_X f$ and decrease. Their limit is θ-plurisubharmonic by distributional convergence and lies below f quasi-everywhere, so it is at most $p = P_\theta(f)$; since $p \le p_j$ for all j, it equals p. For each fixed k, the same coefficient $H_k = \min\{1, (f - p_k)_+\}$ gives

$$\int_X H_k \, \mathrm{MA}_{\theta_j}(p_j) = 0 \qquad (j \geq k).$$

All p_j are bounded potentials for the fixed Hermitian form $\theta + \omega$. Expanding the products with background θ_j with respect to this fixed background, we may use convergence of bounded products and uniform capacity bounds to pass the last identity to the limit, with the quasi-continuous weight H_k; this gives $\int_X H_k \, \mathrm{MA}_\theta(p) = 0$. Exhausting $\{p < f\}$ as before completes the proof. □

Theorem 13.1.2 *Let θ be smooth and semipositive, and let f be a quasi-continuous obstacle. If $p = P_\theta(f)$ is not identically $-\infty$, then $p \leq f$ quasi-everywhere and*

$$\mathbf{1}_{\{p<f\}} \mathrm{MA}_\theta(p) = 0.$$

Here the total extended mass of p may be infinite.

Proof The local envelope theorem, applied to a countable family realizing the supremum (Choquet's lemma), gives $p \leq f$ outside a pluripolar set. Choose $M > \sup_X p$ and replace f by $\min(f, M)$. This does not change the envelope, since p itself is a competitor for the smaller obstacle. Since $p < M$, the contact set is also unchanged, so it suffices to prove the theorem for the smaller obstacle; that is, we may assume that f is bounded above.

Set $f_j = \max(f, -j)$ and $p_j = P_\theta(f_j)$. The constants $-j$ are competitors, so p_j is bounded. Theorem 13.1.1 gives $p_j \leq f_j$ quasi-everywhere and

$$\mathbf{1}_{\{p_j<f_j\}} \mathrm{MA}_\theta(p_j) = 0.$$

The sequence p_j decreases and stays above p. Its limit is therefore θ-plurisubharmonic, it lies below f quasi-everywhere, and so it is a competitor for p. Hence $p_j \downarrow p$.

Fix an integer $k \geq 1$ and $C > 0$, and define the bounded nonnegative quasi-continuous function

$$H_{k,C} = \min\{1, (f - p_k)_+\} \, \min\{1, (p + C)_+\}.$$

Its values on pluripolar sets are immaterial. Where this coefficient is positive, $p_k < f$ and $p > -C$. For $j \geq k$, we then have $p_j \leq p_k < f \leq f_j$ and $p_j \geq p > -C$ there. Plurifine locality and Theorem 13.1.1 therefore imply

$$\int_X H_{k,C} \, \mathrm{MA}_\theta(\max(p_j, -C)) = 0.$$

The truncated potentials are uniformly bounded and decrease to $\max(p, -C)$, so their measures converge weakly by bounded Bedford–Taylor continuity. The uniform capacity bounds and the weighted convergence in Section 1.8 also allow testing against $H_{k,C}$. Hence the last identity holds with p in place of p_j. By plurifine locality, this says that the extended measure of p vanishes on $\{p_k < f\} \cap \{p > -C\}$. Off the pole set of p, these sets increase to $\{p < f\}$ as first k and then C tend to infinity.

Continuity of positive measures along increasing sequences proves the assertion, even if the total extended mass is infinite. □

For a smooth big background, constants need not be competitors, and a strictly θ-plurisubharmonic barrier with poles replaces the constant lower truncations. The same contact property for quasi-continuous obstacles finite almost everywhere is proved in this setting in Theorem 14.7.2. Combined with ordered contact, either contact theorem controls the measures of rooftop envelopes. In the following bound, the strict inequality in the first term assigns the common contact set $\{p = u = v\}$ to the second term.

Proposition 13.1.3 *Let θ be a smooth real $(1,1)$-form that is semipositive or big, and let $u, v \in \mathrm{PSH}(X,\theta)$. If $p = P_\theta(u,v)$ is not identically $-\infty$, then*

$$\mathrm{MA}_\theta(p) \le \mathbf{1}_{\{p=u<v\}}\mathrm{MA}_\theta(u) + \mathbf{1}_{\{p=v\}}\mathrm{MA}_\theta(v).$$

Proof The envelope lies below both obstacles quasi-everywhere, hence everywhere, since the obstacles are upper semicontinuous. By the contact theorem (Theorem 13.1.2 or Theorem 14.7.2), its measure is carried by $\{p = \min(u,v)\}$. Partition this set into $\{p = u < v\}$ and $\{p = v\}$, and apply Proposition 6.2.1 on each part. All measures vanish on the pluripolar pole sets, which can therefore be discarded throughout. □

Proposition 13.1.4 *Let θ be smooth and semipositive. Every envelope fixed point φ satisfies*

$$\mathrm{MA}_\theta(\varphi) \le \mathbf{1}_{\{\varphi=0\}}\theta^n.$$

In particular, its extended mass is finite.

Proof Since $\varphi = P_\theta[\varphi] \le 0$, the function φ is a competitor for $P_\theta(\varphi+1,0)$. This rooftop is also a competitor for $P_\theta[\varphi] = \varphi$, being at most $\varphi+1$ and at most zero, so it equals φ. Now apply Proposition 13.1.3 with $u = \varphi+1$ and $v = 0$. The contact set $\{\varphi = \varphi+1 < 0\}$ is contained in the pole set of φ, which the extended measure does not charge. Only contact with zero contributes, and this gives the asserted bound. □

13.1.1 Affine growth and projective envelopes

The contact property concerns the regularized envelope. For the classical weighted extremal functions on $\mathbb{C}^n$, the obstacle is imposed at every point of a compact set, and one may ask when the regularized envelope still touches the obstacle there. Compactifying $\mathbb{C}^n$ to $\mathbb{P}^n$ turns the logarithmic growth allowance into a semipositive background. This correspondence distinguishes contact of the raw supremum with the obstacle from contact of its upper semicontinuous regularization, and it shows how both depend on the growth allowance.

In the rest of this section we work on $\mathbb{C}^n$ and on $\mathbb{P}^n$ rather than on X. Write $\chi(z) = \log(1+\|z\|^2)$ on $\mathbb{C}^n$, and let ω_{FS} be the Fubini–Study form on $\mathbb{P}^n$ with this local potential, so that $\int_{\mathbb{P}^n}\omega_{\mathrm{FS}}^n = 1$ with our normalization of dd^{c}. For $\delta > 0$ put

$$\theta_\delta = \tfrac{\delta}{2}\omega_{\mathrm{FS}}, \qquad \mathcal{L}_\delta = \{u \in \mathrm{PSH}(\mathbb{C}^n) : u(z) \le \delta \log^+\|z\| + C_u\}.$$

Here $\log^+ = \max(\log, 0)$, and C_u is a constant depending on u. Thus $\mathcal{L}_\delta$ is the class of plurisubharmonic functions of logarithmic growth at most δ. Let $\mathcal{L}^+_\delta$ consist of the members of $\mathcal{L}_\delta$ that are also bounded below by $\delta \log^+\|z\| - C$ for some constant C.

Lemma 13.1.1 *The map $u \mapsto u - \delta\chi/2$, followed by the canonical extension across the hyperplane at infinity, is a bijection from $\mathcal{L}_\delta$ onto* $\mathrm{PSH}(\mathbb{P}^n, \theta_\delta)$.

Proof Use homogeneous coordinates $[Z_0 : \cdots : Z_n]$ and the affine chart $Z_0 \neq 0$. On a chart $Z_i \neq 0$ meeting $H = \{Z_0 = 0\}$, the local plurisubharmonic representative of $p = u - \delta\chi/2$ is

$$p + \frac{\delta}{2}\log\frac{\sum_{j=0}^n |Z_j|^2}{|Z_i|^2} = u + \delta \log |Z_0/Z_i|.$$

This function is locally bounded above near H, by the growth bound on u, because the norm of the affine coordinates is at most a constant, depending on the chart, divided by $|Z_0/Z_i|$. By Lemma 1.3.7, it therefore extends canonically across H. Since the local potentials of θ_δ differ by smooth functions on overlaps, the extensions agree there.

Conversely, every $p \in \mathrm{PSH}(\mathbb{P}^n, \theta_\delta)$ is bounded above, since $\mathbb{P}^n$ is compact. The function $u = p + \delta\chi/2$ is plurisubharmonic on the affine chart, and

$$0 \le \tfrac{1}{2}\chi - \log^+\|z\| \le \tfrac{1}{2}\log 2$$

gives the required growth bound. Neither function is identically $-\infty$ on the affine chart. Uniqueness of the canonical extension shows that the two maps are inverse to each other. □

Fix a non-pluripolar compact set $K \subset \mathbb{C}^n$ and a bounded real function ψ on K. Define the raw and the regularized envelope

$$V_\delta = \sup\{u \in \mathcal{L}_\delta : u|_K \le \psi\}, \qquad F_\delta = V^*_\delta,$$

where the obstacle condition is imposed at every point of K. On $\mathbb{P}^n$ put

$$G_\delta = \sup\{p \in \mathrm{PSH}(\mathbb{P}^n, \theta_\delta) : p|_K \le \psi - \delta\chi/2\}.$$

Proposition 13.1.5 *The regularized envelope G^*_δ on $\mathbb{P}^n$ is bounded and θ_δ-plurisubharmonic. On the affine chart,*

$$V_\delta = \tfrac{\delta}{2}\chi + G_\delta, \qquad F_\delta = \tfrac{\delta}{2}\chi + G^*_\delta \in \mathcal{L}^+_\delta. \tag{13.1}$$

Moreover, $V_\delta = F_\delta$ almost everywhere.

Proof By Lemma 13.1.1, the map $u \mapsto u - \delta\chi/2$ is a bijection between the two families of competitors, which proves the identity for V_δ. Constants below $\inf_K(\psi - \delta\chi/2)$ are competitors for G_δ.

Since all competitors for G_δ lie below the constant $\sup_K(\psi - \delta\chi/2)$ on K, Lemma 1.19.1 gives a common upper bound for them. Together with a constant competitor, the upper-envelope theorem shows that G^*_δ is bounded and θ_δ-plurisubharmonic. Addition of the smooth function $\delta\chi/2$ in (13.1) commutes with regularization, and the two-sided bounds for G^*_δ give $F_\delta \in \mathcal{L}^+_\delta$.

Locally, adding a potential of θ_δ makes the competitors plurisubharmonic. The upper-envelope theorem recalled in Chapter 1 shows that regularization changes their supremum only on a pluripolar set. Thus $G_\delta = G^*_\delta$ almost everywhere, and adding $\delta\chi/2$ gives the same assertion for V_δ. □

The regularized envelope does not change if the obstacle is imposed only outside a pluripolar subset of K. Within the growth class this can be seen directly: a function in $\mathcal{L}_\delta$ with poles on the exceptional set repairs each competitor.

Lemma 13.1.2 *For every pluripolar set $E \subseteq \mathbb{C}^n$ and every $\delta > 0$, there is $b \in \mathcal{L}_\delta$ with $b = -\infty$ on E. Given a non-pluripolar compact set K, it can be chosen with $b \le 0$ on K.*

Proof Put $E_j = E \cap \overline{B}(0, j)$. Each E_j is pluripolar as a subset of $\mathbb{P}^n$: it is locally pluripolar near every affine point, and a neighborhood of the hyperplane at infinity does not meet this bounded set. By Josefson's theorem on compact manifolds, [Xia, Theorem 1.1.5], there is a quasi-plurisubharmonic function on $\mathbb{P}^n$, not identically $-\infty$, that equals $-\infty$ on E_j. Rescaling it so that it becomes θ_1-plurisubharmonic and subtracting its supremum gives

$$p_j \in \mathrm{PSH}(\mathbb{P}^n, \theta_1), \qquad p_j \le 0, \qquad p_j|_{E_j} = -\infty.$$

The L^1 norms of these normalized potentials are uniformly bounded by Theorem 1.4.1. The partial sums

$$p_N = \sum_{j=1}^{N} 2^{-j} p_j$$

decrease, have uniformly bounded L^1 norms, and remain θ_1-plurisubharmonic because $\theta_1 \ge 0$ and the coefficients sum to at most one. By Corollary 1.4.1, their limit p belongs to $\mathrm{PSH}(\mathbb{P}^n, \theta_1)$. Every point of E is a pole of one of the summands, hence $p = -\infty$ on E. By Lemma 13.1.1,

$$b = \delta(p + \chi/2) \in \mathcal{L}_\delta$$

has the required properties. Its supremum on K is finite, since b is bounded above on the compact set K and is not identically $-\infty$ on K, which is non-pluripolar. Subtracting this supremum gives $b \le 0$ on K. □

Corollary 13.1.1 *The envelope F_δ is unchanged if $u|_K \le \psi$ is imposed only quasi-everywhere, or only on $K \setminus E$ for any pluripolar $E \subseteq K$.*

Proof Let $u \in \mathcal{L}_\delta$ satisfy $u \le \psi$ on $K \setminus E$, where E is pluripolar. Choose b as in the lemma, with $b = -\infty$ on E and $b \le 0$ on K, and put $m = \inf_K \psi$. For $\epsilon > 0$ define

$$u_\epsilon = \frac{u + \epsilon b + \epsilon m}{1 + \epsilon}.$$

This function belongs to $\mathcal{L}_\delta$. On $K \setminus E$, the inequalities $u \le \psi$, $b \le 0$ and $m \le \psi$ give $u_\epsilon \le \psi$, and on E the pole of b gives $u_\epsilon = -\infty$. Thus u_ϵ is a competitor for V_δ, so $u_\epsilon \le F_\delta$; moreover, $u_\epsilon \to u$ almost everywhere as $\epsilon \downarrow 0$. By Lemma 1.3.3, $u \le F_\delta$ everywhere. Taking the supremum over u and regularizing proves the asserted equalities.

Alternatively, apply Proposition 1.19.2 on $\mathbb{P}^n$ with the big background θ_δ and the bounded obstacle $\psi - \delta\chi/2$, and then use (13.1). □

These equalities concern regularized envelopes. The raw envelope V_δ is still defined with the obstacle imposed at every point of K.

Changing δ changes both the background θ_δ and the obstacle $\psi - \delta\chi/2$. Nevertheless, the set of parameters for which contact holds has a simple structure. Put

$$\Lambda = \{\delta > 0 : V_\delta|_K = \psi\}, \qquad \Lambda_{\mathrm{reg}}(a) = \{\delta \in \Lambda : F_\delta(a) = \psi(a)\} \quad (a \in K).$$

The parameters $\delta \in \Lambda$ are those for which the raw envelope touches the obstacle at every point of K; we say that *raw contact* holds for them. For $a \in K$, the parameters in $\Lambda_{\mathrm{reg}}(a)$ are those for which, in addition, the regularized envelope touches the obstacle at a; we say that *regular contact* holds at a.

Theorem 13.1.3 *The set Λ is empty, $(0, \infty)$, or $[\lambda, \infty)$ for some $\lambda > 0$. If $\Lambda = [\lambda, \infty)$, each $\Lambda_{\mathrm{reg}}(a)$ is empty, $\{\lambda\}$, or Λ. If $\Lambda = (0, \infty)$, each $\Lambda_{\mathrm{reg}}(a)$ is empty or Λ. The same alternatives hold for $\bigcap_{a \in K} \Lambda_{\mathrm{reg}}(a)$.*

Proof Let $m = \inf_K \psi$. Inclusion of the growth classes and scaling of competitors give, for $0 < \alpha < \beta$,

$$0 \le V_\beta - V_\alpha \le \frac{\beta - \alpha}{\alpha}(V_\alpha - m). \tag{13.2}$$

Indeed, if u is a competitor for V_β, then $(\alpha/\beta)(u - m) + m$ is a competitor for V_α, since $\psi \ge m$. The constant m is also a competitor, so all terms are finite and the right-hand side is nonnegative. The estimate shows that $V_\delta(z)$ depends continuously

on $\delta > 0$ at every point z. Since $V_\delta \le \psi$ on K and V_δ increases with δ, the set Λ is closed upwards, and by continuity it is relatively closed in $(0, \infty)$. This proves the three possible forms of Λ.

For $0 \le t \le 1$, convex combinations of competitors give

$$V_{(1-t)\alpha+t\beta} \ge (1-t)V_\alpha + tV_\beta.$$

By the preceding proposition, the same inequality holds for the regularized envelopes almost everywhere, and hence everywhere by Lemma 1.3.3. Thus $F_\delta(z)$ is a concave nondecreasing function of δ at every point z.

For $a \in K$ and $\delta \in \Lambda$, the defect $d_\delta = F_\delta(a) - \psi(a)$ is nonnegative, concave and nondecreasing in δ. Suppose $d_\alpha = 0$, and that there is $\eta \in \Lambda$ with $\eta < \alpha$. For every $\beta > \alpha$, write α as a convex combination of η and β with positive weights. Concavity then forces both nonnegative defects d_η and d_β to vanish, and monotonicity gives $d_\delta = 0$ for all $\delta \in \Lambda$ with $\delta < \alpha$. Hence a zero of the defect at a parameter other than the smallest element of Λ forces every defect to vanish. This proves the alternatives for each $\Lambda_{\mathrm{reg}}(a)$, and intersecting them gives the alternatives for $\bigcap_{a\in K} \Lambda_{\mathrm{reg}}(a)$. □

Thus raw contact persists as the growth allowance increases, whereas regular contact at a point may hold only at the smallest contact parameter. The correspondence with $\mathbb{P}^n$ keeps the background and the obstacle matched throughout this variation.

13.1.1.1 Growth slopes and supporting probabilities

By concavity, the rate at which F_δ grows when the growth allowance δ is increased is at least its rate of growth for large δ, and the latter is the classical extremal function of K, without weight. For continuous weights, supporting probabilities express the initial rate of growth through tests by functions of the fixed class $\mathcal{L}_1$.

When the weight varies, we write $V_{\delta,q}$ and $F_{\delta,q} = V^*_{\delta,q}$ for the raw and regularized envelopes defined as above, with a bounded obstacle q on the fixed compact set K in place of ψ. Thus $F_\delta = F_{\delta,\psi}$. Set

$$V_K = V_{1,0}, \qquad V^*_K = F_{1,0}, \qquad m = \inf_K \psi, \qquad M = \sup_K \psi.$$

Thus V^*_K is the extremal function of K. Since the constant 0 is a competitor for V_K, and since competitors can be scaled and translated by constants, we have $V^*_K \ge 0$ and

$$\delta V^*_K + m \le F_\delta \le \delta V^*_K + M. \tag{13.3}$$

Lemma 13.1.3 *For $0 < \alpha < \beta$, one has on $\mathbb{C}^n$*

$$(\beta - \alpha)V^*_K \le F_\beta - F_\alpha \le \frac{\beta - \alpha}{\alpha}(F_\alpha - m). \tag{13.4}$$

Proof If u is a competitor for $V_\alpha = V_{\alpha,\psi}$ and v is a competitor for $V_K = V_{1,0}$, then $u + (\beta - \alpha)v$ is a competitor for V_β. Taking the suprema over u and v independently

gives

$$V_\beta \geq V_\alpha + (\beta - \alpha)V_K.$$

By Proposition 13.1.5, the raw envelopes agree almost everywhere with their regularizations, so this inequality holds almost everywhere for the regularizations, and hence everywhere by Lemma 1.3.3. This is the first inequality. The same argument applied to (13.2) gives the second. □

Proposition 13.1.6 *For every $a \in \mathbb{C}^n$ and $\tau > 0$, the right derivative*

$$D_\tau(a) = \lim_{h \downarrow 0} \frac{F_{\tau+h}(a) - F_\tau(a)}{h}$$

exists and is finite. The difference quotients decrease as $h > 0$ increases, and

$$V_K^*(a) \leq \frac{F_{\tau+h}(a) - F_\tau(a)}{h} \leq D_\tau(a) \leq \frac{F_\tau(a) - m}{\tau}. \tag{13.5}$$

As $h \to \infty$, they converge to $V_K^*(a)$, with the error bound

$$0 \leq \frac{F_{\tau+h}(a) - F_\tau(a)}{h} - V_K^*(a) \leq \frac{M - m}{h}. \tag{13.6}$$

Moreover, $D_\tau(a) = V_K^*(a)$ if and only if

$$F_\delta(a) = F_\tau(a) + (\delta - \tau)V_K^*(a) \qquad (\delta \geq \tau). \tag{13.7}$$

Proof For $0 < h_1 < h_2$, concavity of $F_\delta(a)$ gives

$$F_{\tau+h_1}(a) - F_\tau(a) \geq \frac{h_1}{h_2}\big(F_{\tau+h_2}(a) - F_\tau(a)\big).$$

Thus the difference quotients decrease with h. Lemma 13.1.3 bounds them between $V_K^*(a)$ and $(F_\tau(a) - m)/\tau$, which proves the existence and finiteness of $D_\tau(a)$ and (13.5). Combining the lower bound for the increments with (13.3) gives (13.6), with a bound independent of a. If $D_\tau(a) = V_K^*(a)$, then by (13.5) every difference quotient equals $V_K^*(a)$, which gives (13.7). Conversely, that formula gives $D_\tau(a) = V_K^*(a)$.□

Corollary 13.1.2 *Let $a \in K$ and $\tau \in \Lambda_{\mathrm{reg}}(a)$. Regular contact at a holds for every $\delta > \tau$ if and only if $D_\tau(a) = 0$. If $D_\tau(a) > 0$, regular contact at a fails for every $\delta > \tau$, and τ is the smallest element of Λ.*

Proof At τ one has $F_\tau(a) = \psi(a)$, and raw contact holds for all $\delta \geq \tau$ by Theorem 13.1.3. If $D_\tau(a) = 0$, then by (13.5) every difference quotient at τ vanishes, so $F_\delta(a) = \psi(a)$ for all $\delta > \tau$. If $D_\tau(a) > 0$, then $F_\delta(a) > \psi(a)$ for all δ slightly larger than τ, and by monotonicity for all $\delta > \tau$. In this case $\Lambda_{\mathrm{reg}}(a)$ contains τ but no larger parameter, so by Theorem 13.1.3 it equals $\{\lambda\}$, where $\lambda = \tau$ is the smallest element of Λ. □

Assume now that the weights are continuous. If the obstacle is imposed only quasi-everywhere on K, the regularized envelope itself becomes a competitor, so the supremum needs no regularization; a constraint imposed at every point would miss the values created by regularization. Indeed, for $q \in C(K, \mathbb{R})$,

$$F_{\delta,q}(z) = \sup\{u(z) : u \in \mathcal{L}_\delta,\ u \le q \text{ q.e. on } K\}. \tag{13.8}$$

The envelope $F_{\delta,q}$ itself is a competitor on the right, since it agrees with the raw envelope off a pluripolar set by Proposition 13.1.5. Conversely, the argument of Corollary 13.1.1 shows that every competitor on the right lies below $F_{\delta,q}$ everywhere.

For $a \in \mathbb{C}^n$, let $\mathcal{J}_a(K)$ be the set of *supporting pairs* (μ, c), where μ is a Borel probability measure on K and $c \ge 0$, such that

$$u(a) \le \int_K f \, d\mu + c \tag{13.9}$$

whenever $u \in \mathcal{L}_1$, $f \in C(K, \mathbb{R})$ and $u \le f$ quasi-everywhere on K. We call μ a *supporting probability* at a.

Theorem 13.1.4 *For every $a \in \mathbb{C}^n$, $q \in C(K, \mathbb{R})$ and $\delta > 0$,*

$$F_{\delta,q}(a) = \min_{(\mu,c)\in\mathcal{J}_a(K)} \left(\int_K q \, d\mu + \delta c \right). \tag{13.10}$$

In particular, $\mathcal{J}_a(K)$ is nonempty and

$$\min_{(\mu,c)\in\mathcal{J}_a(K)} c = V_K^*(a).$$

Proof On the real Banach space $C(K)$, put $T(f) = F_{1,f}(a)$. By (13.8), T is concave, since convex combinations of competitors are competitors. Comparison of obstacles and translation by constants show that T is nondecreasing and satisfies

$$T(f + t) = T(f) + t, \qquad |T(f) - T(g)| \le \|f - g\|_\infty.$$

Fix $f_0 \in C(K)$. The directional derivative of the convex Lipschitz function $-T$ at f_0 is finite and sublinear. By the Hahn–Banach theorem, there is a continuous linear functional dominated by it, and since difference quotients of a convex function are monotone, this functional supports $-T$ at f_0. Changing the sign, we obtain a continuous linear functional ℓ with

$$T(f) \le T(f_0) + \ell(f - f_0) \qquad (f \in C(K)).$$

Testing $f = f_0 + th$ with $h \ge 0$ and $t > 0$, and using monotonicity, gives $\ell(h) \ge 0$. Testing with $f = f_0 \pm t$ gives $\ell(1) = 1$. By the Riesz representation theorem, $\ell(f) = \int_K f \, d\mu$ for a Borel probability measure μ on K. Set $c = T(f_0) - \int_K f_0 \, d\mu$. The supporting inequality at $f = 0$ gives $c \ge T(0) = V_K^*(a) \ge 0$. Together with (13.8), it shows that $(\mu, c) \in \mathcal{J}_a(K)$ and

$$T(f_0) = \int_K f_0 \, d\mu + c.$$

Conversely, applying (13.9) to $u = F_{1,f_0}$, which lies below f_0 quasi-everywhere on K, shows that $T(f_0) \le \int_K f_0 \, d\mu + c$ for every pair in $\mathcal{J}_a(K)$. This proves (13.10) for $\delta = 1$, with the minimum attained. The identity $F_{\delta,q} = \delta F_{1,q/\delta}$ gives the general case, and the zero obstacle gives the last assertion. □

Theorem 13.1.5 *If $\psi \in C(K, \mathbb{R})$, then for every $a \in \mathbb{C}^n$ and $\tau > 0$,*

$$D_\tau(a) = \min \left\{ c : (\mu, c) \in \mathcal{J}_a(K), \ \int_K \psi \, d\mu + \tau c = F_\tau(a) \right\}. \tag{13.11}$$

Consequently, $D_\tau(a) = V_K^*(a)$ if and only if there is a Borel probability measure μ on K such that

$$(\mu, V_K^*(a)) \in \mathcal{J}_a(K), \qquad \int_K \psi \, d\mu = F_\tau(a) - \tau V_K^*(a).$$

Proof Each defining inequality of $\mathcal{J}_a(K)$ is preserved under weak convergence of the probability measures and convergence of the constants, because the test function f is continuous. Since the Borel probability measures on the compact metric space K form a weakly compact set, the pairs in $\mathcal{J}_a(K)$ with $c \le C$ form a compact set for each finite C.

Call a pair in $\mathcal{J}_a(K)$ *active* at τ if it satisfies the equality in (13.11). Such pairs exist by Theorem 13.1.4, and since $\int_K \psi \, d\mu \ge m = \inf_K \psi$, they satisfy

$$0 \le c \le \frac{F_\tau(a) - m}{\tau}.$$

The set of active pairs is therefore compact, and the minimum of c over it is attained. By Theorem 13.1.4 at $\tau + h$, each active pair gives $F_{\tau+h}(a) \le F_\tau(a) + hc$, hence $D_\tau(a) \le c$.

Conversely, for $h > 0$ choose a pair (μ_h, c_h) attaining the minimum in (13.10) at $\tau + h$, with $q = \psi$. The representation at τ gives

$$F_\tau(a) \le \int_K \psi \, d\mu_h + \tau c_h = F_{\tau+h}(a) - h c_h.$$

Thus $0 \le c_h \le (F_{\tau+h}(a) - F_\tau(a))/h$, and these constants are bounded by (13.5). Along a sequence $h \downarrow 0$, compactness gives a limiting pair $(\mu, c) \in \mathcal{J}_a(K)$. The same bound makes $F_{\tau+h}(a) \to F_\tau(a)$ and $hc_h \to 0$, and continuity of ψ then gives $\int_K \psi \, d\mu + \tau c = F_\tau(a)$. Thus the limit pair is active, and it satisfies $c \le D_\tau(a)$. This proves (13.11). Finally, every pair has $c \ge V_K^*(a)$ by Theorem 13.1.4, so the attainment of the minimum gives the stated criterion. □

At a point a of regular contact, $F_\tau(a) = \psi(a)$, so the criterion involves only the original weight and tests by functions in $\mathcal{L}_1$. If the defining tests instead required

$u \le f$ at every point of K, the pair $(\delta_a, 0)$, where δ_a is the unit point mass at $a \in K$, would always be allowed; the resulting infimum would be at most $\psi(a)$ and would not detect a defect created by regularization.

13.1.1.2 Variation of continuous weights

Supporting probabilities also describe how the envelope responds to changes of the weight, jointly with changes of the growth allowance. Keep the non-pluripolar compact set $K \subset \mathbb{C}^n$ fixed. For $a \in \mathbb{C}^n$, $\delta > 0$ and $q \in C(K, \mathbb{R})$, let

$$\mathcal{J}_a^{\mathrm{act}}(\delta, q) = \left\{ (\mu, c) \in \mathcal{J}_a(K) : \int_K q \, \mathrm{d}\mu + \delta c = F_{\delta,q}(a) \right\}. \tag{13.12}$$

be the set of pairs that are active at (δ, q). We give the weights the uniform norm, the probability measures the weak topology, and the constants the usual topology of $\mathbb{R}$.

Lemma 13.1.4 *The set $\mathcal{J}_a^{\mathrm{act}}(\delta, q)$ is nonempty, convex and compact. For $\delta, \eta \ge \epsilon > 0$ and $p, q \in C(K, \mathbb{R})$,*

$$|F_{\eta,p}(a) - F_{\delta,q}(a)| \le \|p - q\|_\infty + |\eta - \delta| \left(V_K^*(a) + \frac{\operatorname{osc}_K q}{\epsilon} \right). \tag{13.13}$$

If $\delta_j \to \delta > 0$, $q_j \to q$ uniformly and $(\mu_j, c_j) \in \mathcal{J}_a^{\mathrm{act}}(\delta_j, q_j)$, then these pairs have a convergent subsequence, and every subsequential limit belongs to $\mathcal{J}_a^{\mathrm{act}}(\delta, q)$.

Proof Nonemptiness follows from Theorem 13.1.4. Since the test functions are continuous, $\mathcal{J}_a(K)$ is closed and convex, and the equality defining active pairs is a closed affine condition. For an active pair, (13.3), applied with the weight q, gives

$$0 \le c \le \frac{F_{\delta,q}(a) - \inf_K q}{\delta} \le V_K^*(a) + \frac{\operatorname{osc}_K q}{\delta}.$$

The pairs in $\mathcal{J}_a(K)$ with bounded constants form a compact set, as in the proof of Theorem 13.1.5; hence the set of active pairs is compact.

With q fixed, Lemma 13.1.3 and (13.3), applied with the weight q, bound $|F_{\eta,q}(a) - F_{\delta,q}(a)|$ by $|\eta - \delta|(V_K^*(a) + \operatorname{osc}_K q/\epsilon)$. Comparison of obstacles and translation by constants bound $|F_{\eta,p}(a) - F_{\eta,q}(a)|$ by $\|p - q\|_\infty$. Adding these bounds gives (13.13).

For the sequence in the statement, the constants c_j have a common bound, by the estimate above, because the weights q_j are uniformly bounded and the parameters δ_j are bounded below by a positive constant. Weak compactness of probability measures gives a convergent subsequence of pairs, and its limit belongs to $\mathcal{J}_a(K)$, which is closed. The estimate (13.13) gives $F_{\delta_j,q_j}(a) \to F_{\delta,q}(a)$, while uniform convergence of the q_j and weak convergence of the μ_j give $\int_K q_j \, \mathrm{d}\mu_j \to \int_K q \, \mathrm{d}\mu$. Passing to the limit in the equality defining active pairs proves the last assertion. □

Proposition 13.1.7 *For $r \in C(K, \mathbb{R})$ and $s \in \mathbb{R}$, one has*

$$\lim_{h \downarrow 0} \frac{F_{\delta+hs,q+hr}(a) - F_{\delta,q}(a)}{h} = \min_{(\mu,c) \in \mathcal{J}_a^{\mathrm{act}}(\delta,q)} \left(\int_K r \, \mathrm{d}\mu + sc \right). \tag{13.14}$$

The same limit holds along any sequence $h_j \downarrow 0$ if s, r in the difference quotient are replaced by s_j, r_j, where $s_j \to s$ and $r_j \to r$ uniformly. Thus the one-sided directional derivative is stable under convergence of the directions.

Proof By compactness of the set of active pairs, the minimum on the right is attained. For a fixed pair (μ, c) active at (δ, q), the representation (13.10) at the perturbed parameters gives

$$F_{\delta+hs,q+hr}(a) \le F_{\delta,q}(a) + h \left(\int_K r \, \mathrm{d}\mu + sc \right).$$

Choosing an active pair that attains the minimum on the right, we see that the upper limit of the difference quotients is at most this minimum. Conversely, choose a pair (μ_h, c_h) active at $(\delta + hs, q + hr)$. The representation at (δ, q) gives

$$\frac{F_{\delta+hs,q+hr}(a) - F_{\delta,q}(a)}{h} \ge \int_K r \, \mathrm{d}\mu_h + sc_h.$$

The estimate (13.13) bounds the difference quotients. Along a sequence of values of h realizing their lower limit, Lemma 13.1.4 gives a subsequence of pairs converging to a pair active at (δ, q). For this pair, $\int_K r \, \mathrm{d}\mu + sc$ is at least the minimum on the right. This proves (13.14).

For convergent directions, the same two inequalities hold. The fixed active pair attaining the minimum gives an upper bound with the right limit. The active pairs at the perturbed parameters still have uniformly bounded constants, and their subsequential limits are active at (δ, q). Uniform convergence of the r_j controls the integrals $\int_K r_j \, \mathrm{d}\mu_{h_j}$, and $s_j \to s$ controls the terms $s_j c_{h_j}$. The lower bound therefore has the same limit. Note that all perturbed growth allowances $\delta + h_j s_j$ are positive for small h_j. □

Corollary 13.1.3 *For fixed a and q, the function $\delta \mapsto F_{\delta,q}(a)$ has finite left and right derivatives $D^-_{\delta,q}(a)$ and $D^+_{\delta,q}(a)$ at every positive parameter, with*

$$D^-_{\delta,q}(a) = \max_{\mathcal{J}_a^{\mathrm{act}}(\delta,q)} c, \qquad D^+_{\delta,q}(a) = \min_{\mathcal{J}_a^{\mathrm{act}}(\delta,q)} c. \tag{13.15}$$

It is differentiable exactly when all active pairs have the same constant c. For each fixed a, q, the set of positive parameters where it fails to be differentiable is at most countable.

Proof Apply (13.14) with $r = 0$ and $s = \pm 1$. The direction $s = -1$ gives minus the left derivative, which proves (13.15). Concavity gives

$$D^+_{\alpha,q}(a) \ge D^-_{\beta,q}(a) \qquad (0 < \alpha < \beta).$$

Hence the open intervals $(D^+_{\delta,q}(a), D^-_{\delta,q}(a))$, which are nonempty exactly at the parameters where differentiability fails, are pairwise disjoint. Choosing a rational number in each of them proves countability. □

Corollary 13.1.4 *For fixed a and $\delta > 0$, the map $q \mapsto F_{\delta,q}(a)$ on $C(K,\mathbb{R})$ is Gâteaux differentiable at q if and only if all pairs active at (δ, q) have the same probability measure μ. In that case its derivative is*

$$r \longmapsto \int_K r \, \mathrm{d}\mu.$$

Proof With $s = 0$, (13.14) shows that the right derivative in the direction r is the minimum of $\int_K r \, \mathrm{d}\mu$ over active pairs, and the direction $-r$ shows that the left derivative is the maximum. If all active pairs have the same probability measure, these values agree and define a continuous linear derivative. Conversely, if the map is Gâteaux differentiable, the minimum and the maximum agree for every continuous r. Continuous functions separate Borel probability measures on K, so all active pairs have the same probability measure; their constant is then determined by (13.12), since $\delta > 0$. □

Example 13.1.1 Let $D \subset \mathbb{C}$ be the open unit disk, let $K = \overline{D}$, and fix $\delta > 0$. For $q_t(z) = -t|z|^2$,

$$F_{\delta,q_t}(0) = \begin{cases} -t, & t \geq 0, \\ 0, & -\delta/2 \leq t \leq 0. \end{cases} \tag{13.16}$$

Thus the map $q \mapsto F_{\delta,q}(0)$ is not Gâteaux differentiable at $q = 0$, and there are active pairs at $(\delta, 0)$ with different probability measures.

Proof For $t \geq 0$, each competitor is at most $-t$ on the unit circle, so the maximum principle for subharmonic functions bounds it by $-t$ on D. This bound persists after regularization on D, and the constant $-t$ is a competitor. Hence $F_{\delta,q_t}(0) = -t$.

For $t = -b$ with $0 \leq b \leq \delta/2$, define

$$u_b(z) = \begin{cases} b|z|^2, & |z| \leq 1, \\ b + \delta \log|z|, & |z| > 1. \end{cases}$$

This function is continuous and subharmonic: its Laplacian has density $4b$ inside the disk, density zero outside, and a nonnegative contribution on the circle coming from the jump $\delta - 2b \geq 0$ of the radial derivative. It belongs to $\mathcal{L}_\delta$ and equals q_{-b} on K. Hence $F_{\delta,q_{-b}}(0) \geq u_b(0) = 0$. On D the raw envelope is at most the continuous function $b|z|^2$, so its regularization at zero is at most zero. This proves (13.16). In particular, the right and left derivatives in t at $t = 0$ are -1 and 0, and Corollary 13.1.4, applied in the direction $r = -|z|^2$, gives the final assertion. □

13.1.1.3 Local regularity and strict weights

Whether the regularized envelope touches the obstacle at a point $a \in K$ depends only on the parts of K near a. Without weight, this local regularity is detected by the relative extremal function $h_{E,B}$ of Definition 1.6.1, for compact pieces E of K near a and small balls B centered at a. If the weight extends to a global function whose complex Hessian has a strict lower bound near a, a failure of this regularity produces a quantitative defect of the weighted envelope.

For a non-pluripolar compact set $E \subset \mathbb{C}^n$, write V_E and V_E^* for the raw and regularized envelopes of growth one with zero obstacle on E; thus $V_K = V_{1,0}$ as before. For other weights and growth allowances, write $F_{\delta,E,q}$ for the regularized envelope with growth allowance δ and obstacle q imposed at every point of E.

Lemma 13.1.5 *Let $a \in \mathbb{C}^n$, $0 < r < R$ and $B = B(a,R)$, and let $E \subseteq \overline{B}(a,r)$ be compact. If E is pluripolar, then $h_{E,B}^* = 0$ on B. If E is non-pluripolar, then*

$$h_{E,B}^*(a) = -1 \quad \Longleftrightarrow \quad V_E^*(a) = 0.$$

Proof In the pluripolar case, choose $b \in \mathcal{L}_1$ with $b = -\infty$ on E by Lemma 13.1.2, and a finite upper bound C for b on B. The functions

$$u_\epsilon = \max\{-1, \epsilon(b - C)\}$$

are competitors for $h_{E,B}$, and they tend to zero almost everywhere as $\epsilon \downarrow 0$. Hence $h_{E,B}^* \geq 0$ almost everywhere, and then everywhere by Lemma 1.3.3. Since $h_{E,B}^* \leq 0$, it vanishes.

Now suppose that E is non-pluripolar. Proposition 13.1.5 gives a finite upper bound $M \geq 1$ for V_E^* on B. For each competitor v for V_E, the function $\max(-1, v/M - 1)$ is a competitor for $h_{E,B}$. Taking suprema and regularizing gives

$$h_{E,B}^*(a) \geq \max\{-1, V_E^*(a)/M - 1\}.$$

As $V_E^* \geq 0$, the equality $h_{E,B}^*(a) = -1$ forces $V_E^*(a) = 0$.

For the converse, choose $r < R_0 < R$ and $k > 0$ with $k \log(R_0/r) > 1$. The plurisubharmonic function

$$L(z) = k \log\big(\|z - a\|/r\big)$$

belongs to $\mathcal{L}_k$ and equals $-\infty$ at a. For a competitor u for $h_{E,B}$, define $W = \max(u + 1, L)$ on B and $W = L$ outside B. On the collar $R_0 < \|z - a\| < R$ we have $L > 1 \geq u + 1$, so the two definitions agree there, and W is plurisubharmonic by Lemma 1.3.2. On E one has $u = -1$ and $L \leq 0$, so $W = 0$; on the ball $B(a,r)$ one has $L < 0 \leq u + 1$, so $W = u + 1$. Hence W/k is a competitor for V_E, with k independent of u. Taking the supremum over u and regularizing at a gives

$$V_E^*(a) \geq (1 + h_{E,B}^*(a))/k.$$

Thus $V_E^*(a) = 0$ forces $h_{E,B}^*(a) = -1$. □

Let $K \subset \mathbb{C}^n$ again be a non-pluripolar compact set. For $a \in K$ and $r > 0$, put $K_r = K \cap \overline{B}(a, r)$.

Definition 13.1.1 The compact set K is *locally pluriregular* at $a \in K$ if every K_r, $r > 0$, is non-pluripolar and $V_{K_r}^*(a) = 0$. For $\delta > 0$ and a bounded function q on K, it is *locally* (δ, q)*-regular* at a if $F_{\delta,K_r,q}(a) = q(a)$ for every $r > 0$.

It suffices to check arbitrarily small radii, since envelopes decrease as the compact set increases. By Lemma 13.1.5, K is locally pluriregular at a if and only if $h_{K_r,B(a,R)}^*(a) = -1$ for all small $0 < r < R$.

Lemma 13.1.6 *Let q be bounded and upper semicontinuous on K, and suppose that raw contact holds for the parameter $\delta > 0$ and the obstacle q on K, that is, $V_{\delta,q} = q$ on K. If K is locally pluriregular at a, then $F_{\delta,K,q}(a) = q(a)$ and K is locally (δ, q)-regular at a. These equalities also hold with δ replaced by any larger parameter.*

Proof Put $M_r = \sup_{K_r} q$. Raw contact, monotonicity of envelopes with respect to the compact set, and (13.3) for K_r give

$$q(a) \le F_{\delta,K,q}(a) \le F_{\delta,K_r,q}(a) \le M_r + \delta V_{K_r}^*(a) = M_r.$$

Since q is upper semicontinuous and $a \in K_r$, we have $M_r \downarrow q(a)$ as $r \downarrow 0$, which gives $F_{\delta,K,q}(a) = q(a)$.

Every compact subset $E \subseteq K$ inherits raw contact: on E, the raw envelope for E is at least the raw envelope for K, which equals q, and at most the obstacle q. For fixed $s > 0$, apply the same bounds with $r < s$ and K_s in place of K, and let $r \downarrow 0$. This proves local (δ, q)-regularity. By Theorem 13.1.3, raw contact also holds for every larger parameter, and applying what has been proved to each of them gives the last assertion. □

Theorem 13.1.6 *Let $a \in K$, $\tau > 0$ and $\Psi \in \mathcal{L}_\tau \cap C(\mathbb{C}^n)$, and put $q = \Psi|_K$. Suppose that, for some $R, c > 0$,*

$$\mathrm{dd^c}\Psi \ge c\omega_0 \quad \text{on } B(a,R), \qquad \omega_0 = \mathrm{dd^c}\|z\|^2.$$

For $0 < r < R$ and $\delta \ge \tau$,

$$F_{\delta,K,q}(a) - \Psi(a) \ge cr^2\big(1 + h_{K_r,B(a,R)}^*(a)\big). \tag{13.17}$$

Regular contact at a, that is, $F_{\delta,K,q}(a) = q(a)$, holds for some $\delta \ge \tau$ if and only if K is locally pluriregular at a. In that case it holds for every $\delta \ge \tau$.

Proof Set $B = B(a, R)$ and $E = K_r$. For a competitor u for $h_{E,B}$, the function

$$H_u(z) = \Psi(z) - c\|z - a\|^2 + cr^2(u(z) + 1)$$

is plurisubharmonic on B, because the assumption on $\mathrm{dd^c}\Psi$ makes $\Psi - c\|z-a\|^2$ plurisubharmonic there. Since $u \le 0$, we have $H_u \le \Psi$ where $\|z-a\| \ge r$. Define $W = \max(\Psi, H_u)$ on B and $W = \Psi$ outside B. The two definitions agree near ∂B, so W is plurisubharmonic on $\mathbb{C}^n$, and it belongs to $\mathcal{L}_\tau$ because it equals Ψ outside B. On E, the equality $u = -1$ gives $H_u \le \Psi$, and on $K \setminus E$ the distance bound gives the same inequality. Thus $W = q$ on K, so W is a competitor for $F_{\delta,K,q}$ for each $\delta \ge \tau$. Since $W \ge H_u$ near a, taking the supremum over u, regularizing, and using the continuity of Ψ, we obtain (13.17).

The function Ψ itself is a competitor, so raw contact holds for every $\delta \ge \tau$. If regular contact holds for one such δ, the left-hand side of the estimate vanishes, so $h^*_{K_r,B(a,R)}(a) = -1$ for all $0 < r < R$. By Lemma 13.1.5, every K_r with $r < R$ is then non-pluripolar and satisfies $V^*_{K_r}(a) = 0$; for $r \ge R$ this follows by monotonicity. Conversely, local pluriregularity and Lemma 13.1.6 give regular contact at a for every $\delta \ge \tau$. □

In this regular case, $V^*_K(a) \le V^*_{K_r}(a) = 0$ by monotonicity, and the right derivative $D_\tau(a)$ with respect to the growth allowance, for the weight q, vanishes by Corollary 13.1.2, since regular contact persists.

Corollary 13.1.5 *Let $\tau > 0$, $\Psi \in \mathcal{L}_\tau \cap C^2(\mathbb{C}^n)$ and $a \in K$. If $F_{\tau,K,\Psi|_K}(a) = \Psi(a)$, but $F_{\delta,K,\Psi|_K}(a) > \Psi(a)$ for some $\delta > \tau$, then*

$$(\mathrm{dd^c}\Psi)^n(a) = 0.$$

Proof The complex Hessian of Ψ is semipositive. If its top power did not vanish at a, it would be positive definite at a, and by continuity $\mathrm{dd^c}\Psi \ge c\omega_0$ on a neighborhood of a for some $c > 0$. Theorem 13.1.6 would then give regular contact at a for every $\delta \ge \tau$, a contradiction. □

13.1.1.4 A regularization defect along a complex disk

Raw contact with a constant obstacle can hold for every positive growth parameter while regularization raises the value of the envelope at a point of the compact set. In the following example, a complex disk through the point, transverse to the planar direction, prevents any local plurisubharmonic function from separating the point from the rest of the compact set, but it does not remove this defect.

In the complex plane, let D be the open unit disk and put

$$p_j = 2 + 2^{-j}, \qquad r_j = \exp(-16\,2^j), \qquad E = \overline{D} \cup \{2\} \cup \bigcup_{j\ge 1} \overline{D}(p_j, r_j).$$

Lemma 13.1.7 *The set E is compact, and every neighborhood of each of its points contains an open disk contained in E. The series*

$$h(\zeta) = \sum_{j\ge 1} 2^{-j} \log|\zeta - p_j| + 2\log 2$$

defines a subharmonic function on $\mathbb{C}$ of logarithmic growth at most one; it satisfies $h(2) = 0$ and is at most $-16 + 2\log 2$ on every small disk $\overline{D}(p_j, r_j)$. The function

$$v(\zeta) = \frac{8\log^+|\zeta| + h(\zeta) - 4\log 2}{9}$$

is subharmonic of logarithmic growth at most one, is nonpositive on $E \setminus \{2\}$, and satisfies $v(2) = 4\log 2/9$.

Proof Since $r_j < 2^{-j-3}$, the small disks are pairwise disjoint and disjoint from $\overline{D}$, and they accumulate only at 2. This proves compactness. Every neighborhood of 2 contains one of the small disks, and every other point of E lies in the closure of the interior of one of the disks.

To show that the series defines a subharmonic function, write $\chi(\zeta) = \log(1+|\zeta|^2)$ on $\mathbb{C}$ and $\theta = \omega_{\mathrm{FS}}/2$ on $\mathbb{P}^1$. By Lemma 13.1.1, each

$$q_j = \log|\zeta - p_j| - \chi/2$$

extends to a θ-plurisubharmonic function on $\mathbb{P}^1$. The Cauchy–Schwarz inequality gives $q_j \le \log 4$, while the value of q_j at infinity is zero. Thus $0 \le \sup q_j \le \log 4$, and Theorem 1.4.1 bounds $\|q_j - \log 4\|_{L^1}$ uniformly. The partial sums

$$w_N = \sum_{j=1}^{N} 2^{-j}(q_j - \log 4)$$

decrease, remain θ-plurisubharmonic and have uniformly bounded L^1 norms. By Corollary 1.4.1, their limit w belongs to $\mathrm{PSH}(\mathbb{P}^1, \theta)$. Since $\sum_j 2^{-j} = 1$,

$$h = w + \chi/2 + \log 4 + 2\log 2$$

on the affine chart. This proves subharmonicity and the growth bound, and $\sum_j j2^{-j} = 2$ gives $h(2) = 0$.

On the jth small disk, all distances to the other centers are less than one, so the corresponding terms are negative, and

$$h \le 2^{-j}\log r_j + 2\log 2 = -16 + 2\log 2.$$

On $\overline{D}$ all distances to the centers are less than four, hence $h \le 4\log 2$ and $v \le 0$. On each small disk $|\zeta| < 4$, so $9v \le 14\log 2 - 16 < 0$. The growth bound for v and its value at 2 follow directly from the formula. □

Now let $n \geq 2$ and $K = E \times \overline{D}^{n-1} \subset \mathbb{C}^n$. For a non-pluripolar compact set $L \subset \mathbb{C}^n$, write $V_{\delta,L}$ and $F_{\delta,L}$ for the raw envelope with growth allowance δ and zero obstacle on L, and for its regularization.

Proposition 13.1.8 *For every point of K and every neighborhood W of it, the set $K \cap W$ is non-pluripolar. For $\delta > 0$ and $a = (2, w)$ with $w \in \overline{D}^{n-1}$,*

$$V_{\delta,K}|_K = 0, \qquad F_{\delta,K}(a) \geq \frac{4\delta}{9} \log 2 > 0. \tag{13.18}$$

For every $r > 0$, the same lower bound holds for $F_{\delta,K\cap\overline{B}(a,r)}(a)$. At $a_0 = (2, 0, \dots, 0)$, every plurisubharmonic function f defined near a_0 satisfies

$$f(a_0) \leq \limsup_{K\setminus\{a_0\} \ni z \to a_0} f(z). \tag{13.19}$$

Thus K is not plurithin at a_0, although the regularized envelope does not touch the obstacle at a_0 for any positive growth parameter.

Proof By the preceding lemma, every neighborhood of a point of K contains a nonempty open subset of K, namely a product of open disks. This proves the first assertion, which applies in particular to each $K \cap \overline{B}(a, r)$, $r > 0$.

Put $b(\zeta) = \log|\zeta - 2| - \log 3$. Since $|\zeta - 2| \leq 3$ on E, we have $b \leq 0$ there, and $b(2) = -\infty$. For $\varepsilon > 0$, the plurisubharmonic function

$$u_\varepsilon(z) = \frac{v(z_1) + \varepsilon b(z_1)}{1 + \varepsilon}$$

belongs to $\mathcal{L}_1$ and satisfies $u_\varepsilon \leq 0$ at every point of K, including the points with $z_1 = 2$, where it equals $-\infty$. Thus $u_\varepsilon \leq F_{1,K}$. Letting $\varepsilon \downarrow 0$ gives $v(z_1) \leq F_{1,K}(z)$ off the hyperplane $\{z_1 = 2\}$, and Lemma 1.3.3 extends this inequality everywhere. The value $v(2) = 4 \log 2/9$ gives the lower bound for $\delta = 1$. Since 0 is a competitor, $V_{\delta,K}|_K = 0$, and scaling of competitors gives $F_{\delta,K} = \delta F_{1,K}$. Replacing K by a smaller compact set only increases the envelope, which proves the local assertion.

Finally, let f be plurisubharmonic near a_0. If $f(a_0) = -\infty$, (13.19) is automatic. Otherwise, restrict f to the complex line through a_0 in which only the second coordinate varies. Small circles in this line centered at a_0 lie in $K \setminus \{a_0\}$, and the submean inequality on these circles gives (13.19). □

13.2 Bounded domination in a semipositive background

We return to the compact manifold X.

The domination principle for Hermitian backgrounds, Theorem 10.2.2, extends to a smooth semipositive background θ provided every bounded θ-plurisubharmonic potential has positive mass. For bounded potentials u, v satisfying the measure

inequality below, contact support bounds $\sup_X P_\theta(bu-(b-1)v)$ from below as the stretching parameter $b>1$ increases. A fixed gap between u and v would then force the L^1 norms of these envelopes, normalized by their suprema, to diverge, contradicting compactness.

We call a smooth semipositive form θ *non-collapsing on bounded potentials* if

$$\int_X \mathrm{MA}_\theta(w)>0 \quad \text{for every } w\in \mathrm{PSH}(X,\theta)\cap L^\infty(X).$$

Every Hermitian form has this property by Corollary 10.2.1. Bigness also implies it, by the following envelope argument.

Proposition 13.2.1 *If a smooth real $(1,1)$-form θ is big, every bounded $u\in \mathrm{PSH}(X,\theta)$ has strictly positive Monge–Ampère mass.*

Proof Choose $\rho\in\mathrm{PSH}(X,\theta)$ and $a>0$ with $\theta_\rho\ge a\omega$, normalize $\rho\le 0$, and put

$$p=P_{a\omega}(u-\rho).$$

The obstacle is finite almost everywhere and bounded below, so Lemma 1.19.2 shows that p is bounded. The obstacle is quasi-continuous off the pluripolar pole set of ρ. The contact theorem, Theorem 13.1.2, applied in the Hermitian background $a\omega$, shows that $\mathrm{MA}_{a\omega}(p)$ is carried by $D=\{p+\rho=u\}$, outside the pole set of ρ.

By Lemma 1.3.3, $p+\rho\le u$ everywhere, and

$$\theta+\mathrm{dd^c}(p+\rho)=(a\omega+\mathrm{dd^c}p)+(\theta_\rho-a\omega)\ge a\omega+\mathrm{dd^c}p\ge 0.$$

On common finite truncation levels, positivity of the mixed products and ordered contact give

$$\mathbf{1}_D\mathrm{MA}_{a\omega}(p)\le \mathbf{1}_D\mathrm{MA}_\theta(p+\rho)\le \mathbf{1}_D\mathrm{MA}_\theta(u).$$

Exhausting by these levels proves the same inequalities for the extended measures. Since p is bounded, its Monge–Ampère mass with respect to the Hermitian form $a\omega$ is positive by Corollary 10.2.1. Integrating the inequalities proves the assertion. □

Theorem 13.2.1 (Guedj–Lu) *Let $\theta\ge 0$ be non-collapsing on bounded potentials. Suppose that $u,v\in\mathrm{PSH}(X,\theta)\cap L^\infty(X)$ and $0\le c<1$. If*

$$\mathbf{1}_{\{u<v\}}\mathrm{MA}_\theta(u)\le c\,\mathbf{1}_{\{u<v\}}\mathrm{MA}_\theta(v),$$

then $u\ge v$.

Proof If the conclusion failed, we could choose $a>0$ such that $E=\{u<v-a\}$ is nonempty. This set has positive volume by Lemma 1.3.4. Fix C with $|u|,|v|\le C$.

For $b>1$ define the bounded envelope

$$w_b=P_\theta\big(bu-(b-1)v\big),\qquad D_b=\{w_b=bu-(b-1)v\}.$$

Since $\theta \geq 0$, constants below the obstacle are competitors. By the bounded contact theorem, Theorem 13.1.1, the measure $\mathrm{MA}_\theta(w_b)$ is concentrated on D_b. The potential $b^{-1}w_b + (1-b^{-1})v$ lies below u quasi-everywhere, hence everywhere by Lemma 1.3.3, and it equals u on D_b outside a pluripolar set. Ordered contact and positivity of the mixed terms give

$$\mathbf{1}_{D_b}\left[b^{-n}\mathrm{MA}_\theta(w_b) + (1-b^{-1})^n\mathrm{MA}_\theta(v)\right] \leq \mathbf{1}_{D_b}\mathrm{MA}_\theta(u).$$

Choose b so large that $(1-b^{-1})^n > c$. Then the hypothesis forces $\mathrm{MA}_\theta(w_b) = 0$ on $D_b \cap \{u < v\}$. Since θ is non-collapsing, w_b has positive total mass, so some of this mass is carried by $D_b \cap \{u \geq v\}$. At a point of this set outside the exceptional pluripolar set,

$$w_b = bu - (b-1)v = u + (b-1)(u-v) \geq -C.$$

Consequently $\sup_X w_b \geq -C$ for all large b.

On the other hand, on the fixed set E the obstacle bound gives $w_b \leq C - (b-1)a$ quasi-everywhere. Hence

$$\int_X |w_b - \sup_X w_b|\,\mathrm{d}V \geq \big((b-1)a - 2C\big)\,\mathrm{vol}_{\mathrm{d}V}(E)$$

for all sufficiently large b. This contradicts the uniform L^1 bound for normalized potentials in Theorem 1.4.1. □

The exponential comparison principle follows as in Corollary 10.2.2. For unbounded potentials, the stretched envelopes must also be kept in the required singularity class; this is the role of the relative classes introduced below.

13.3 Upper and lower volumes

Let θ be any smooth real $(1,1)$-form. Taking the infimum and the supremum of the mass over a singularity type gives two invariants with values in $[0, +\infty]$. They can differ, because a bounded change of potential need not preserve the mass.

Definition 13.3.1 For $u \in \mathrm{PSH}(X,\theta)$, define

$$\underline{\mathrm{vol}}_\theta(u) = \inf_{v \in \mathrm{PSH}(X,\theta),\ v \sim u} \int_X \mathrm{MA}_\theta(v),$$
$$\overline{\mathrm{vol}}_\theta(u) = \sup_{v \in \mathrm{PSH}(X,\theta),\ v \sim u} \int_X \mathrm{MA}_\theta(v).$$

These are the *lower* and *upper volumes* of the singularity type of u in the background θ. When $\mathrm{PSH}(X,\theta)$ is nonempty, we write $\underline{\mathrm{vol}}(\theta)$ and $\overline{\mathrm{vol}}(\theta)$ for their values at the potential V_θ with minimal singularities.

For semipositive θ, the singularity type of the zero potential consists of the bounded potentials. Extending the lower mass of Definition 6.5.1 to this background, we put

$$v_-(\theta) = \underline{\mathrm{vol}}_\theta(0) = \inf_{v\in \mathrm{PSH}(X,\theta)\cap L^\infty(X)} \int_X \mathrm{MA}_\theta(v).$$

The condition $v_-(\theta) > 0$ is stronger than the non-collapsing property used in bounded domination: it requires a single positive lower bound for the masses of all bounded potentials. Singularity volumes under a bounded mass hypothesis are compared in Chapter 30.

Both volumes are invariant under bounded changes of u, by definition. They are also invariant under the smooth change of decomposition $(\theta, u) \mapsto (\theta + \mathrm{dd^c} f, u - f)$, for $f \in C^\infty(X, \mathbb{R})$: the map $v \mapsto v - f$ identifies the competitors, their currents and their measures. Scaling gives

$$\underline{\mathrm{vol}}_{t\theta}(tu) = t^n \underline{\mathrm{vol}}_\theta(u), \qquad \overline{\mathrm{vol}}_{t\theta}(tu) = t^n \overline{\mathrm{vol}}_\theta(u) \quad (t > 0).$$

Pullback by a modification also identifies the entire ordinary singularity type. The measure identity below gives preservation of both volumes in the exact pulled background.

Proposition 13.3.1 *Let $\mu : Y \to X$ be a modification of connected compact complex manifolds, let θ be a smooth real $(1,1)$-form on X, and let $u \in \mathrm{PSH}(X,\theta)$. Then*

$$\mu_* \mathrm{MA}^{\mathrm{ext}}_{\mu^*\theta}(u \circ \mu) = \mathrm{MA}^{\mathrm{ext}}_\theta(u).$$

Both singularity volumes satisfy

$$\underline{\mathrm{vol}}_{\mu^*\theta}(u \circ \mu) = \underline{\mathrm{vol}}_\theta(u), \qquad \overline{\mathrm{vol}}_{\mu^*\theta}(u \circ \mu) = \overline{\mathrm{vol}}_\theta(u),$$

including infinite values.

Proof Choose a proper analytic set $S \subset X$ such that μ is an isomorphism outside $D = \mu^{-1}(S)$. On these complements, bounded truncations commute with composition by μ, and their products commute with the biholomorphic change of coordinates. Passing to the increasing limits gives the measure identity there. By Theorem 6.1.1, the two measures give no mass to S and D, which proves the global identity and equality of total masses.

Pullback is a bijection between the potentials in the two backgrounds by Proposition 1.22.4. Surjectivity of μ preserves and reflects bounded differences, so this bijection identifies the ordinary-type competitor families. Their masses agree by the first assertion. Taking their infima and suprema proves the volume identities. □

The background upstairs is the exact pullback $\mu^*\theta$, which may be degenerate even when $\theta > 0$. These identities do not compare volumes for an independently chosen Hermitian form on Y.

13.4 Relative envelope classes

Fix a reference potential $\varphi \in \mathrm{PSH}(X,\theta)$. For $b \geq 1$, the stretched obstacle $bu - (b-1)\varphi = \varphi + b(u-\varphi)$ magnifies the difference between u and φ by the factor b, and so becomes more singular where u lies below φ. Requiring a competitor below every finite stretch defines a relative class that is stable under convex combinations and finite rooftops.

For $u \in \mathrm{PSH}(X,\theta)$ and $b \geq 1$, define the family of competitors

$$\mathcal{A}_b(u,\varphi) = \left\{ h \in \mathrm{PSH}(X,\theta) : b^{-1}h + (1-b^{-1})\varphi \leq u \right\}.$$

For $b = 1$ the inequality means $h \leq u$. Away from the poles of u and φ, the inequality means $h \leq bu - (b-1)\varphi$. The convex combination on the left is defined everywhere, so the definition does not require a value of $bu - (b-1)\varphi$ at common poles. When $\mathcal{A}_b(u,\varphi)$ is nonempty, we write

$$Q_b(u,\varphi) = P_\theta(bu - (b-1)\varphi)$$

for its upper envelope. Since the obstacle is finite almost everywhere, the competitors have a common upper bound by Section 1.19, so $Q_b(u,\varphi)$ is then a θ-plurisubharmonic function; in particular, it is not identically $-\infty$. The upper-envelope theorem gives its defining inequality almost everywhere, and Lemma 1.3.3 makes it pointwise; thus $Q_b(u,\varphi)$ is the largest member of $\mathcal{A}_b(u,\varphi)$.

Definition 13.4.1 The *relative envelope class* of φ is

$$\mathcal{E}_{\mathrm{env}}(X,\theta,\varphi) = \{u \in \mathrm{PSH}(X,\theta) : u \preceq \varphi,\ \mathcal{A}_b(u,\varphi) \neq \varnothing \text{ for every } b \geq 1\}.$$

When the background θ is fixed, we abbreviate $\mathcal{E}_\varphi = \mathcal{E}_{\mathrm{env}}(X,\theta,\varphi)$.

Proposition 13.4.1 *The class $\mathcal{E}_{\mathrm{env}}(X,\theta,\varphi)$ is convex, contains all potentials of the singularity type of φ, and is stable under bounded changes of its members. If u belongs to it, $v \in \mathrm{PSH}(X,\theta)$, $u \leq v$ and $v \preceq \varphi$, then v belongs to it. In particular, it is stable under maxima of two members. Replacing φ by another member of $\mathrm{PSH}(X,\theta)$ of the same singularity type does not change the class. For every smooth real function f,*

$$u \in \mathcal{E}_{\mathrm{env}}(X,\theta,\varphi) \quad\Longleftrightarrow\quad u - f \in \mathcal{E}_{\mathrm{env}}(X,\theta + \mathrm{dd^c} f, \varphi - f).$$

Proof If $u \geq \varphi - C$, then $h = \varphi - bC$ belongs to $\mathcal{A}_b(u,\varphi)$ for each b; hence every $u \sim \varphi$ belongs to the class. More generally, if $u' \geq u - C$ and $h \in \mathcal{A}_b(u,\varphi)$, then $h - bC \in \mathcal{A}_b(u',\varphi)$. Since the condition $u \preceq \varphi$ is also unchanged by bounded changes of u, the class is stable under such changes. A convex combination of two competitors is a competitor for the same convex combination of the two potentials, which proves convexity. Finally, a competitor for u is a competitor for any larger v, and the assumption $v \preceq \varphi$ gives the remaining condition.

If $\varphi' \in \mathrm{PSH}(X,\theta)$ and $\varphi' \sim \varphi$, choose $C \geq 0$ with $|\varphi' - \varphi| \leq C$ off their common pole set. For $h \in \mathcal{A}_b(u,\varphi)$, the function $h - (b-1)C$ belongs to $\mathcal{A}_b(u,\varphi')$: the

required inequality holds off the poles, and it extends everywhere by Lemma 1.3.3. The reverse implication follows by interchanging the references, and $u \preceq \varphi$ is equivalent to $u \preceq \varphi'$.

For the last assertion, note that $h \mapsto h - f$ is a bijection from $\mathrm{PSH}(X, \theta)$ onto $\mathrm{PSH}(X, \theta + \mathrm{dd}^{\mathrm{c}} f)$. It preserves the order $\preceq$ and transforms each stretching inequality into

$$b^{-1}(h - f) + (1 - b^{-1})(\varphi - f) \leq u - f.$$

This identity also holds at poles, because f is smooth and finite. Thus the corresponding families of competitors are in bijection for every $b \geq 1$. □

Lemma 13.4.1 *If $u \in \mathcal{E}_\varphi$ and $u \leq \varphi$, then $Q_b(u, \varphi) \in \mathcal{E}_\varphi$ for every $b \geq 1$. More generally, if $u, w \in \mathcal{E}_\varphi$ and $u \leq w$, then $Q_b(u, w) \in \mathcal{E}_\varphi$.*

Proof Fix $b, s \geq 1$ and put $h = Q_{bs}(u, \varphi)$. Its defining inequality gives, off the pole sets,

$$s^{-1}h + (1 - s^{-1})\varphi \leq bu - (b - 1)\varphi.$$

The left-hand side is θ-plurisubharmonic, so it is at most $Q_b(u, \varphi)$. Hence $h \in \mathcal{A}_s(Q_b(u, \varphi), \varphi)$ for every s. Also $Q_b(u, \varphi) \leq u \leq \varphi$, so $Q_b(u, \varphi) \preceq \varphi$. The inequalities between convex combinations extend across the poles by Lemma 1.3.3, which proves the first assertion.

For the second assertion, choose a constant C such that $u - C \leq \varphi$ and $w - C \leq \varphi$. Since $Q_b(u - C, w - C) = Q_b(u, w) - C$ and class membership is unchanged by translation, we may assume $u, w \leq \varphi$. Because $u \leq w \leq \varphi$, the obstacle for $Q_b(u, w)$ lies above that for $Q_b(u, \varphi)$ and below u. Thus

$$Q_b(u, \varphi) \leq Q_b(u, w) \leq u \leq \varphi.$$

Since $Q_b(u, \varphi) \in \mathcal{E}_\varphi$ by the first assertion, the stability under increase proved in Proposition 13.4.1 gives the conclusion. □

Proposition 13.4.2 *If $u_1, \dots, u_N \in \mathcal{E}_\varphi$, $N \geq 1$, then the rooftop envelope $P_\theta(\min_i u_i)$ is not identically $-\infty$ and belongs to $\mathcal{E}_\varphi$.*

Proof Adding a common constant to all u_i, we may assume $u_i \leq \varphi$. By Lemma 13.4.1 and Proposition 13.4.1,

$$h = \frac{1}{N} \sum_{i=1}^{N} Q_N(u_i, \varphi) \in \mathcal{E}_\varphi.$$

Each summand is at most φ. For every i, the defining inequality of $Q_N(u_i, \varphi)$ therefore gives

$$h \leq N^{-1} Q_N(u_i, \varphi) + (1 - N^{-1})\varphi \leq u_i.$$

These inequalities between convex combinations also hold at common poles. Thus h is a competitor for $p = P_\theta(\min_i u_i)$, so p is not identically $-\infty$, and $h \leq p \leq u_1 \preceq \varphi$. Stability under increase gives $p \in \mathcal{E}_\varphi$, and undoing the translation preserves this conclusion. □

The finiteness of the family is essential: every $\varphi - j$ belongs to $\mathcal{E}_\varphi$, whereas $P_\theta(\inf_{j\geq 1}(\varphi - j)) \equiv -\infty$. The constructions of common envelopes for sequences in Chapter 31 require additional estimates.

Proposition 13.4.3 *If $u \in \mathcal{E}_\varphi$, then for every smooth real function F,*

$$P_{\theta,F}[u] = P_{\theta,F}[\varphi].$$

In particular, $P_\theta[u] = P_\theta[\varphi]$.

Proof The relation $u \preceq \varphi$ gives $P_{\theta,F}[u] \leq P_{\theta,F}[\varphi]$. For the reverse inequality, let $a \in (0,1)$ and choose $h_a \in \mathcal{A}_{1/(1-a)}(u,\varphi)$, so that $a\varphi + (1-a)h_a \leq u$. Combining competitors below F gives

$$aP_{\theta,F}[\varphi] + (1-a)P_{\theta,F}[h_a] \leq P_{\theta,F}[u].$$

Indeed, if g_1 and g_2 are competitors for $P_{\theta,F}[\varphi]$ and $P_{\theta,F}[h_a]$, then $ag_1 + (1-a)g_2$ lies below F and is at least as singular as $a\varphi + (1-a)h_a \leq u$; taking the two upper envelopes preserves the inequality, by local regularization. Write $m = \min_X F$ and $M = \max_X F$. Translating competitors gives

$$P_\theta[h_a] + m \leq P_{\theta,F}[h_a] \leq P_\theta[h_a] + M.$$

Every $P_\theta[h_a]$ has supremum zero, since it lies above $h_a - \sup_X h_a$ and below zero. The uniform L^1 bound for normalized potentials in Theorem 1.4.1 therefore bounds the L^1 norms of the $P_{\theta,F}[h_a]$ uniformly in a. Letting $a \uparrow 1$ in the first inequality gives $P_{\theta,F}[\varphi] \leq P_{\theta,F}[u]$ almost everywhere, and by Lemma 1.3.3 the inequality holds everywhere. □

13.5 Model references and positive mass

In this section θ is semipositive and big. Suppose that a potential $u \in \mathrm{PSH}(X,\theta)$ has a competitor in a smaller background $a\theta$, $0 < a < 1$, that is, $P_{a\theta}(u) \not\equiv -\infty$. Then the big form $(1-a)\theta$ remains available: an envelope in this background has positive mass, and the contact property transfers this mass to u. To obtain such competitors for all members of a relative class, we use a reference φ satisfying

$$P_\theta[\varphi] = \varphi, \qquad P_{\varepsilon\theta}(\varphi) \not\equiv -\infty \quad \text{for some } 0 < \varepsilon < 1. \tag{13.20}$$

We call such a φ a *model reference* and fix one such ε. Note that $\varphi = P_\theta[\varphi] \leq 0$. For $u \in \mathcal{E}_\varphi$, the envelope of $u - \varphi$ belongs to the relative envelope class $\mathcal{E}_0 = \mathcal{E}_{\mathrm{env}}(X,\theta,0)$ of the zero potential, and stretching realizes it in an arbitrarily small background. Under a bounded mass hypothesis, Chapter 30 uses instead the condition (30.5), in which a positive lower volume replaces the condition on the smaller background; the two conditions are compared there.

Lemma 13.5.1 *Let φ be a model reference. If $u \in \mathcal{E}_\varphi$ and $u \le \varphi$, then*

$$w = P_\theta(u-\varphi) \in \mathcal{E}_0, \qquad w \le 0, \qquad w+\varphi \le u.$$

Proof Since $\varphi \le 0$, the potential u lies below the obstacle $u-\varphi$ away from the pole set of φ, so it is a competitor. Hence the envelope w is not identically $-\infty$. It is at most zero, since $u-\varphi \le 0$, and it satisfies $w+\varphi \le u$ off the poles, hence everywhere by Lemma 1.3.3. For $b \ge 1$, let $h_b = Q_b(u,\varphi)$. Then, off the poles,

$$h_b \le bu - (b-1)\varphi \le b(u-\varphi).$$

Since $\theta \ge 0$, the function $b^{-1}h_b$ is θ-plurisubharmonic, and so it is a competitor for w. Hence $h_b \le bw$, so $\mathcal{A}_b(w,0)$ is nonempty for every b. Since also $w \le 0$, this means exactly that $w \in \mathcal{E}_0$. □

Lemma 13.5.2 *Let $0 < a < 1$ and $u \in \mathrm{PSH}(X,\theta)$. If $q = P_{a\theta}(u)$ is not identically $-\infty$, then*

$$\int_X \mathrm{MA}_\theta(u) \ge (1-a)^n v_-(\theta),$$

and the mass on the left is strictly positive, even when $v_-(\theta) = 0$.

Proof The obstacle $u-q$ is nonnegative away from the poles, so by Lemma 1.19.2 the envelope $p = P_{(1-a)\theta}(u-q)$ is bounded. By the contact theorem, its measure is carried by $D = \{p+q = u\}$, and $p+q \le u$ everywhere. Since $p+q$ is θ-plurisubharmonic, positivity of mixed products and ordered contact imply

$$\mathrm{MA}_{(1-a)\theta}(p) \le \mathbf{1}_D \mathrm{MA}_\theta(p+q) \le \mathbf{1}_D \mathrm{MA}_\theta(u),$$

where all assertions are first restricted to the complement of the poles. Writing $p = (1-a)\widetilde{p}$ with $\widetilde{p} \in \mathrm{PSH}(X,\theta) \cap L^\infty(X)$ and integrating, we obtain the lower bound from the definition of $v_-(\theta)$. Finally, the bounded potential p has strictly positive mass by Proposition 13.2.1, since $(1-a)\theta$ is big. □

Theorem 13.5.1 *Let φ be a model reference, with ε as in (13.20). For every $u \in \mathcal{E}_\varphi$ and every $0 < \delta < 1-\varepsilon$, the envelope $P_{(\varepsilon+\delta)\theta}(u)$ is not identically $-\infty$. Consequently,*

$$\int_X \mathrm{MA}_\theta(u) \ge (1-\varepsilon)^n v_-(\theta), \qquad \int_X \mathrm{MA}_\theta(u) > 0.$$

The mass may be infinite.

Proof After adding a constant to u, we may assume $u \le \varphi$. Let $w \in \mathcal{E}_0$ be as in Lemma 13.5.1. Since $w \in \mathcal{E}_0$, the envelope $P_\theta(w/\delta)$ is not identically $-\infty$, and $\delta P_\theta(w/\delta) \le w$. The potential

$$P_{\varepsilon\theta}(\varphi) + \delta P_\theta(w/\delta) \le \varphi + w \le u$$

belongs to $\mathrm{PSH}(X,(\varepsilon+\delta)\theta)$, so it is a competitor for $P_{(\varepsilon+\delta)\theta}(u)$. Applying Lemma 13.5.2 with $a=\varepsilon+\delta$ and letting $\delta\downarrow 0$ gives the uniform estimate. The positivity follows from the same lemma with any one such δ. □

13.6 Infinite mass inside the envelope class

We now take the Hermitian background $\theta=\omega$ and the reference $\varphi=0$. If ω does not have the bounded mass property, that is, if the upper mass $v_+(\omega)$ of Definition 6.5.1 is infinite, then the series constructed in Theorem 6.6.1 has infinite mass. It splits into a smooth finite sum and a tail whose curvature is bounded below by an arbitrarily small multiple of $-\omega$. Multiplying a sufficiently late tail by the stretching factor gives a competitor for that stretch, so the series lies in the relative envelope class of zero.

Proposition 13.6.1 *If $v_+(\omega)=+\infty$, the potential U in Theorem 6.6.1 can be chosen so that, in addition,*

$$U\in\mathcal{E}_{\mathrm{env}}(X,\omega,0),\qquad P_\omega[U]=0.$$

The same conclusions hold for εU, $0<\varepsilon\le 1$. Each of these potentials has infinite extended mass and trivial multiplier ideals at every positive weight.

Proof Use the smooth nonpositive ω-plurisubharmonic functions u_j, $j\ge 1$, of Theorem 6.6.1 and their convergent series $U=\sum_{j\ge1}2^{-j}u_j$. For each integer $N\ge 1$, write

$$U=A_N+V_N,\qquad A_N=\sum_{j\le N}2^{-j}u_j,\qquad V_N=\sum_{j>N}2^{-j}u_j,\qquad \delta_N=2^{-N}.$$

The head A_N is smooth, and since the finite partial sums of the tail decrease, $V_N\in\mathrm{PSH}(X,\delta_N\omega)$; the tail is not identically $-\infty$, because $U=A_N+V_N$ is not.

Fix $b>1$ and choose N so large that $b\delta_N\le 1$. Then

$$h_b=bV_N+\min_X(bA_N)$$

is ω-plurisubharmonic, because $\mathrm{dd}^{\mathrm{c}}h_b\ge -b\delta_N\omega\ge-\omega$. Moreover, $h_b\le bU$. Thus $h_b\in\mathcal{A}_b(U,0)$ for every b, and since $U\le 0$, this proves $U\in\mathcal{E}_{\mathrm{env}}(X,\omega,0)$. For εU, use the tails εV_N, and choose N with $b\varepsilon\delta_N\le 1$. By Proposition 13.4.3, the singularity envelope of each of these potentials is $P_\omega[0]=0$. Their infinite mass and trivial multiplier ideals are given by Corollary 6.6.1. □

The bound on the mass in Proposition 13.1.4 concerns the envelope fixed point itself. This example shows that potentials with the same singularity envelope as a fixed point, even with trivial multiplier ideals at every positive weight, need not have finite mass.

Corollary 13.6.1 *The following conditions on a Hermitian metric ω are equivalent:*

(1) $v_+(\omega) < +\infty$*;*
(2) *every member of* $\mathcal{E}_{\mathrm{env}}(X, \omega, 0)$ *has finite extended mass;*
(3) *every* $u \in \mathrm{PSH}(X, \omega)$ *with* $P_\omega[u] = 0$ *has finite extended mass.*

Proof If $v_+(\omega) < +\infty$, all ω-plurisubharmonic functions have finite extended mass by Proposition 6.5.2. If $v_+(\omega) = +\infty$, Proposition 13.6.1 contradicts each of the other two conditions. □

Chapter 14
Equations with prescribed singularities

Throughout this chapter we fix a Hermitian metric ω on X and a smooth positive probability volume form $\mathrm{d}V$. Unless another measure is named, L^p norms, volumes and the phrase "almost everywhere" refer to $\mathrm{d}V$, while capacity and convergence in capacity refer to Cap_ω from Section 1.8. The background θ is a smooth real $(1,1)$-form whose positivity is specified in each section. For a smooth real $(1,1)$-form α and $u \in \mathrm{PSH}(X,\alpha)$ we write $\alpha_u = \alpha + \mathrm{dd^c}u$, and we call $\{u = -\infty\}$ the *pole set* of u; it is pluripolar and has zero volume. We write $\mathrm{MA}_\theta(u)$ for the extended non-pluripolar Monge–Ampère measure $\mathrm{MA}^{\mathrm{ext}}_\theta(u)$ of Theorem 6.1.1. It equals $(\theta + \mathrm{dd^c}u)^n$ when u is bounded, charges no pluripolar set, and may have infinite total mass; we keep the superscript where this possibility matters. Finally, $s_+ = \max(s,0)$ for real s.

We use the following notation from earlier chapters. As in Definition 1.12.1, $u \preceq v$ means that $u \le v + C$ for some constant C, and $u \sim v$ means that $u \preceq v$ and $v \preceq u$; the equivalence classes of $\sim$ are the ordinary singularity types. For an obstacle f, $P_\theta(f)$ is the largest θ-plurisubharmonic function lying below f quasi-everywhere, $P_\theta(u,v) = P_\theta(\min(u,v))$ is the rooftop envelope, and $V_\theta = P_\theta(0)$; a potential has minimal singularities if it is equivalent to V_θ (Section 1.19). The ordinary envelope $P_\theta[u]$ and the envelope fixed points, those u with $P_\theta[u] = u$, are defined in Definition 1.19.1. Recall that θ is big if some $\rho \in \mathrm{PSH}(X,\theta)$ satisfies $\theta_\rho \ge \delta\omega$ with $\delta > 0$. We call such a ρ a *strict barrier*; by Theorem 1.15.2 it can be chosen with analytic singularities.

We seek potentials u in the ordinary singularity type of a given reference $\varphi \in \mathrm{PSH}(X,\theta)$ solving

$$\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u}\mu \quad (\lambda > 0) \qquad \text{or} \qquad \mathrm{MA}_\theta(u) = c\mu,$$

where μ is a given measure, typically $f\,\mathrm{d}V$ with $f \in L^p$ and $p > 1$, and the constant $c > 0$ is part of the unknown. When φ is unbounded, the comparison principles for bounded potentials no longer apply, and a limit of approximate solutions may leave the prescribed type. For a semipositive big background, both difficulties are overcome by a smaller background. If $P_{\delta\theta}(\varphi) \not\equiv -\infty$ for some $0 < \delta < 1$, then the part $\delta\theta$ of the background can carry the singularity of φ, while bounded envelopes in the

remaining big background $(1-\delta)\theta$ have Monge–Ampère measures of positive mass. This gives a domination principle for singular potentials (Theorem 14.1.1), and hence uniqueness. Existence starts from bounded equations with L^p densities, solved with a subsolution built from a strict barrier. A compactness criterion with a common lower barrier identifies limits of Monge–Ampère measures, and an addition theorem for weighted measures in a fixed type removes a possible deficit of mass in a limit. Together with a uniform estimate relative to the reference (Theorem 14.11.2), these results solve both equations in the type of an envelope fixed point that admits such a smaller-background envelope (Theorem 14.11.1). At exponent zero, comparison determines the constant c but, in general, not the potential.

If θ is big but not semipositive, V_θ may be unbounded and the smaller-background construction is not available. A strict analytic barrier ρ takes over its role. For two potentials bounded below by ρ minus a constant, a small perturbation by ρ forces a negative infimum of their difference to be attained away from the poles of ρ, where a local comparison applies. Resolving the singularities of analytic approximants of V_θ reduces the equations to semipositive big backgrounds. Stability above the barrier then produces solutions with minimal singularities which are locally Hölder continuous off the poles of ρ (Theorems 14.15.1, 14.15.2 and 14.16.1). They are smooth off these poles when the density is smooth and strictly positive on the whole complement (Theorem 14.17.1).

The same barrier controls smooth equations as a semipositive background degenerates (Theorem 14.18.1). For small resolutions of threefold nodes with a closed background, the potentials converge smoothly away from the exceptional curves, and comparing the limiting and approximating metrics reduces to controlling the diameters of neighborhoods of these curves. In the projective example of Theorem 11.6.1, where the normalized potential is not unique, symmetry selects the zero-exponent limit, while local examples show that a positive density on a small open set does not by itself give regularity. Resolved logarithmic poles and minimal types on blowups give explicit equations whose data are determined by the residual form and the Jacobian of the modification.

The last part of the chapter concerns a Hermitian background h and general right-hand sides. Solvability of $\mathrm{MA}_h(u) = c\mu$ for every nonzero finite non-pluripolar measure μ is equivalent to a positive lower bound for the masses of bounded h-plurisubharmonic functions. For singular data supported on shrinking coordinate spheres, a bounded-density test against a fixed probability supplies a strict Hölder reference, a normalized Hölder solution of the homogeneous equation and bounded exponential solutions (Proposition 14.25.1, Corollary 14.25.1, and Theorem 14.25.1), even when the lower mass vanishes. For an individual nonnegative density $f \in L^1$, bounded truncations and Gauduchon tests determine the largest coefficient a for which $\mathrm{MA}_h(u) \geq a f \, \mathrm{d}V$ has a solution. Passing from this threshold to an exact equation at exponent zero requires control of the potentials as well as of their measures. At a positive exponent, exponential decay controls the mass on deep sublevels (Theorem 14.33.1); this control is lost as the exponent tends to zero.

14.1 Domination with a smaller background

Throughout this section θ is semipositive and big. Let $0 < \delta < 1$. When a singular potential lies above a $\delta\theta$-plurisubharmonic function, the gap between them can be measured by an envelope in the remaining background $(1-\delta)\theta$. This background is again semipositive and big, so its bounded potentials have Monge–Ampère measures of positive mass by Proposition 13.2.1, and bounded domination applies to them. It bounds the envelope from below. A family of stretched envelopes then converts a strict measure inequality into a pointwise inequality, as in the bounded case of Theorem 13.2.1.

We say that $u \in \mathrm{PSH}(X,\theta)$ *admits a smaller-background envelope* if $P_{\delta\theta}(u) \not\equiv -\infty$ for some $0 < \delta < 1$. This property depends only on the ordinary singularity type of u: if $u' \geq u - C$, then $P_{\delta\theta}(u) - C$ is a competitor for $P_{\delta\theta}(u')$.

Lemma 14.1.1 *Suppose $u, v \in \mathrm{PSH}(X,\theta)$, $v \preceq u$, and $\mathrm{MA}_\theta^{\mathrm{ext}}(u)(\{u < v\}) = 0$. If $0 < \delta < 1$ and $v_\delta = P_{\delta\theta}(v) \not\equiv -\infty$, then $u \geq v_\delta$.*

Proof Choose C with $v - C \leq u$. Since $v_\delta \leq v$, the obstacle $u - v_\delta$ is bounded below by $-C$ off the pole sets, and it is finite almost everywhere. Hence the envelope

$$p = P_{(1-\delta)\theta}(u - v_\delta)$$

is bounded by Lemma 1.19.2, and by contact support (Theorem 13.1.2) its measure is carried by $D = \{p + v_\delta = u\}$. Moreover $p + v_\delta \leq u$ everywhere, and

$$\theta + \mathrm{dd^c}(p + v_\delta) = ((1-\delta)\theta + \mathrm{dd^c} p) + (\delta\theta + \mathrm{dd^c} v_\delta)$$

is a sum of two positive currents. Positivity of mixed products and ordered contact therefore give

$$\mathbf{1}_D \mathrm{MA}_{(1-\delta)\theta}(p) \leq \mathbf{1}_D \mathrm{MA}_\theta^{\mathrm{ext}}(u);$$

this inequality is first proved on common finite truncation levels and then extended by exhaustion. Off the pole sets, every point of $D \cap \{p < 0\}$ satisfies $u = p + v_\delta < v_\delta \leq v$. The hypothesis therefore gives $\mathrm{MA}_{(1-\delta)\theta}(p)(\{p < 0\}) = 0$. Since $(1-\delta)\theta$ is semipositive and big, bounded domination (Theorem 13.2.1, with Proposition 13.2.1), applied to p and the constant 0 with coefficient zero, yields $p \geq 0$. Hence $u \geq p + v_\delta \geq v_\delta$. □

Theorem 14.1.1 *Let $u \in \mathrm{PSH}(X,\theta)$ satisfy $P_{\delta\theta}(u) \not\equiv -\infty$ for some $0 < \delta < 1$. Suppose $v \in \mathrm{PSH}(X,\theta)$, $v \preceq u$, and $0 \leq c < 1$. If*

$$\mathbf{1}_{\{u<v\}} \mathrm{MA}_\theta^{\mathrm{ext}}(u) \leq c\, \mathbf{1}_{\{u<v\}} \mathrm{MA}_\theta^{\mathrm{ext}}(v),$$

then $u \geq v$.

Proof Since $\max(u,v) = v$ on the plurifine open set $\{u < v\}$, plurifine locality shows that replacing v by $\max(u,v)$ preserves the hypothesis; it does not change the

conclusion. We may therefore assume $u \le v$, and since $v \preceq u$ there is $C \ge 0$ with $u \le v \le u + C$. For $b > 1$ consider the stretched envelopes

$$p_b = P_\theta(bu - (b-1)v), \qquad D_b = \{p_b = bu - (b-1)v\}.$$

The function $u - (b-1)C$ is a competitor, so $p_b \not\equiv -\infty$; and since $bu - (b-1)v \le u$, we have $u - (b-1)C \le p_b \le u$. By contact support, the measure of p_b is concentrated on D_b. The potential $b^{-1}p_b + (1-b^{-1})v$ lies below u and agrees with it on D_b, so ordered contact and positivity of mixed products give

$$\mathbf{1}_{D_b}\left[b^{-n}\mathrm{MA}_\theta^{\mathrm{ext}}(p_b) + (1-b^{-1})^n \mathrm{MA}_\theta^{\mathrm{ext}}(v)\right] \le \mathbf{1}_{D_b}\mathrm{MA}_\theta^{\mathrm{ext}}(u).$$

Choose b so large that $(1-b^{-1})^n > c$. On $D_b \cap \{u < v\}$ the hypothesis then forces $\mathrm{MA}_\theta^{\mathrm{ext}}(p_b)$ to vanish. Since the masses may be infinite, we justify this subtraction as follows. On each set where $u, v, p_b > -k$, every measure involved is finite, being bounded by the mass of the corresponding bounded truncation. We subtract the finite terms on each such set and then take the union over k, so no infinite masses are ever subtracted.

It follows that the measure of p_b is carried by $D_b \cap \{u = v\} \subset \{p_b = u\}$. We apply Lemma 14.1.1 to the pair (p_b, u): their singularities are equivalent, $\mathrm{MA}_\theta^{\mathrm{ext}}(p_b)(\{p_b < u\}) = 0$, and $P_{\delta\theta}(u) \not\equiv -\infty$. We obtain

$$p_b \ge P_{\delta\theta}(u)$$

for all sufficiently large b. Suppose now that $u \ge v$ fails. By Lemma 1.3.3, the set $\{u < v\}$ has positive volume. Since both potentials are finite almost everywhere, some set $E = \{u < v - a\}$ with $a > 0$ has positive volume and both functions are finite on E. On E the obstacle inequality gives

$$P_{\delta\theta}(u) \le p_b \le v - ba$$

quasi-everywhere. Letting b tend to infinity through the integers shows that the quasi-plurisubharmonic function $P_{\delta\theta}(u) \not\equiv -\infty$ equals $-\infty$ on a set of positive volume, a contradiction. Thus $u \ge v$ off the pole sets, and Lemma 1.3.3 gives the inequality everywhere. □

Corollary 14.1.1 *Let $u, v \in \mathrm{PSH}(X, \theta)$ satisfy $v \preceq u$, and suppose that u admits a smaller-background envelope. If $\lambda > 0$ and*

$$\mathrm{e}^{-\lambda u}\mathrm{MA}_\theta^{\mathrm{ext}}(u) \le \mathrm{e}^{-\lambda v}\mathrm{MA}_\theta^{\mathrm{ext}}(v)$$

off the pole sets, then $u \ge v$. In particular, for every $\lambda > 0$ and every positive measure μ, the equation $\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u}\mu$ has at most one solution in an ordinary singularity type admitting a smaller-background envelope.

Proof Fix $t > 0$. On $\{u < v - t\}$ the assumed inequality gives $\mathrm{MA}_\theta^{\mathrm{ext}}(u) \le \mathrm{e}^{-\lambda t}\mathrm{MA}_\theta^{\mathrm{ext}}(v - t)$. The theorem, applied to u and $v - t$ with $c = \mathrm{e}^{-\lambda t}$, gives $u \ge v - t$; now let $t \downarrow 0$. For two solutions of the same equation in the stated type, apply this

result in both directions. The weighted measures are compared off the common pole sets, which these measures do not charge, so no value of an infinite weight is needed.□

14.2 Bounded equations in a semipositive big background

In this section θ is again semipositive and big, and we solve the exponential and the normalized equations with L^p densities by bounded potentials. The basic tool is a bounded subsolution. A strict barrier, corrected by the solution of a Hermitian equation, is composed with a bounded convex function; the result is a bounded θ-plurisubharmonic function whose Monge–Ampère measure dominates a prescribed density. The derivative of the convex function decays polynomially near the poles of the barrier, and we compensate for this decay by multiplying the auxiliary density by the reciprocal weight.

Fix a strict barrier $\rho \in \mathrm{PSH}(X,\theta)$ and $0 < a \le 1$ such that

$$\theta + \mathrm{dd^c}\rho \ge a\omega, \qquad \rho \le -1.$$

No property of ρ other than these two inequalities will be used.

Lemma 14.2.1 *Fix $p > 1$ and $L > 0$. There is $b > 0$ such that, for every $f \ge 0$ with $\|f\|_{L^p(\mathrm{d}V)} \le L$, one can find $s \in \mathrm{PSH}(X,\theta)$ satisfying*

$$-1 \le s \le 0, \qquad \mathrm{MA}_\theta(s) \ge b f \,\mathrm{d}V.$$

The constant b depends only on the fixed geometry and on ρ, a, p, L.

Proof Choose $1 < q < p$. Since a fixed quasi-plurisubharmonic function belongs to every finite L^r space, Hölder's inequality gives a uniform L^q bound for

$$g = (-\rho)^{2n} f.$$

By Theorem 10.1.1 there are $c > 0$ and a continuous ω-plurisubharmonic v, normalized by $\sup_X v = -1$, such that

$$\omega_v^n = c(1+g)\,\mathrm{d}V.$$

The construction in that theorem gives a uniform upper bound for c, because in its Gauduchon trace estimate the root integral of $1+g$ is bounded below by the root integral of 1. The lower-density estimate of Theorem 10.3.1 gives $c\|1+g\|_q \ge c_q > 0$, so c is also bounded below. The potential estimate of the same theorem then gives $-C \le v \le -1$ with a uniform C.

Put $h = \rho + av \le -1$. Then $\theta_h \ge a\omega_v$. On $(-\infty,-1]$ define

$$\chi(t) = -t^{-1} - 1, \qquad \chi'(t) = t^{-2} \in (0,1], \qquad \chi''(t) = -2t^{-3} > 0,$$

and set $s = \chi(h)$, with value -1 at the poles of h. To justify both the positivity of $\theta + \mathrm{dd}^{\mathrm{c}} s$ and the computation of its Monge–Ampère measure, we first work with the bounded functions $h_k = \max(h, -k)$, $k \geq 1$. The chain rule for bounded potentials and $\theta \geq 0$ give

$$\theta + \mathrm{dd}^{\mathrm{c}} \chi(h_k) = (1 - \chi'(h_k))\theta + \chi'(h_k)\theta_{h_k} + \chi''(h_k)\, \mathrm{d}h_k \wedge \mathrm{d}^{\mathrm{c}} h_k \geq 0.$$

These bounded potentials decrease to s, so $s \in \mathrm{PSH}(X, \theta)$ and $-1 \leq s \leq 0$. On $\{h > -k\}$, locality and positivity of mixed products give

$$\mathrm{MA}_\theta(s) \geq a^n |h|^{-2n} \omega_v^n \geq a^n c |h|^{-2n} (-\rho)^{2n} f \, \mathrm{d}V.$$

Letting $k \to \infty$, we obtain this inequality on the set where h is finite; its complement is pluripolar and has zero volume. Since $|h| \leq (-\rho) + aC \leq (1 + aC)(-\rho)$, the assertion follows with any common lower bound for $a^n c (1 + aC)^{-2n}$. □

The lemma gives a subsolution for each density in an L^p-bounded family. It does not give a lower bound for the masses of all bounded θ-plurisubharmonic functions.

14.2.1 The exponential equation

We approximate θ from above by the Hermitian forms $\theta + \varepsilon\omega$. The bounded subsolution provides a common lower barrier for the corresponding solutions, and exponential comparison shows that they decrease as ε decreases. Their limit solves the equation in the original background.

Theorem 14.2.1 *Let $0 \leq f \in L^p(\mathrm{d}V)$, $p > 1$, be nonzero, and let $\lambda > 0$. There is a unique bounded $v \in \mathrm{PSH}(X, \theta)$ such that*

$$\mathrm{MA}_\theta(v) = \mathrm{e}^{\lambda v} f \, \mathrm{d}V.$$

For fixed λ, these solutions are uniformly bounded when $\|f\|_p$ is bounded above and $\int_X f^{1/n} \, \mathrm{d}V$ is bounded away from zero.

Proof For $0 < \varepsilon \leq 1$, set $\theta_\varepsilon = \theta + \varepsilon\omega$. By the Hermitian existence theorem Theorem 10.1.2, there is a continuous solution v_ε of

$$\mathrm{MA}_{\theta_\varepsilon}(v_\varepsilon) = \mathrm{e}^{\lambda v_\varepsilon} f \, \mathrm{d}V.$$

Take s, b from Lemma 14.2.1, and put $w = s + \lambda^{-1} \log b$. Positivity of bounded products gives

$$\mathrm{MA}_{\theta_\varepsilon}(w) \geq \mathrm{MA}_\theta(s) \geq b f \, \mathrm{d}V \geq \mathrm{e}^{\lambda w} f \, \mathrm{d}V,$$

and bounded exponential comparison (Corollary 10.2.2) yields $w \leq v_\varepsilon$. If $0 < \varepsilon' < \varepsilon$, then $v_{\varepsilon'}$ is also θ_ε-plurisubharmonic and

$$\mathrm{MA}_{\theta_\varepsilon}(v_{\varepsilon'}) \geq \mathrm{e}^{\lambda v_{\varepsilon'}} f \, \mathrm{d}V,$$

so the same comparison gives $v_{\varepsilon'} \le v_\varepsilon$. Hence v_ε decreases to a bounded θ-plurisubharmonic function v with $w \le v \le v_1$.

To pass to the limit in the equation, we use the fixed Hermitian background $\Omega = \theta + \omega$ and the expansion

$$(\theta_\varepsilon + \mathrm{dd^c} v_\varepsilon)^n = \sum_{k=0}^{n} \binom{n}{k} (\Omega + \mathrm{dd^c} v_\varepsilon)^k \wedge \big(-(1-\varepsilon)\omega\big)^{n-k}.$$

Continuity of bounded products along monotone sequences applies to every term, and the smooth coefficients converge. Dominated convergence applies to the right-hand sides. This proves the equation. Uniqueness follows from bounded domination in the semipositive big background (Theorem 13.2.1 and Proposition 13.2.1) by the usual exponential comparison argument.

For the uniform assertion, note first that the lower barrier w is uniform by Lemma 14.2.1. The upper barrier v_1 solves an equation in the fixed Hermitian background Ω. The proof of Lemma 10.4.1 bounds its supremum using only an upper bound for the density norm and a positive lower bound for the root integral: these two bounds control, respectively, the Hölder term and the denominator in (10.10), and they survive the smooth approximation used there. Thus v_1, and hence v, has a uniform upper bound. □

Local continuity of this bounded solution will follow from Theorem 14.5.1.

14.2.2 The normalized equation

For the normalized equation the approximating potentials need not be monotone. Upper envelopes and lower envelopes of their tails provide monotone sequences on either side of an L^1 cluster limit. Comparison identifies the two limits, and hence the equation, while the constant is controlled by the Gauduchon trace and the bounded subsolution.

Theorem 14.2.2 *For every nonzero $0 \le f \in L^p(\mathrm{d}V)$, $p > 1$, there are a bounded $\varphi \in \mathrm{PSH}(X, \theta)$ and a uniquely determined $c > 0$ such that*

$$\mathrm{MA}_\theta(\varphi) = c f \, \mathrm{d}V, \qquad \sup_X \varphi = 0.$$

The construction gives uniform bounds for $\|\varphi\|_\infty$, c and c^{-1} when $\|f\|_p$ is bounded above and $\int_X f^{1/n} \, \mathrm{d}V$ is bounded away from zero.

Only the constant c is asserted to be unique; the normalized potential need not be unique, as Theorem 11.6.1 shows already for a Hermitian background.

Proof *Step 1: approximating equations and their constants.* For integers $j \ge 1$, put $\omega_j = \theta + 2^{-j}\omega$, and choose continuous normalized solutions

$$\mathrm{MA}_{\omega_j}(\varphi_j) = c_j f \, \mathrm{d}V, \qquad \sup_X \varphi_j = 0.$$

We first bound c_j. Fix a Gauduchon metric γ_0; when $n = 1$ any Hermitian form will do, and the calculation below reduces to Stokes' theorem. The smooth approximation in the proof of Theorem 10.1.1, together with the Gauduchon trace, gives a common upper bound: the numerator $\int_X \omega_j \wedge \gamma_0^{n-1}$ is bounded above by $\int_X (\theta + \omega) \wedge \gamma_0^{n-1}$, and the root integral of f is positive and fixed. Here the estimate is applied to the smooth approximating equations before passing to their continuous limits.

For a lower bound, take s, b from Lemma 14.2.1. If $c_j < b$, then

$$\mathrm{MA}_{\omega_j}(\varphi_j) \le (c_j/b)\mathrm{MA}_{\omega_j}(s + A)$$

for every constant A, and strict domination in the Hermitian background ω_j (Theorem 10.2.2) would give $\varphi_j \ge s + A$ for every A, which is absurd. Thus $c_j \ge b$. In fact the constants decrease with j: if $k > j$, positivity gives $\mathrm{MA}_{\omega_j}(\varphi_k) \ge c_k f \, \mathrm{d}V$, and the same argument excludes $c_j < c_k$. Hence $c_j \downarrow c > 0$.

Step 2: a uniform bound for the potentials. For the Hermitian form $\Omega = \theta + \omega$, all φ_j are normalized Ω-plurisubharmonic functions. Using uniform exponential integrability (Lemma 1.5.1) and Hölder's inequality, choose $\gamma > 0$ small and $1 < q < p$ such that

$$g_j = \mathrm{e}^{-\gamma\varphi_j} f$$

is bounded in L^q. Since $\varphi_j \le 0$, we have $g_j \ge f$. Theorem 14.2.1, applied with integrability exponent q and exponential exponent γ, therefore gives uniformly bounded $w_j \in \mathrm{PSH}(X, \theta)$ with

$$\mathrm{MA}_\theta(w_j) = \mathrm{e}^{\gamma w_j} g_j \, \mathrm{d}V.$$

Choose $C_0 \ge \max\{1, \sup_j c_j\}$ and set $z_j = w_j - \gamma^{-1} \log C_0$. Then

$$\mathrm{MA}_{\omega_j}(z_j) \ge \mathrm{e}^{\gamma z_j} c_j g_j \, \mathrm{d}V, \qquad \mathrm{MA}_{\omega_j}(\varphi_j) = \mathrm{e}^{\gamma\varphi_j} c_j g_j \, \mathrm{d}V,$$

and exponential comparison gives $z_j \le \varphi_j \le 0$. Thus all φ_j take values in a common bounded interval.

Step 3: the upper envelopes. Extract a subsequence converging in L^1 and almost everywhere to the canonical θ-plurisubharmonic representative φ. We keep the indices j; the coefficients of ω in ω_j still decrease to zero. Define

$$\Phi_j^+ = \left(\sup_{\ell \ge j} \varphi_\ell\right)^*, \qquad h_j = \inf_{\ell \ge j} \varphi_\ell, \qquad p_j = P_\theta(h_j).$$

All these functions take values in a common bounded interval. The upper envelopes are ω_j-plurisubharmonic and decrease to φ, since the regularized upper envelope agrees almost everywhere with the L^1 limit; this also follows from the local Hartogs lemma applied to the bounded tails.

For $\ell \ge j$, positivity gives $\mathrm{MA}_{\omega_j}(\varphi_\ell) \ge c_\ell f \, \mathrm{d}V \ge c f \, \mathrm{d}V$. By ordered contact (Lemma 1.7.1), finite maxima of these functions satisfy the same lower bound. Continuity of bounded products along increasing sequences, followed by the decreasing limit in j and the expansion in the smooth background, gives

$$\mathrm{MA}_{\omega_j}(\Phi_j^+) \ge c f \, \mathrm{d}V, \qquad \mathrm{MA}_\theta(\varphi) \ge c f \, \mathrm{d}V. \tag{14.1}$$

Step 4: the lower envelopes. For the reverse inequality we use lower envelopes, which carry a useful exponential weight. For $N \ge j$ put

$$p_{j,N} = P_\theta\left(\min_{j \le \ell \le N} \varphi_\ell\right).$$

The obstacle is continuous and bounded, so the measure of $p_{j,N}$ is carried by its contact set. Partition this set into disjoint Borel pieces according to the first index ℓ at which $p_{j,N} = \varphi_\ell$. On such a piece, positivity and ordered contact in the background ω_ℓ give

$$\mathrm{MA}_\theta(p_{j,N}) \le \mathrm{MA}_{\omega_\ell}(p_{j,N}) \le c_\ell f \, \mathrm{d}V.$$

Moreover $p_{j,N} = \varphi_\ell \ge h_j$ there, and $c_\ell \le c_j$. Summing over the pieces therefore yields the global inequality

$$\mathrm{MA}_\theta(p_{j,N}) \le \mathrm{e}^{p_{j,N} - h_j} c_j f \, \mathrm{d}V.$$

As $N \to \infty$, the envelopes decrease to p_j. Indeed, their limit lies below each tail obstacle quasi-everywhere and is thus a competitor for $P_\theta(h_j)$, while the reverse inequality is immediate. Continuity of bounded products along monotone sequences and dominated convergence give

$$\mathrm{MA}_\theta(p_j) \le \mathrm{e}^{p_j - h_j} c_j f \, \mathrm{d}V.$$

The functions p_j increase. Let $\varphi' = (\lim_j p_j)^*$. Since $h_j \to \varphi$ almost everywhere, we have $\varphi' \le \varphi$ for the canonical representatives. Passing to the increasing limit and using (14.1), we obtain

$$\mathrm{MA}_\theta(\varphi') \le \mathrm{e}^{\varphi'-\varphi} c f \,\mathrm{d}V \le \mathrm{e}^{\varphi'-\varphi}\mathrm{MA}_\theta(\varphi).$$

Bounded exponential comparison forces $\varphi' \ge \varphi$. Thus $\varphi' = \varphi$, and the last inequality, together with (14.1), proves the equation. If necessary, subtracting $\sup_X \varphi$ gives the required normalization.

Step 5: uniformity and uniqueness of c. All bounds used above depend only on the two stated density bounds and the fixed data, which proves the uniform assertion for the constructed solution. Finally, two different positive constants for the same f would contradict strict domination after an arbitrary translation of one of the bounded solutions, exactly as in the lower bound for c_j. This proves the uniqueness of c. □

For $\lambda > 0$, let v_λ be the bounded solution of $\mathrm{MA}_\theta(v_\lambda) = \mathrm{e}^{\lambda v_\lambda} f \,\mathrm{d}V$, and let (φ, c) be a normalized solution given by Theorem 14.2.2. The two exponential barriers used in Proposition 10.6.1 give

$$\|\lambda v_\lambda - \log c\|_\infty \le \lambda \operatorname{osc}_X \varphi$$

also in this semipositive background.

14.3 A quantitative stability estimate

If a θ-plurisubharmonic function exceeds a bounded solution only by a small amount in L^1, the excess is also uniformly small. To prove this, we restrict the density of the solution to a strict superlevel set of the difference and construct a subsolution for the restricted density. Domination bounds the height of the superlevel set in terms of the norm of the restricted density, and Hölder's inequality converts its volume into a power of the L^1 error.

Throughout this section θ is semipositive and big, and $p > 1$ is fixed.

Theorem 14.3.1 *Fix $L, C_0 > 0$. Let $u \in \mathrm{PSH}(X,\theta)$ satisfy*

$$-C_0 \le u \le 0, \qquad \mathrm{MA}_\theta(u) = f\,\mathrm{d}V, \qquad 0 \le f \in L^p(\mathrm{d}V), \quad \|f\|_p \le L.$$

For every

$$0 < \eta < \frac{p-1}{np+p-1}$$

there is a constant C, depending only on the fixed data and η, such that every $v \in \mathrm{PSH}(X,\theta)$ with $v \le 0$ satisfies

$$\sup_X (v-u)_+ \le C\left(\int_X (v-u)_+\,\mathrm{d}V\right)^\eta.$$

The comparison potential v need not be bounded.

Proof Replacing v by $\max(v,u)$ leaves both sides unchanged, so we may assume $-C_0 \le u \le v \le 0$. Put $I = \int_X (v-u)\,\mathrm{d}V$. If $I = 0$, the two canonical potentials agree everywhere and there is nothing to prove, so we assume $I > 0$.

Choose $q \in (1,p)$, to be specified at the end. For $\delta > 0$ put

$$E_\delta = \{u < v - \delta\}, \qquad g_\delta = \mathbf{1}_{E_\delta} f, \qquad m_\delta = \|g_\delta\|_q.$$

If $m_\delta > 0$, apply Lemma 14.2.1 to g_δ/m_δ. It gives $h \in \mathrm{PSH}(X,\theta)$ and $b > 0$ such that

$$-1 \le h \le 0, \qquad \mathrm{MA}_\theta(h) \ge b\, g_\delta/m_\delta\,\mathrm{d}V.$$

The constant b does not depend on δ, f, u, v, since the auxiliary density has L^q norm one.

First suppose $0 < m_\delta < b/2$, and take

$$t = (2m_\delta/b)^{1/n} \in (0,1), \qquad w = (1-t)v + th - \delta - C_0 t.$$

Because $h - v \le C_0$, we have $w \le v - \delta$, and hence $\{u < w\} \subset E_\delta$. Positivity of bounded mixed products gives

$$\mathrm{MA}_\theta(w) \ge t^n \mathrm{MA}_\theta(h) \ge 2g_\delta\,\mathrm{d}V.$$

On $\{u < w\}$ the last measure equals $2\mathrm{MA}_\theta(u)$. Bounded strict domination in the semipositive big background (Theorem 13.2.1) therefore implies $u \ge w$. Consequently

$$v - u \le v - w = \delta + C_0 t + t(v-h) \le \delta + (C_0+1)t.$$

If $m_\delta = 0$, the measure of u vanishes on E_δ, and the same domination theorem with coefficient zero, applied to u and $v - \delta$, gives $v - u \le \delta$. If $m_\delta \ge b/2$, the bound $v - u \le C_0$ gives the following inequality after an increase of its constant. Thus in every case

$$\sup_X (v-u) \le \delta + C_1 m_\delta^{1/n}. \tag{14.2}$$

Hölder's inequality and Chebyshev's inequality give

$$m_\delta \le \|f\|_p \, \mathrm{d}V(E_\delta)^{1/q-1/p} \le L(I/\delta)^{(p-q)/(pq)}.$$

Set $a = (p-q)/(npq) > 0$. For $0 < I \le 1$, choose $\delta = I^{a/(1+a)}$. Substituting in (14.2) yields

$$\sup_X (v-u) \le C_2 I^{\eta_q}, \qquad \eta_q = \frac{p-q}{npq+p-q}.$$

As $q \downarrow 1$, the exponent η_q tends to $(p-1)/(np+p-1)$. For the prescribed η we choose $q > 1$ so close to 1 that $\eta_q > \eta$; then $I^{\eta_q} \le I^\eta$ on $(0,1]$. When $I > 1$, the bound $v - u \le C_0$ gives the same conclusion after increasing C. This proves the theorem. □

Corollary 14.3.1 *Fix $C_0 > 0$. Let $u_j, u \in \mathrm{PSH}(X,\theta)$ satisfy $-C_0 \le u_j, u \le 0$ and*

$$\mathrm{MA}_\theta(u_j) = f_j \, \mathrm{d}V, \qquad \mathrm{MA}_\theta(u) = f \, \mathrm{d}V, \qquad \sup_j \|f_j\|_p + \|f\|_p < +\infty.$$

If $u_j \to u$ in L^1, then $u_j \to u$ uniformly. More precisely, for every exponent η as in the theorem,

$$\|u_j - u\|_\infty \le C \|u_j - u\|^\eta_{L^1(\mathrm{d}V)}.$$

Proof Apply the theorem first with solution u and comparison potential u_j, and then with solution u_j and comparison potential u. The constants are uniform because of the common range and the common density bound. The larger of the two suprema is the uniform norm, and each integral of a positive part is at most the full L^1 difference. □

The corollary assumes that the limit u already solves an equation with an L^p density. In an existence proof, this must be established before the corollary can be applied.

14.4 Hölder continuity from bounded stability

Bounded stability also gives a Hölder modulus. We apply it to Demailly's Chern-connection regularization of a solution: the L^1 error of the regularization controls its pointwise error, and a gradient estimate for the smooth averages then gives the modulus. We use the averaging operators R_t and the transforms $\Phi_{c,\delta}$ of Lemma 1.21.1, with the constants A, K given there, together with the estimates of Lemma 1.21.2. Interpolating between the smoothing error and the gradient bound yields the exponent below.

Theorem 14.4.1 *Let $p > 1$ and let $u \in \mathrm{PSH}(X,\omega) \cap L^\infty(X)$ solve*

$$\mathrm{MA}_\omega(u) = f\,\mathrm{d}V, \qquad 0 \le f \in L^p(\mathrm{d}V).$$

Then u is Hölder continuous with every exponent

$$0 < \beta < \frac{2(p-1)}{np + 3(p-1)}.$$

The Hölder constants are uniform for a fixed bound $-C_0 \le u \le 0$ and a fixed bound for $\|f\|_p$. In particular, the continuous solutions constructed in Theorem 10.1.1 have this regularity.

Proof After adding a constant we may assume $-C_0 \le u \le 0$. Choose

$$0 < \eta < \frac{p-1}{np + p - 1}, \qquad \alpha = 2\eta < 1.$$

For small $\delta > 0$ set

$$c = \delta^\alpha, \qquad e = Ac + 2K\delta, \qquad r = -C_0 - 1, \qquad v_\delta = \frac{\Phi_{c,\delta} + er}{1+e}.$$

The curvature estimate of Lemma 1.21.1 gives $v_\delta \in \mathrm{PSH}(X,\omega)$. Evaluating the infimum defining $\Phi_{c,\delta}$ at $t = \delta$ gives $\Phi_{c,\delta} \le R_\delta u \le 0$. On the other hand,

$$\Phi_{c,\delta} \ge u - K(\delta^2 + \delta),$$

since $R_t u + Kt^2 \ge u$, $Kt \ge 0$ and $-c\log(t/\delta) \ge 0$ for $0 < t \le \delta$. For small δ this lower bound is at least r, and therefore

$$v_\delta \le \Phi_{c,\delta} \le R_\delta u \le 0.$$

The Hermitian form ω is semipositive and big, so Theorem 14.3.1 applies in the background ω. Together with the L^1 estimate of Lemma 1.21.2, it gives

$$\sup_X (v_\delta - u)_+ \le C\left(\int_X (v_\delta - u)_+\,\mathrm{d}V\right)^\eta \le C\|R_\delta u - u\|_1^\eta \le C\delta^\alpha.$$

Since $e \le C\delta^\alpha$ and $u - r \le C_0 + 1$, it follows that

$$\Phi_{c,\delta} - u = (1+e)(v_\delta - u) + e(u - r) \le C\delta^\alpha. \tag{14.3}$$

We now bound the minimizing radius from below. Fix z and a radius $t = t(z) \in (0,\delta]$ at which the infimum is attained. The lower estimate at this radius and (14.3) give

$$-c\log(t/\delta) \le \Phi_{c,\delta}(z) - u(z) + K(\delta^2 + \delta) \le C\delta^\alpha = Cc.$$

Thus $t(z) \ge a\delta$ with the constant $a = \mathrm{e}^{-C} > 0$, which is independent of z and δ. Since $R_s u + Ks^2$ is increasing in s,

$$\begin{aligned} R_{a\delta}u + K(a\delta)^2 &\le R_t u + Kt^2 \\ &= \Phi_{c,\delta} + K\delta^2 + K\delta - Kt + c\log(t/\delta) \\ &\le \Phi_{c,\delta} + K\delta^2 + K\delta. \end{aligned}$$

Combining this with (14.3) and the lower bound $R_s u - u \ge -Ks^2$, and setting $s = a\delta$, we obtain

$$\|R_s u - u\|_\infty \le Cs^\alpha$$

for every sufficiently small $s > 0$.

Finally, let x, y be points at a small distance d. The gradient estimate $\|\nabla R_s u\|_\infty \le C/s$ gives

$$|u(x) - u(y)| \le 2Cs^\alpha + Cd/s.$$

With $s = d^{1/(1+\alpha)}$, both terms are bounded by a constant times $d^{\alpha/(1+\alpha)}$, and larger distances are controlled by the bound on the oscillation. This proves Hölder continuity with exponent $\alpha/(1+\alpha)$. Letting η approach its upper endpoint gives every β in the theorem; smaller exponents follow on compact X by changing the constant. □

14.4.1 Regularity for a measure with a Hölder reference

The same smoothing argument applies to a singular solution measure dominated by the product of a Hölder potential. Its square-capacity bound supplies stability, and the weighted Chern estimate supplies the smoothing error.

Theorem 14.4.2 *Let $u \in \mathrm{PSH}(X,\omega) \cap C^{0,\alpha}(X)$, $0 < \alpha \le 1$, and suppose $\varphi \in \mathrm{PSH}(X,\omega) \cap C(X)$ satisfies*

$$\omega_\varphi^n = \mu \le A\omega_u^n, \qquad A > 0.$$

Then φ is Hölder continuous with exponent

$$\beta = \frac{\alpha}{(\alpha + 2n)(6n+1) + \alpha} > 0.$$

Its Hölder constant is uniform for fixed bounds on A, $\|u\|_{C^{0,\alpha}}$ and the oscillation of φ.

Proof Normalize $\sup_X \varphi = 0$ and write $M = \|\varphi\|_\infty$. By Proposition 1.8.1, the measure μ has a square-capacity bound with a fixed constant. Put

$$\eta = \frac{2\alpha}{\alpha + 2n}, \qquad \gamma = \frac{1}{6n+1}, \qquad q = \eta\gamma/2 < 1.$$

The weighted estimate of Lemma 1.21.6 gives $\|R_\delta\varphi - \varphi\|_{L^1(\mu)} \le C\delta^\eta$.

Use the constants A_0, K of Lemma 1.21.1, taking $A_0 \ge 1$, and define the unshifted transform

$$F = \inf_{0<t\le\delta}\{R_t\varphi + Kt^2 + Kt - b\log(t/\delta)\}.$$

It differs from $\Phi_{b,\delta}$ by the constant $K(\delta^2+\delta)$, so

$$\omega + \mathrm{dd^c}F \ge -(A_0 b + 2K\delta)\omega, \qquad \varphi \le F \le R_\delta\varphi + 2K\delta$$

when $\delta \le 1$. Choose $\varepsilon = \delta^q$ and $b = (\varepsilon - 2K\delta)/A_0$. For small δ, $\varepsilon \le 1/2$ and $\varepsilon/(2A_0) \le b \le \varepsilon/A_0$.

Set $T = (1-\varepsilon)F$. Then $\omega + \mathrm{dd^c}T \ge \varepsilon^2\omega$. The transform is continuous: its positive logarithmic penalty excludes radii near zero uniformly in the base point for each fixed δ, b, and the minimum of its continuous defining function on the resulting compact interval depends continuously on the base point. Take $B \ge M + 2K + 1$ and set $\psi = T - B\varepsilon$. Since $R_\delta\varphi \le 0$, we have $-M - B \le \psi \le 0$. Moreover,

$$\psi - \varphi \le (1-\varepsilon)(R_\delta\varphi - \varphi + 2K\delta) + \varepsilon(M - B) \le (1-\varepsilon)(R_\delta\varphi - \varphi + 2K\delta).$$

The weighted smoothing estimate and the fixed bound for $\mu(X)$ give $\int(\psi-\varphi)_+\,\mathrm{d}\mu \le C\delta^\eta$. Thus Proposition 10.3.1, with a fixed competitor bound $H \ge M + B + 1$, gives

$$\sup_X(T - \varphi) \le C\delta^{\eta\gamma} + B\varepsilon \le C_1\varepsilon.$$

Since $\varphi \le 0$,

$$0 \le F - \varphi = \frac{T - \varphi + \varepsilon\varphi}{1-\varepsilon} \le 2C_1\varepsilon.$$

At a minimizing radius $t_0 \in (0,\delta]$, monotonicity of $R_t\varphi + Kt^2$ implies

$$b\log(\delta/t_0) \le F - \varphi \le 2C_1\varepsilon, \qquad t_0 \ge \kappa\delta, \quad \kappa = \exp(-4A_0C_1) > 0.$$

The constant κ is independent of δ and the point. Applying monotonicity again gives $R_{\kappa\delta}\varphi - \varphi \le 2C_1\delta^q$. With the lower bound $R_r\varphi - \varphi \ge -Kr^2$ and $r = \kappa\delta$, this proves $\|R_r\varphi - \varphi\|_\infty \le Cr^q$.

Finally Lemma 1.21.2 gives $\|\nabla R_r\varphi\|_\infty \le C/r$. For points a distance s apart,

$$|\varphi(x) - \varphi(y)| \le 2Cr^q + Cs/r.$$

Take $r = s^{1/(1+q)}$ for small s; boundedness handles larger distances. The exponent is $q/(1+q) = \beta$. □

14.5 Local continuity in a semipositive big background

We return to a semipositive big background θ. Where θ degenerates, regularization loses some positivity, and this curvature error can be repaired by adding a small multiple of a strict barrier. Bounded stability then shows that a bounded solution is continuous wherever the barrier is locally bounded.

Fix $\rho \in \mathrm{PSH}(X,\theta)$ with $\theta + \mathrm{dd}^c\rho \geq \kappa\omega$ for some $\kappa > 0$. For bounded $u \in \mathrm{PSH}(X,\theta)$ we use the averages $R_t u$, the transforms $\Phi_{c,\delta}$ and the curvature modulus $\epsilon(\delta)$, with the constants A, K, from Section 1.21.1 and Lemma 1.21.3.

Theorem 14.5.1 *Let $p > 1$ and let $u \in \mathrm{PSH}(X,\theta) \cap L^\infty(X)$ satisfy*

$$\mathrm{MA}_\theta(u) = f\,\mathrm{d}V, \qquad 0 \leq f \in L^p(\mathrm{d}V).$$

Then u is continuous on every open set $U \subseteq X$ on which ρ is locally bounded.

Proof After adding constants we may assume $-C_0 \leq u \leq 0$ and $\rho \leq -C_0 - 1$. Choose

$$0 < \eta < \frac{p-1}{np+p-1}, \qquad \alpha = 2\eta < 1,$$

and set, for small $\delta > 0$,

$$c = \delta^\alpha + \epsilon(\delta), \qquad e = Ac + \epsilon(\delta), \qquad s = e/\kappa, \qquad v_\delta = \frac{\Phi_{c,\delta} + s\rho}{1+s}.$$

Since $s\kappa = e$, the curvature bounds for $\Phi_{c,\delta}$ and ρ give $v_\delta \in \mathrm{PSH}(X,\theta)$. Moreover

$$\rho \leq -C_0 - 1 \leq \Phi_{c,\delta} \leq R_\delta u \leq 0$$

for small δ: the lower bound follows from $\Phi_{c,\delta} \geq u - K(\delta^2 + \delta)$, exactly as in the proof of Theorem 14.4.1. Hence $v_\delta \leq \Phi_{c,\delta} \leq R_\delta u \leq 0$.

Theorem 14.3.1 allows an unbounded comparison potential, so it applies to v_δ. Together with the L^1 smoothing estimate, it gives

$$\sup_X (v_\delta - u)_+ \leq C\left(\int_X (v_\delta - u)_+\,\mathrm{d}V\right)^\eta \leq C\delta^\alpha.$$

Fix M and consider the points where $\rho \geq -M$. Since $s \leq Cc$ and $c \to 0$, the identity

$$\Phi_{c,\delta} - u = (1+s)(v_\delta - u) + s(u - \rho)$$

gives $\Phi_{c,\delta} - u \leq C_M c$ there.

At a radius t where the infimum defining $\Phi_{c,\delta}$ is attained, the same lower estimate yields

$$-c\log(t/\delta) \leq \Phi_{c,\delta} - u + K(\delta^2 + \delta) \leq C_M c.$$

Thus $t \geq a_M \delta$ with $a_M > 0$ independent of the point and of δ. Since $R_t u + Kt^2$ is increasing in t, we obtain

$$R_{a_M\delta}u + K(a_M\delta)^2 \leq R_t u + Kt^2 \leq \Phi_{c,\delta} + K\delta^2 + K\delta.$$

This upper bound and the lower bound $R_s u \geq u - Ks^2$ imply

$$\sup_{\{\rho \geq -M\}} |R_{a_M \delta} u - u| \leq C_M \big(\delta^\alpha + \epsilon(\delta)\big) \longrightarrow 0.$$

On every compact subset of U, the function ρ is bounded below. The smooth functions $R_{a_M \delta} u$ therefore converge uniformly to u on each such compact set, which proves that u is continuous on U. □

The proof also gives a modulus of continuity on each compact subset of U, obtained by combining the uniform smoothing error with the gradient bound C/t. A Hölder exponent would require a power bound for the modulus $\epsilon(\delta)$. For potentials that are locally bounded off the poles of a strict analytic barrier, Lemma 1.21.7 refines the classical expansion and gives a curvature error linear in δ. Combined with stability above a strict barrier, this yields local Hölder continuity even for solutions with minimal singularities (Theorem 14.16.1). Neither argument gives continuity across the pole set of the barrier.

14.6 Homogeneous replacement on a coordinate ball

To show that the Monge–Ampère measure of an envelope vanishes off the contact set, we shall replace the envelope on small balls by a solution of the homogeneous equation with the same boundary values. We first recall the smooth Dirichlet problem with a smooth positive density; the replacement is obtained by letting a constant density tend to zero, and continuous boundary values are then handled by uniform approximation.

In this section we work on the ball $B = B_R = \{|z| < R\} \subset \mathbb{C}^n$, put $\beta = \mathrm{dd^c}|z|^2$, and let θ be any smooth real $(1,1)$-form defined near $\overline{B}$. Distances and the Laplacian Δ are Euclidean.

Lemma 14.6.1 *Let $\varphi \in C^\infty(\partial B)$, and let F be a smooth strictly positive function on $\overline{B}$. There is a unique smooth function v on $\overline{B}$ such that*

$$\theta + \mathrm{dd^c} v > 0, \qquad (\theta + \mathrm{dd^c} v)^n = F\beta^n, \qquad v|_{\partial B} = \varphi.$$

Proof Extend φ to a smooth function $\widetilde{\varphi}$ on $\overline{B}$. For sufficiently large A, the function $\underline{v} = \widetilde{\varphi} + A(|z|^2 - R^2)$ is a smooth strict subsolution with the prescribed boundary values: $\theta + \mathrm{dd^c}\underline{v}$ is positive and its determinant is at least $(\max_{\overline{B}} F)\beta^n$. For $n \geq 2$, the classical smooth Dirichlet theorem of Guan–Li therefore applies on the ball, with the arbitrary smooth background $\chi = \theta$ and the smooth positive right-hand side F. Their operator is $(\mathrm{i}/2)\partial\bar\partial$, so our potential is π times theirs. No closedness condition is needed here; such conditions enter only in their separate theorems on compact manifolds. For $n = 1$ the lemma is the Dirichlet problem for the Poisson equation. For uniqueness, integrate the derivative of $\log\det$ along the segment between the two positive matrices: the difference of the logarithms of the two determinants becomes a

uniformly elliptic linear operator with smooth coefficients applied to the difference of the solutions, and the maximum principle applies. □

The same argument gives smooth comparison on subdomains D of the ball. Let a, b be smooth functions on $\overline{D}$ with $\theta + \mathrm{dd^c} a > 0$ and $\theta + \mathrm{dd^c} b > 0$. If $(\theta + \mathrm{dd^c} a)^n \geq (\theta + \mathrm{dd^c} b)^n$ in D and $a \leq b$ on ∂D, then $a \leq b$ in D. Indeed, integrating the derivative of the logarithm of the determinant along the segment between the two positive matrices gives a linear elliptic inequality for $a - b$, and the maximum principle proves the assertion. The boundary of D need not be smooth for this argument.

Theorem 14.6.1 *For every $\varphi \in C(\partial B)$ there exists a continuous θ-plurisubharmonic function H_φ on $\overline{B}$ such that*

$$(\theta + \mathrm{dd^c} H_\varphi)^n = 0 \quad \text{on } B, \qquad H_\varphi|_{\partial B} = \varphi.$$

It dominates every continuous θ-plurisubharmonic function p on $\overline{B}$ with $p|_{\partial B} \leq \varphi$. For $\varphi, \psi \in C(\partial B)$, the construction satisfies

$$\|H_\varphi - H_\psi\|_{C(\overline{B})} \leq \|\varphi - \psi\|_{C(\partial B)}.$$

For smooth boundary data the constructed function is Lipschitz on $\overline{B}$.

Proof *Step 1: boundary barriers.* We first take φ smooth and $0 < \varepsilon \leq 1$, and let v_ε be the solution of Lemma 14.6.1 with the constant density $F \equiv \varepsilon$. The strict subsolution $\underline{v}$ constructed there for $F \equiv 1$ lies below every v_ε, by smooth comparison. Choose a smooth function q with $q = \varphi$ on the boundary and $\Delta q = -C$, where C is so large that $\theta + \mathrm{dd^c} v_\varepsilon \geq 0$ implies $\Delta v_\varepsilon \geq -C$. The maximum principle for the Laplacian gives $v_\varepsilon \leq q$. Both barriers are smooth and equal $\widetilde{\varphi}$ on the boundary. Consequently

$$|v_\varepsilon(z) - \widetilde{\varphi}(z)| \leq C_1 \operatorname{dist}(z, \partial B), \tag{14.4}$$

with C_1 independent of ε.

Step 2: a Lipschitz bound independent of ε. Let $h \in \mathbb{C}^n$ be small, and set $D_h = \{z \in B : z + h \in B\}$. Since θ is smooth, there is $C_2 > 0$, independent of the translation h, such that

$$\theta(z) - \theta(z + h) + C_2 |h| \beta \geq 0.$$

For a constant $C_3 > 0$ to be fixed, define on D_h

$$w(z) = v_\varepsilon(z + h) + C_2 |h| (|z|^2 - R^2) - C_3 |h|.$$

Then $\theta + \mathrm{dd^c} w \geq \theta(z + h) + \mathrm{dd^c} v_\varepsilon(z + h) > 0$, and the determinant of $\theta + \mathrm{dd^c} w$ is at least $\varepsilon \beta^n$, because the Euclidean volume form is translation invariant. On ∂D_h, one of the points z and $z + h$ lies on ∂B, and the other has distance at most $|h|$ from ∂B. Estimate (14.4) and the Lipschitz bound for $\widetilde{\varphi}$ therefore give $w \leq v_\varepsilon$ on ∂D_h if C_3 is

chosen sufficiently large, and smooth comparison extends this inequality to all of D_h. Together with the same argument for $-h$, this gives

$$|v_\varepsilon(z+h) - v_\varepsilon(z)| \le C_4|h|,$$

with constants independent of ε. The same bound for arbitrary pairs of points follows by subdividing the segment joining them inside the convex ball, and it extends to $\overline{B}$ because each v_ε is continuous there.

Step 3: the limit $\varepsilon \to 0$. Smooth comparison also shows that v_ε increases as ε decreases. By the barriers and the common Lipschitz bound, the limit H_φ is Lipschitz and the convergence is uniform on $\overline{B}$. The inequality $\theta + \mathrm{dd^c} v_\varepsilon > 0$ of currents passes to the limit, and continuity of local bounded products under uniform convergence gives $(\theta + \mathrm{dd^c} H_\varphi)^n = 0$. For smooth boundary values φ, ψ, denote the solutions of Lemma 14.6.1 with $F \equiv \varepsilon$ by $v_{\varepsilon,\varphi}$ and $v_{\varepsilon,\psi}$. Smooth comparison gives $\|v_{\varepsilon,\varphi} - v_{\varepsilon,\psi}\|_\infty \le \|\varphi - \psi\|_\infty$, and passing to the limit proves the contraction for smooth data.

Step 4: continuous boundary values. For continuous φ, choose smooth $\varphi_j \to \varphi$ uniformly on ∂B. By the contraction, H_{φ_j} is uniformly Cauchy. Its limit H_φ is continuous and θ-plurisubharmonic, has the prescribed boundary values, and satisfies the homogeneous equation, again by continuity of bounded products under uniform convergence. Passing to the limit also proves the contraction for all continuous boundary data.

Step 5: domination. It remains to prove the domination property, which does not follow from a comparison of total masses. First take φ smooth and p as in the statement. For $\delta > 0$ put $p_\delta = p + \delta(|z|^2 - R^2)$, so that $\theta + \mathrm{dd^c} p_\delta \ge \delta\beta$. By Lemma 1.3.9, every C^2 function a touching p_δ from above at an interior point z_0 satisfies

$$\theta(z_0) + \mathrm{dd^c} a(z_0) \ge \delta\beta.$$

Suppose that $p_\delta - v_\varepsilon$ had a positive maximum. Since this difference is nonpositive on the boundary, the maximum would be attained at an interior point, where v_ε plus the maximum touches p_δ from above. The determinant of $\theta + \mathrm{dd^c} v_\varepsilon$ at that point would then be at least $\delta^n\beta^n$, contradicting the equation for v_ε when $\varepsilon < \delta^n$. Hence $p_\delta \le v_\varepsilon$ for small ε. Letting first ε and then δ decrease to zero, we obtain $p \le H_\varphi$.

Finally, for continuous φ, take the smooth approximants φ_j above and set $a_j = \|\varphi_j - \varphi\|_\infty$. The boundary values of $p - a_j$ are at most φ_j, so the result for smooth data gives $p - a_j \le H_{\varphi_j}$. Uniform convergence proves $p \le H_\varphi$. □

By the domination property, H_φ is the largest continuous θ-plurisubharmonic function on $\overline{B}$ whose boundary values are at most φ. This is the property needed for replacing an envelope locally.

14.7 Contact support in a big background

Throughout this section, θ is an arbitrary smooth big background, not necessarily semipositive. For a continuous obstacle, regularization shows that the envelope is continuous off the poles of a strict analytic barrier. On a small ball where the envelope stays below the obstacle, a homogeneous replacement then shows that the envelope already solves the homogeneous equation, so its Monge–Ampère measure vanishes away from the contact set.

By Theorem 1.15.2, applied to a strict barrier with a sufficiently small curvature error, we may fix $\rho \in \mathrm{PSH}(X,\theta)$ with analytic singularities and a smooth remainder after resolution such that

$$\theta + \mathrm{dd^c}\rho \geq \kappa\omega, \qquad \kappa > 0.$$

Its pole set $Z = \{\rho = -\infty\}$ is an analytic, hence pluripolar, subset of X.

Theorem 14.7.1 *Let $h \in C(X)$. Then $p = P_\theta(h)$ is a θ-plurisubharmonic function, continuous on $X \setminus Z$, whose Monge–Ampère measure satisfies*

$$\mathbf{1}_{\{p<h\}}\mathrm{MA}_\theta(p) = 0.$$

Here $\mathrm{MA}_\theta(p)$ is allowed to have infinite total mass.

Proof Subtract a constant from ρ so that $\rho + 2 \leq h$. Then $\rho + 2$ is a competitor, and since the obstacle is continuous, the envelope lies below it everywhere; thus

$$\rho + 2 \leq p \leq h.$$

In particular, p is locally bounded off Z. We first prove that p is continuous there; this part does not use the contact assertion.

Apply Lemma 1.21.7 to $p - \sup_X p$ and add back the constant. The transforms $\Phi_{c,\delta}$ of that lemma are defined on X and, with fixed constants $A, K, C > 0$ and $\epsilon(\delta) = C\delta$, satisfy

$$\theta + \mathrm{dd^c}\Phi_{c,\delta} \geq -(Ac + \epsilon(\delta))\omega. \tag{14.5}$$

Off Z the infimum defining $\Phi_{c,\delta}$ is attained at a positive radius, and

$$p - K(\delta^2 + \delta) \leq \Phi_{c,\delta} \leq R_\delta p \leq R_\delta h.$$

For small δ the first inequality gives $\Phi_{c,\delta} \geq \rho + 1$, hence $\rho \leq \Phi_{c,\delta}$ on X.

Set

$$m(\delta) = \sup_{0<t\leq\delta} \|R_t h - h\|_\infty, \qquad c = m(\delta) + \epsilon(\delta) + \delta, \qquad s = \frac{Ac + \epsilon(\delta)}{\kappa}.$$

The averaging kernels are positive, have integral one and are supported in balls of radius comparable to t, so uniform continuity of h gives $m(\delta) \to 0$. Define

$$v_\delta = \frac{\Phi_{c,\delta} + s\rho}{1+s}.$$

By the choice of s, the strict barrier and (14.5) show that v_δ is θ-plurisubharmonic. Since $\rho \le \Phi_{c,\delta}$,

$$v_\delta \le \Phi_{c,\delta} \le R_\delta h \le h + m(\delta).$$

Thus $v_\delta - m(\delta)$ is a competitor for the envelope, and $v_\delta \le p + m(\delta)$.

Let $L \Subset X \setminus Z$ be compact. On L the difference $p - \rho$ is bounded above. Since $s \le Cc$, the identity

$$\Phi_{c,\delta} - p = (1+s)(v_\delta - p) + s(p - \rho)$$

therefore gives $\Phi_{c,\delta} - p \le C_L c$ on L. At a radius t where the infimum is attained,

$$-c\log(t/\delta) \le \Phi_{c,\delta} - p + K(\delta^2 + \delta) \le C_L c.$$

Since $c \ge \delta$, this yields $t \ge a_L \delta$ with a fixed $a_L > 0$. Because $R_t p + Kt^2$ is increasing in t, it follows that

$$p - K(a_L\delta)^2 \le R_{a_L\delta} p \le \Phi_{c,\delta} + K\delta^2 + K\delta.$$

Consequently $R_{a_L\delta} p \to p$ uniformly on L. These averages are smooth for positive radius, even though p is unbounded on X. Applying this to compact neighborhoods of the points of $X \setminus Z$ proves that p is continuous on $X \setminus Z$.

We turn to the contact assertion. By the continuity just proved, the set $\{p < h\} \setminus Z$ is open. Let x be one of its points, and choose a small coordinate ball B_r centered at x whose closure lies in this set. Let H be the homogeneous replacement of Theorem 14.6.1 with boundary values $p|_{\partial B_r}$. Its domination property gives $H \ge p$ on the ball.

We claim that $H \le h$ on B_r if r is small enough. Indeed, in the chosen Euclidean coordinates z, with Laplacian Δ, the inequality $\theta + dd^c H \ge 0$ implies a fixed bound $\Delta H \ge -C$. Comparison with the function $\sup_{\partial B_r} p + C'(r^2 - |z-x|^2)$, with C' fixed large enough, gives

$$H \le \sup_{\partial B_r} p + C' r^2.$$

As $r \to 0$, the right-hand side tends to $p(x)$, whereas $\inf_{B_r} h \to h(x) > p(x)$. This proves the claim for sufficiently small r.

Now replace p by H on the ball. The resulting function is θ-plurisubharmonic. To see this, fix $a > 0$ and take $\max\{p, H - a\}$ inside the ball and p outside. Since H and p are continuous with equal boundary values, $H - a < p$ on a collar of ∂B_r, so this is an ordinary local maximum construction. Letting $a \downarrow 0$ gives the function equal to H on B_r and to p outside, with locally uniform convergence near the boundary of the ball. This function is bounded above by h on all of X, so the definition of the envelope forces it to be at most p. Thus $p = H$ on B_r, and $\mathrm{MA}_\theta(p)$ vanishes there.

These balls cover $\{p < h\} \setminus Z$. There the extended measure agrees with the local bounded product, and it does not charge the pluripolar set Z. This proves the contact assertion on X; no bound on the total mass of $\mathrm{MA}_\theta(p)$ was needed. □

14.7.1 Quasi-continuous obstacles

We now extend the contact property to discontinuous obstacles. Continuous approximations of an obstacle need not preserve every competitor of its envelope pointwise. For lower semicontinuous obstacles, the approximation of Lemma 1.19.3 repairs this, and quasi-continuity then allows us to pass to limits of weighted measures. An unbounded obstacle is truncated at finite levels; in an arbitrary smooth background this produces signed products, whose limits are controlled by Lemma 1.8.7 before we restrict to the region where the product is positive. The strict analytic barrier ρ and its pole set Z are those fixed above.

Proposition 14.7.1 *If f is bounded and lower semicontinuous, then $p = P_\theta(f)$ is locally bounded on $X \setminus Z$, and*

$$\mathbf{1}_{\{p<f\}}\mathrm{MA}_\theta(p) = 0.$$

Proof Using the infimum construction in the proof of Proposition 13.1.2, take continuous $f_j \uparrow f$ with common bounds $m \le f_j \le M$, and shift ρ below m. The envelopes $p_j = P_\theta(f_j)$ increase and satisfy

$$\rho \le p_j \le M.$$

Their regularized limit $q = (\lim_j p_j)^*$ is therefore θ-plurisubharmonic. Outside a pluripolar set it equals the pointwise limit, which is at most f; hence $q \le p = P_\theta(f)$.

We prove the reverse inequality without using a domination theorem. Let u be any competitor for $P_\theta(f)$, and let $u_t \le f$ be the potentials given by Lemma 1.19.3, which satisfy this inequality everywhere. For fixed $t, \eta > 0$, the sets

$$\{u_t < f_j + \eta\}, \qquad j \ge 1,$$

are open, increase with j, and cover X. By compactness, $u_t \le f_j + \eta$ everywhere for all large j. Thus $u_t - \eta$ is a competitor for p_j, and $q \ge u_t - \eta$. Letting first $\eta \downarrow 0$ and then $t \downarrow 0$, we obtain $q \ge u$ almost everywhere, hence everywhere by Lemma 1.3.3. Taking the supremum over all competitors u gives $q \ge p$, so $q = p$.

For fixed k, the set $U_k = \{p < f_k\}$ is open. If $j \ge k$, then $p_j \le p < f_k \le f_j$ on U_k, so Theorem 14.7.1 gives $\mathrm{MA}_\theta(p_j) = 0$ there. On every relatively compact open subset of $X \setminus Z$ the functions p_j have common bounds. After a common smooth correction and a finite expansion, the local Bedford–Taylor continuity along increasing sequences shows that their measures converge to $\mathrm{MA}_\theta(p)$ there. Since the measure of an open set is at most the lower limit of the measures of the approximating

sequence, $\mathrm{MA}_\theta(p)$ vanishes on $U_k \setminus Z$. The union of these sets is $\{p < f\} \setminus Z$, and the extended measure does not charge the pluripolar set Z. □

Proposition 14.7.2 *The conclusion of Proposition 14.7.1 holds for every bounded quasi-continuous obstacle f.*

Proof By Lemma 1.8.5, there are bounded lower semicontinuous f_j with common bounds and $f_j \downarrow f$ quasi-everywhere. The envelopes $p_j = P_\theta(f_j)$ decrease to $p = P_\theta(f)$. Indeed, the common lower barrier shows that the limit is not identically $-\infty$; the limit lies below f quasi-everywhere and is thus a competitor for $P_\theta(f)$, while monotonicity gives the other inequality. All these functions have common local bounds off Z.

For fixed k, put $H_k = \min\{1, (f - p_k)_+\}$ on $X \setminus Z$, a bounded quasi-continuous function there. If $j \geq k$, then on $\{H_k > 0\}$ we have $p_j \leq p_k < f \leq f_j$ outside a pluripolar set, so Proposition 14.7.1 gives $H_k \mathrm{MA}_\theta(p_j) = 0$ off Z.

Let g be continuous with compact support in $X \setminus Z$. The continuity of bounded products against quasi-continuous weights from Section 1.6 applies to the fixed quasi-continuous coefficient gH_k. Consequently $H_k \mathrm{MA}_\theta(p) = 0$ off Z. As $k \to \infty$, the sets $\{H_k > 0\}$ exhaust $\{p < f\} \setminus Z$, and Z is not charged because it is pluripolar.□

For an unbounded obstacle, we truncate and use the convergence of signed products in Lemma 1.8.7.

Theorem 14.7.2 *Let θ be smooth and big. Let f be a quasi-continuous obstacle, finite almost everywhere, such that $p = P_\theta(f) \not\equiv -\infty$. Then $p \leq f$ quasi-everywhere and*

$$\mathbf{1}_{\{p<f\}} \mathrm{MA}_\theta(p) = 0.$$

As before, the measure $\mathrm{MA}_\theta(p)$ may have infinite total mass.

Proof As in the proof of Theorem 13.1.2, the local envelope theorem and a countable Choquet family give $p \leq f$ quasi-everywhere. Set $f_j = \max(f, -j)$ and $p_j = P_\theta(f_j)$. Then p is a competitor for every f_j. Since $f_j \leq f_1$ and f_1 is finite almost everywhere, the finite-sublevel argument in Section 1.19 gives a common upper bound for all competitors. Thus the envelopes p_j are θ-plurisubharmonic and uniformly bounded above. Choose M strictly larger than this bound.

The obstacle $g_j = \min(f_j, M)$ is bounded and quasi-continuous. Since $p_j < M$ and $p_j \leq f_j$ quasi-everywhere, p_j is a competitor for $P_\theta(g_j)$; the reverse inequality follows from $g_j \leq f_j$. Thus $p_j = P_\theta(g_j)$, and Proposition 14.7.2 gives contact support for p_j with respect to g_j. Because $p_j < M$, no contact occurs at the artificial upper cutoff, so

$$\mathbf{1}_{\{p_j<f_j\}} \mathrm{MA}_\theta(p_j) = 0. \tag{14.6}$$

Each p_j is locally bounded off Z, with a lower barrier of the form $\rho - C_j$. The sequence decreases to p: its limit is not identically $-\infty$ because it dominates p, and it lies below f quasi-everywhere, so it is itself a competitor for $P_\theta(f)$.

Fix a Hermitian form $\Omega \geq \theta$. For integers $C, k \geq 1$, consider the bounded Ω-plurisubharmonic functions

$$v_{j,C} = \max(p_j, -C), \qquad v_C = \max(p, -C),$$

and set

$$H_{k,C} = \min\{1, (f - p_k)_+\} \min\{1, (p + C)_+\} \quad \text{on } X \setminus Z,$$

extended by zero on Z. This function is bounded and quasi-continuous. Indeed, off Z the function p_k is a finite quasi-plurisubharmonic function, truncation by bounded continuous functions preserves quasi-continuity, and the pluripolar set Z can be removed by an open set of arbitrarily small capacity. At a pole of p the second factor vanishes.

For $j \geq k$, on $\{H_{k,C} > 0\}$ we have, outside pluripolar sets,

$$p_j \geq p > -C, \qquad p_j \leq p_k < f \leq f_j.$$

By plurifine locality, the signed measure $\nu_{j,C} = (\theta + \mathrm{dd^c} v_{j,C})^n$ therefore agrees there with $\mathrm{MA}_\theta(p_j)$, and (14.6) gives

$$H_{k,C}\, \nu_{j,C} = 0.$$

For fixed C, the potentials $v_{j,C}$ have common global bounds and decrease to v_C, so Lemma 1.8.7 yields

$$\int_X H_{k,C} (\theta + \mathrm{dd^c} v_C)^n = 0.$$

On the set where $H_{k,C}$ is positive we have $p > -C$, so the restricted product in Theorem 6.1.1 identifies $H_{k,C}(\theta + \mathrm{dd^c} v_C)^n$ with the positive measure $H_{k,C}\mathrm{MA}_\theta(p)$; on the complement the coefficient is zero. Hence $\mathrm{MA}_\theta(p)$ vanishes on $\{H_{k,C} > 0\}$.

Finally, if $p(x)$ is finite and $p(x) < f(x)$, then $p_k(x) < f(x)$ for large k and $p(x) > -C$ for large C. The countable union of the sets $\{H_{k,C} > 0\}$ therefore covers $\{p < f\}$ outside $Z \cup \{p = -\infty\}$. Both excluded sets are pluripolar, and the theorem follows. □

14.8 Compactness with a common lower barrier

We return to a semipositive big background θ. Convergence of potentials in L^1 does not by itself imply convergence of their Monge–Ampère measures. We give a criterion for convergence in capacity when the potentials stay within a bounded distance of a reference admitting a smaller-background envelope. This common lower barrier ensures that all finite and infinite rooftop envelopes of the sequence are θ-plurisubharmonic. A small error integral of each potential against its own Monge–Ampère measure bounds the corresponding error of the rooftops by a summable tail. Weighted lower semicontinuity passes this bound to the limit, and singular domination identifies the limit of the lower envelopes with the L^1 limit. Squeezing the sequence between lower and upper envelopes then gives convergence in capacity, and a domination of the measures also controls their mass on deep sublevels.

Theorem 14.8.1 *Let $\theta \geq 0$ be big. Suppose $\varphi \in \mathrm{PSH}(X,\theta)$ satisfies $P_{\delta\theta}(\varphi) \not\equiv -\infty$ for some $0 < \delta < 1$. Let $u_j \in \mathrm{PSH}(X,\theta)$ satisfy, for a fixed C,*

$$\varphi - C \leq u_j \leq \varphi + C, \qquad u_j \longrightarrow u \text{ in } L^1(X).$$

If

$$I_j := \int_X |e^{u_j} - e^{u}|\, \mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \longrightarrow 0, \tag{14.7}$$

then $u_j \to u$ in capacity.

Proof The canonical representative of the limit also lies between $\varphi - C$ and $\varphi + C$. It suffices to show that every subsequence has a further subsequence converging in capacity. We may therefore assume that $I_j \leq 2^{-j}$ and that $u_j \to u$ almost everywhere. For $N \geq j$ define

$$p_{j,N} = P_\theta(\min\{u_j, \ldots, u_N\}), \qquad p_j = P_\theta\left(\inf_{\ell \geq j} u_\ell\right).$$

All these envelopes lie between $\varphi - C$ and $\varphi + C$. The contact theorem and ordered contact give an inequality for the finite rooftops. Partition the contact set of $p_{j,N}$ according to the first index ℓ for which $p_{j,N} = u_\ell$. On the corresponding piece, the measure of $p_{j,N}$ is bounded by that of u_ℓ, and $e^{p_{j,N}} = e^{u_\ell}$. Therefore

$$\int_X |e^{p_{j,N}} - e^{u}|\, \mathrm{MA}_\theta^{\mathrm{ext}}(p_{j,N}) \leq \sum_{\ell=j}^{N} I_\ell \leq 2^{1-j}.$$

Only positive measures enter this argument, so it applies also when their total masses are infinite.

As $N \to \infty$, $p_{j,N}$ decreases to p_j; the limit is the envelope of the infimum because every competitor lies below every finite rooftop. The sequence p_j increases, and its canonical limit p is θ-plurisubharmonic. By Lemma 1.8.9, both monotone limits hold in capacity. Applying Lemma 6.3.1 to the bounded nonnegative weights $|e^{p_{j,N}} - e^{u}|$, first in N and then in j, we obtain

$$\int_X |e^{p} - e^{u}|\, \mathrm{MA}_\theta^{\mathrm{ext}}(p) = 0.$$

The inequalities $p_j \leq u_\ell$ for all $\ell \geq j$ imply $p \leq u$, first almost everywhere and then for the canonical representatives. Also $p \sim u \sim \varphi$. Off the pole sets, $e^{p} < e^{u}$ exactly on $\{p < u\}$, so $\mathrm{MA}_\theta^{\mathrm{ext}}(p)(\{p < u\}) = 0$. Since $P_{\delta\theta}(\varphi) - C$ is a competitor for $P_{\delta\theta}(p)$, the latter is not identically $-\infty$. Theorem 14.1.1, applied with coefficient zero, gives $p \geq u$, and hence $p = u$.

Finally, by Hartogs' lemma and the almost-everywhere convergence, $U_j = (\sup_{\ell \geq j} u_\ell)^*$ decreases to u. The inequalities $p_j \leq u_j \leq U_j$, together with the convergence in capacity of both monotone sequences, prove the claim. □

Proposition 14.8.1 *In Theorem 14.8.1, the two bounds on u_j may be replaced by*

$$\varphi - C \le u_j \le C,$$

provided that the L^1 limit satisfies $u \preceq \varphi$. In particular, the approximants may be bounded while φ is unbounded.

Proof The L^1 limit satisfies $u \ge \varphi - C$, so the additional hypothesis gives $u \sim \varphi$. We repeat the construction of the finite rooftops in the theorem. Every $p_{j,N}$ is still θ-plurisubharmonic and lies between $\varphi - C$ and C, which is enough for contact support and for the boundedness of the exponential weights. The resulting inequality is again

$$\int_X |e^{p_{j,N}} - e^{u}| \, \mathrm{MA}_\theta^{\mathrm{ext}}(p_{j,N}) \le 2^{1-j}.$$

The limits p_j exist because of the common lower bound, and $p_j \le u$ follows from $p_j \le u_\ell$ for every $\ell \ge j$ and almost-everywhere convergence. Thus $\varphi - C \le p_j \le u$, so all p_j and their increasing limit p have the same ordinary singularity type as φ. Monotone convergence in capacity and weighted lower semicontinuity give $\mathrm{MA}_\theta^{\mathrm{ext}}(p)(\{p < u\}) = 0$, and singular domination applies to (p, u) exactly as before, so $p = u$. The upper envelopes of the tails decrease to u, and the same squeezing argument gives convergence in capacity. Neither the finite rooftops nor the individual approximants needed to have the singularity type of φ. □

Corollary 14.8.1 *In the setting of Theorem 14.8.1, with the bounds $\varphi - C \le u_j \le \varphi + C$, suppose either*

(1) $\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \le \nu$ *for a fixed finite non-pluripolar measure ν; or*
(2) $\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \le A\omega_{w_j}^n$, *where A is fixed and $w_j \in \mathrm{PSH}(X, \omega)$ are uniformly bounded and converge in capacity to a bounded w.*

Then $u_j \to u$ in capacity, all the measures $\mathrm{MA}_\theta^{\mathrm{ext}}(u_j)$ and $\mathrm{MA}_\theta^{\mathrm{ext}}(u)$ have finite mass, and

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \rightharpoonup \mathrm{MA}_\theta^{\mathrm{ext}}(u).$$

Proof In the first case, Lemma 1.23.1, applied to the exponentials e^{u_j}, proves (14.7). In the second case we use Lemma 1.23.3 instead, since these exponentials are bounded and have a common lower bound for their curvature. In both cases the criterion gives convergence in capacity.

The masses are uniformly bounded by those of the dominating measures. For the deep sublevels we use $u_j \ge \varphi - C$, which gives $\{u_j < -T\} \subset \{\varphi < C - T\}$. In the first case the masses of these sublevels are at most $\nu(\{\varphi < C - T\})$, which tends to zero as $T \to \infty$ because ν does not charge the pole set of φ. In the second case Lemma 1.8.6 bounds them by $C' \, \mathrm{Cap}_\omega(\{\varphi < C - T\})$, which also tends to zero. The tail criterion Theorem 7.4.1, in the general-background form of Theorem 7.6.1, now gives finiteness of the limiting measure and weak convergence. □

The reference φ in these results need not be an envelope fixed point; the smaller-background condition suffices. Envelope fixed points enter when the two barriers must be derived from an a priori estimate, as in Theorem 14.11.2. When no common lower barrier is available, one has to be constructed in a relative envelope class; this problem is treated in Section 31.6.

14.9 A bounded subsolution theorem

The bounded exponential equation remains solvable for right-hand sides that are singular with respect to smooth volume, provided they have a bounded density with respect to the Monge–Ampère measure of a bounded potential. We regularize this potential to obtain equations with bounded densities with respect to smooth volume; their solutions are controlled by a moving dominating measure. When the density is allowed to vanish, the normalizations are bounded by the mixed density inequality of Lemma 1.7.3 and the trace estimate for a fixed reference in Lemma 1.8.10.

Theorem 14.9.1 *Let θ be semipositive and big. Suppose*

$$\mu = f\,\mathrm{MA}_\theta(\psi), \qquad \psi \in \mathrm{PSH}(X,\theta)\cap L^\infty(X), \qquad 0 \le f \in L^\infty(\mathrm{MA}_\theta(\psi)),$$

and $\mu(X) > 0$. For every $\lambda > 0$ there is a unique bounded $u \in \mathrm{PSH}(X,\theta)$ satisfying

$$\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u}\mu.$$

Proof Write $\nu = \mathrm{MA}_\theta(\psi)$, a finite non-pluripolar measure.

Step 1: smooth strictly positive density. First suppose f is smooth and strictly positive. Choose a Hermitian form $\Omega \ge \theta$ and, by Theorem 1.11.1, smooth Ω-plurisubharmonic functions $\psi_j \downarrow \psi$. The envelopes

$$q_j = P_\theta(\psi_j)$$

lie between ψ and ψ_j, so they are uniformly bounded and decrease to ψ. Contact support and ordered contact in the background Ω give

$$\mathrm{MA}_\theta(q_j) \le \mathbf{1}_{\{q_j=\psi_j\}}\Omega^n_{\psi_j}.$$

In particular, each $\mathrm{MA}_\theta(q_j)$ has a bounded density with respect to smooth volume. Moreover $\mathrm{MA}_\theta(q_j)(X) > 0$ by Proposition 13.2.1. Theorem 14.2.1 therefore gives bounded $u_j \in \mathrm{PSH}(X,\theta)$ with

$$\mathrm{MA}_\theta(u_j) = \mathrm{e}^{\lambda u_j} f\,\mathrm{MA}_\theta(q_j).$$

Since f is bounded above and away from zero, we can choose C such that $\mathrm{e}^{\lambda(q_j-C)} f \le 1 \le \mathrm{e}^{\lambda(q_j+C)} f$ for all j. Then $q_j - C$ and $q_j + C$ are a subsolution and a supersolution, and bounded exponential comparison gives $q_j - C \le u_j \le q_j + C$.

Extract an L^1 limit u, which is again bounded. The moving domination

$$\mathrm{MA}_\theta(u_j) \le C'\Omega^n_{\psi_j}$$

and Corollary 14.8.1, applied with the reference zero, give convergence in capacity. Continuity of bounded products under convergence in capacity, with the quasi-continuous weights $\mathrm{e}^{\lambda u_j} f$, then gives

$$\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u} f\nu.$$

Step 2: bounded measurable density. Choose smooth positive functions f_j with a common upper bound $L > 0$ such that $f_j \to f$ in $L^1(\nu)$. Such an approximation exists: by regularity of the finite measure ν, f can be approximated by continuous functions on large compact sets, and continuous functions by smooth ones uniformly; truncating to a fixed bounded interval and adding a positive constant tending to zero preserves the bounds and the convergence. Step 1 gives bounded u_j with

$$\mathrm{MA}_\theta(u_j) = \mathrm{e}^{\lambda u_j} f_j\nu.$$

For a fixed C we have $\mathrm{e}^{\lambda(\psi-C)} f_j \le 1$ for all j, so $\psi - C$ is a subsolution and $u_j \ge \psi - C$. The upper bound requires a separate argument, because $\inf_X f_j$ may tend to zero.

The construction in Step 1 also gives the mixed inequality

$$\theta_{u_j} \wedge \theta_\psi^{n-1} \ge \mathrm{e}^{\lambda u_j/n} f_j^{1/n}\nu. \tag{14.8}$$

To prove it without a mixed inequality for arbitrary singular measures, we use the approximants $u_{j,k}$ and q_k of Step 1, for which

$$\mathrm{MA}_\theta(u_{j,k}) = \mathrm{e}^{\lambda u_{j,k}} f_j \mathrm{MA}_\theta(q_k),$$

and both Monge–Ampère measures have densities with respect to smooth volume. Lemma 1.7.3 applies to the pair $(u_{j,k}, q_k)$. For fixed j, both sequences are uniformly bounded and converge in capacity to (u_j, ψ), so continuity of bounded products against quasi-continuous weights passes the mixed inequality to the limit and yields (14.8).

Put $M_j = \sup_X u_j$, $v_j = u_j - M_j$ and $c_j = \mathrm{e}^{\lambda M_j}$. Suppose the M_j were unbounded above. After extraction, $M_j \to +\infty$ and $v_j \to v$ in $L^1(X)$, where $v \in \mathrm{PSH}(X,\theta)$ is normalized. By Lemma 1.23.1, $\mathrm{e}^{\lambda v_j/n} \to \mathrm{e}^{\lambda v/n}$ in $L^1(\nu)$. Together with the inequalities

$$|f_j^{1/n} - f^{1/n}|^n \le |f_j - f|, \qquad 0 \le f_j \le L,$$

this gives

$$\int_X \mathrm{e}^{\lambda v_j/n} f_j^{1/n}\,\mathrm{d}\nu \longrightarrow \int_X \mathrm{e}^{\lambda v/n} f^{1/n}\,\mathrm{d}\nu > 0;$$

the last integral is positive because $\mu(X) > 0$ and ν does not charge the pole set of v. Integrating (14.8) and applying Lemma 1.8.10, we find some $a > 0$ such that, along

the extraction,

$$ac_j^{1/n} \le \int_X \theta_{v_j} \wedge \theta_\psi^{n-1} \le C_\psi,$$

contradicting $M_j \to +\infty$. Thus the u_j are uniformly bounded above as well as below.

Extract an L^1 limit u. Now $\mathrm{MA}_\theta(u_j) \le C''\nu$, so Corollary 14.8.1 gives convergence in capacity and weak convergence of the Monge–Ampère measures. The right-hand sides converge in total variation, by the convergence of exponentials against the fixed measure ν and the estimate

$$\int_X |\mathrm{e}^{\lambda u_j} f_j - \mathrm{e}^{\lambda u} f|\,\mathrm{d}\nu \le C\|f_j - f\|_{L^1(\nu)} + \|f\|_\infty \int_X |\mathrm{e}^{\lambda u_j} - \mathrm{e}^{\lambda u}|\,\mathrm{d}\nu.$$

Consequently $\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u}\mu$. Uniqueness follows from bounded exponential comparison. □

14.10 Adding weighted Monge–Ampère measures

Let u and v be potentials of the same ordinary singularity type. We show that the sum of their weighted measures $\mathrm{e}^{-\lambda u}\mathrm{MA}_\theta(u) + \mathrm{e}^{-\lambda v}\mathrm{MA}_\theta(v)$ is again of the form $\mathrm{e}^{-\lambda a}\mathrm{MA}_\theta(a)$ for a potential a of that type. Truncating u and v gives bounded equations, solved by the bounded subsolution theorem, whose solutions have a common lower barrier. Their exponential error tends to zero even though the approximating masses may grow, so the lower-barrier criterion identifies the limit. This addition step will remove a deficit of mass in the existence proof of Section 14.11.

Theorem 14.10.1 *Let $\theta \ge 0$ be big, and suppose $\varphi \in \mathrm{PSH}(X,\theta)$ satisfies $P_{\delta\theta}(\varphi) \not\equiv -\infty$ for some $0 < \delta < 1$. Let $u, v \in \mathrm{PSH}(X,\theta)$ satisfy $u, v \sim \varphi$, and let $\lambda > 0$. If*

$$\mu = \mathrm{e}^{-\lambda u}\mathrm{MA}_\theta^{\mathrm{ext}}(u) + \mathrm{e}^{-\lambda v}\mathrm{MA}_\theta^{\mathrm{ext}}(v)$$

is a finite measure, then there exists $a \in \mathrm{PSH}(X,\theta)$, with $a \sim \varphi$, such that

$$\mathrm{MA}_\theta^{\mathrm{ext}}(a) = \mathrm{e}^{\lambda a}\mu.$$

Here the weights are evaluated off the pole sets. The solution a is unique in the ordinary singularity type of φ.

Proof *Step 1: truncated equations and barriers.* Choose $S \ge \max(\sup_X u, \sup_X v)$. A common translation reduces the theorem to the case $u, v \le 0$: translating u and v by $-S$ multiplies μ by $\mathrm{e}^{\lambda S}$, and the resulting solution is then translated back by S.

For integers $j \ge 1$, set $u_j = \max(u, -j)$, $v_j = \max(v, -j)$ and

$$\mu_j = \mathrm{e}^{-\lambda u_j}\mathrm{MA}_\theta(u_j) + \mathrm{e}^{-\lambda v_j}\mathrm{MA}_\theta(v_j).$$

For $s_j = (u_j + v_j)/2$, positivity of mixed products gives

$$\mu_j \le 2^n e^{\lambda j} \mathrm{MA}_\theta(s_j).$$

Thus μ_j has a bounded density with respect to the Monge–Ampère measure of the bounded potential s_j, and $\mu_j \neq 0$ by Proposition 13.2.1. The bounded subsolution theorem Theorem 14.9.1 therefore gives bounded $a_j \in \mathrm{PSH}(X,\theta)$ with $\mathrm{MA}_\theta(a_j) = e^{\lambda a_j}\mu_j$, and bounded exponential comparison yields

$$a_j \le \min(u_j, v_j) \le 0.$$

Choose C with $|u - v| \le C$ off the common pole set; then $|u_j - v_j| \le C$. Put

$$D = C/2 + n\lambda^{-1}\log 2, \qquad b_j = s_j - D.$$

Because $|u_j - v_j| \le C$, positivity of mixed products gives

$$e^{-\lambda b_j}\mathrm{MA}_\theta(b_j) \ge 2^{-n} e^{\lambda D - \lambda s_j}\big(\mathrm{MA}_\theta(u_j) + \mathrm{MA}_\theta(v_j)\big) \ge \mu_j.$$

Hence $a_j \ge b_j \ge w$, where

$$w = (u+v)/2 - D \sim \varphi$$

is a fixed θ-plurisubharmonic function. Extract a subsequence with $a_j \to a$ in $L^1(X)$. The upper barriers decrease to $\min(u,v)$, so $w \le a \le \min(u,v)$ and $a \sim \varphi$.

Step 2: convergence in capacity. Write $E_j = \{\min(u,v) > -j\}$. By locality, $\mu_j = \mu$ on E_j; since $a_j \le 0$, it follows that

$$\int_{E_j} |e^{a_j} - e^a|\,\mathrm{MA}_\theta(a_j) \le \int_X |e^{a_j} - e^a|\,d\mu \longrightarrow 0$$

by Lemma 1.23.1. On $X \setminus E_j$ we have $a_j \le -j$ and $a \le -j$, whence $|e^{a_j} - e^a| \le e^{-j}$. Moreover

$$\mathrm{MA}_\theta(a_j) = e^{\lambda(a_j - u_j)}\mathrm{MA}_\theta(u_j) + e^{\lambda(a_j - v_j)}\mathrm{MA}_\theta(v_j) \le \mathrm{MA}_\theta(u_j) + \mathrm{MA}_\theta(v_j).$$

Choose a Hermitian form $\Omega \ge \theta$. Since $\mathrm{MA}_\theta(u_j) \le \mathrm{MA}_\Omega(u_j)$ and $-j \le u_j \le 0$, and similarly for v_j, the range estimate of Proposition 7.1.1, with $r_n = \max(n-2, 0)$, gives

$$\int_{X\setminus E_j} |e^{a_j} - e^a|\,\mathrm{MA}_\theta(a_j) \le C' e^{-j}(1+j)^{r_n} \longrightarrow 0.$$

The lower-barrier criterion Proposition 14.8.1 now gives $a_j \to a$ in capacity. Note that only a polynomial bound for the masses of the approximating measures was needed.

Step 3: the limiting equation. We identify the equation on sets where w is bounded below, without first proving weak convergence of the measures $\mathrm{MA}_\theta(a_j)$. For $T > 0$, let g_T be the continuous cutoff from the proof of Lemma 6.3.1, and put $\zeta_T = g_T(w)$. Where $\zeta_T > 0$, we have $w > -2T$, hence every a_j and a is above $-2T$. If $j > 2T$ and

$x \notin E_j$, the inequalities $w(x) \le a_j(x) \le -j$ force $\zeta_T(x) = 0$. Consequently, for all $j > 2T$,

$$\zeta_T \mathrm{MA}_\theta(a_j) = \zeta_T e^{\lambda a_j} \mu.$$

We test this identity against a continuous function. On the left we may replace a_j by $\max(a_j, -2T)$ and use continuity of bounded products under convergence in capacity, with the fixed bounded quasi-continuous weight ζ_T. On the right, the exponentials converge against the fixed measure μ, which gives convergence in total variation. Therefore

$$\zeta_T \mathrm{MA}_\theta^{\mathrm{ext}}(a) = \zeta_T e^{\lambda a} \mu.$$

As $T \to \infty$, the cutoffs increase to one off the pole set of w, which no measure involved charges. This proves the equation and, in particular, shows that $\mathrm{MA}_\theta^{\mathrm{ext}}(a)$ has finite mass. Uniqueness follows from Corollary 14.1.1. □

14.11 Equations in a prescribed ordinary type

We return to a semipositive big background θ and now require the solution to have the ordinary singularity type of a fixed reference φ. Throughout this section, $\varphi \in \mathrm{PSH}(X, \theta)$ is an envelope fixed point admitting a smaller-background envelope; that is, (13.20) holds:

$$P_\theta[\varphi] = \varphi, \qquad P_{\varepsilon\theta}(\varphi) \not\equiv -\infty \quad \text{for some } 0 < \varepsilon < 1.$$

We fix such an ε. Note that $\varphi \le 0$, since every competitor for $P_\theta[\varphi]$ is nonpositive. For a normalized solution u, the fixed-point property gives the upper bound $u \le \varphi$, while the smaller-background envelope $P_{\varepsilon\theta}(\varphi)$ yields a uniform lower bound $u \ge \varphi - C$. A supersolution and the addition theorem then prove existence in this type.

Theorem 14.11.1 *Let θ and φ be as above, and let $\mu = f\,\mathrm{d}V$, where $0 \le f \in L^p(\mathrm{d}V)$, $p > 1$, and $\mu(X) > 0$. Then:*

(1) *For every $\lambda > 0$ there is a unique $u \in \mathrm{PSH}(X,\theta)$ with $u \sim \varphi$ such that*

$$\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u}\mu.$$

(2) *There are $u \in \mathrm{PSH}(X,\theta)$ with $u \sim \varphi$ and a uniquely determined constant $c > 0$ such that*

$$\mathrm{MA}_\theta(u) = c\mu.$$

The potential in part (2) need not be unique up to an additive constant, even for a Hermitian background and the reference $\varphi = 0$; see the counterexample in Theorem 11.6.1.

The proof uses two estimates in the prescribed type. The first is a lower bound for the norm of a Monge–Ampère density.

Lemma 14.11.1 *Fix $q > 1$. There is $b_q > 0$ such that every $u \in \mathrm{PSH}(X,\theta)$ with $u \sim \varphi$ and*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = F\,\mathrm{d}V, \qquad 0 \le F \in L^q(\mathrm{d}V),$$

satisfies $\|F\|_q \ge b_q$. For fixed θ and ε, the constant b_q is independent of φ.

Proof Since $u \sim \varphi$, the smaller-background envelope $P_{\varepsilon\theta}(u)$ is not identically $-\infty$. If $F = 0$, then Theorem 14.1.1, applied to u and $u + 1$ with coefficient zero, would give $u \ge u + 1$; hence $N = \|F\|_q > 0$.

Apply Lemma 14.2.1 in the semipositive big background $(1-\varepsilon)\theta$ to F/N, whose L^q norm is one. It gives a bounded s with $-1 \le s \le 0$ and a constant $b_q > 0$, depending only on this fixed background and on q, such that

$$\mathrm{MA}_{(1-\varepsilon)\theta}(s) \ge (b_q/N)F\,\mathrm{d}V.$$

Put $h = P_{\varepsilon\theta}(\varphi) + s$. This is a θ-plurisubharmonic function with $h \preceq u$. Since θ_h is the sum of the positive currents $\varepsilon\theta + \mathrm{dd}^{\mathrm{c}}P_{\varepsilon\theta}(\varphi)$ and $(1-\varepsilon)\theta + \mathrm{dd}^{\mathrm{c}}s$, the same density bound holds for $\mathrm{MA}_\theta^{\mathrm{ext}}(h)$. To justify this, we truncate $P_{\varepsilon\theta}(\varphi)$ at finite levels, use positivity of bounded mixed products, and exhaust the set where $P_{\varepsilon\theta}(\varphi)$ is finite; its pole set has zero volume.

If $N < b_q$, we would have

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) \le (N/b_q)\mathrm{MA}_\theta^{\mathrm{ext}}(h + t) \quad \text{for every } t \in \mathbb{R}.$$

Since $N/b_q < 1$, Theorem 14.1.1 would then imply $u \ge h + t$ for every t, which is impossible at a point where both potentials are finite. Thus $N \ge b_q$. The construction of s used no property of φ, which proves the last assertion. □

The lemma bounds the L^q norm of the density from below; it gives no positive lower bound for the total mass $\int_X F\,\mathrm{d}V$.

The second estimate bounds a normalized solution from below by φ minus a uniform constant. It is what keeps limits of solutions in the ordinary singularity type of φ.

Theorem 14.11.2 *Let θ and φ be as above. Suppose $u \in \mathrm{PSH}(X,\theta)$, $u \sim \varphi$, $\sup_X u = 0$, and*

$$\mathrm{MA}_\theta(u) \le f\,\mathrm{d}V, \qquad 0 \le f \in L^p(\mathrm{d}V), \quad p > 1.$$

There is a constant C, depending only on the fixed geometry, φ, p, and an upper bound for $\|f\|_{L^p}$, such that

$$\varphi - C \le u \le \varphi.$$

Proof The upper bound follows directly from the fixed-point property: since $u \le 0$ and $u \preceq \varphi$, the function u is a competitor for $P_\theta[\varphi] = \varphi$.

For the lower bound we construct a subsolution ψ of the type of φ whose measure dominates a multiple of $\mathrm{e}^{-\gamma u}\mathrm{MA}_\theta(u)$, and then apply singular domination. Put $\varphi_\varepsilon = P_{\varepsilon\theta}(\varphi)$, so that $\varphi_\varepsilon \le \varphi \le 0$. Uniform exponential integrability (Lemma 1.5.1) for the normalized potentials u and exponential integrability for the fixed function φ_ε allow us to choose $\gamma > 0$ and $1 < q < p$ such that

$$g = \mathrm{e}^{-\gamma(\varphi_\varepsilon + u)} f$$

has a uniform L^q bound. Explicitly, we first choose $q < p$ and apply Hölder's inequality with exponents p/q and $p/(p-q)$; then we choose γ so small that the exponential factor is controlled by the Cauchy–Schwarz inequality and the two exponential integrability estimates.

Theorem 14.2.2, applied in the semipositive big background $(1-\varepsilon)\theta$ to the density $1+g$, gives a bounded v with $\sup_X v = 0$ and a constant $c > 0$ such that

$$((1-\varepsilon)\theta + \mathrm{dd^c} v)^n = c(1+g)\,\mathrm{d}V.$$

Both $\|v\|_\infty$ and c^{-1} are uniformly bounded. Adding the constant one to g makes the root integral of the density at least one, so no lower bound for the integral of f is needed.

Put $h = \varphi_\varepsilon + v \le \varphi$, which is θ-plurisubharmonic, and define

$$\chi(t) = \frac{1}{1-t} \quad (t \le 0), \qquad \psi = \varphi + \chi(h - \varphi),$$

where the formula for ψ is evaluated off the pole sets. Then $0 \le \chi \le 1$, $0 < \chi' \le 1$, and $\chi'' > 0$. For bounded potentials with $h \le \varphi$, Lemma 1.7.6, applied with $G(x,y) = x + \chi(y - x)$, gives

$$\theta + \mathrm{dd^c} G(\varphi, h) \ge (1 - \chi'(h-\varphi))\theta_\varphi + \chi'(h-\varphi)\theta_h \ge 0.$$

For unbounded potentials we apply this bounded assertion to $\varphi_k = \max(\varphi, -k)$ and $h_k = \max(h, -k) \le \varphi_k$. Since G is nondecreasing in both variables, $G(\varphi_k, h_k)$ decreases as k increases. Its limit is θ-plurisubharmonic and lies between φ and $\varphi + 1$; hence it is not identically $-\infty$, and it equals ψ. Locality on common finite levels and positivity of bounded products give

$$\mathrm{MA}^{\mathrm{ext}}_\theta(\psi) \ge (\varphi - h + 1)^{-2n}\mathrm{MA}^{\mathrm{ext}}_\theta(h) \ge c(\varphi - h + 1)^{-2n}\mathrm{e}^{-\gamma\varphi_\varepsilon}\mathrm{e}^{-\gamma u} f\,\mathrm{d}V,$$

where the second inequality uses $\mathrm{MA}_\theta^{\mathrm{ext}}(h) \geq ((1-\varepsilon)\theta + \mathrm{dd}^{\mathrm{c}} v)^n \geq cg\,\mathrm{d}V$. These inequalities are first obtained off the pole sets; since pole sets have zero volume, they extend by exhaustion to all Borel sets.

Write $T = -\varphi_\varepsilon \geq 0$. If $C_1 \geq 1 + \|v\|_\infty$, then $\varphi - h + 1 \leq T + C_1$. Since

$$A := \inf_{T \geq 0} \frac{\mathrm{e}^{\gamma T}}{(T + C_1)^{2n}} > 0,$$

we obtain, with a uniform $d > 0$,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(\psi) \geq d\mathrm{e}^{-\gamma u}\mathrm{MA}_\theta^{\mathrm{ext}}(u).$$

Choose $K = 2 + \gamma^{-1}|\log d|$. On $\{u < \psi - K\}$ we have $u < 1 - K$, because $\psi \leq \varphi + 1 \leq 1$; hence

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) \leq d^{-1}\mathrm{e}^{\gamma(1-K)}\mathrm{MA}_\theta^{\mathrm{ext}}(\psi - K) \leq \mathrm{e}^{-\gamma}\mathrm{MA}_\theta^{\mathrm{ext}}(\psi - K).$$

The potentials u and $\psi - K$ have the same ordinary singularity type. Moreover, $u \geq \varphi - C_u$ for some constant C_u, so $P_{\varepsilon\theta}(u) \geq \varphi_\varepsilon - C_u$ is not identically $-\infty$. Theorem 14.1.1 therefore yields $u \geq \psi - K \geq \varphi - K$. All constants used to choose K are uniform over the family in the theorem; the possibly nonuniform constant C_u serves only to show that the smaller-background envelope of u is not identically $-\infty$, and it enters no estimate. □

The existence proof starts from a supersolution in the prescribed type. It is obtained from a bounded solution by a rooftop envelope with φ.

Lemma 14.11.2 *For nonzero $0 \leq f \in L^p(\mathrm{d}V)$, $p > 1$, and $\lambda > 0$, there exists $w \in \mathrm{PSH}(X, \theta)$ with $w \sim \varphi$ such that*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(w) \leq \mathrm{e}^{\lambda w} f\,\mathrm{d}V.$$

Proof Let v be the bounded solution of $\mathrm{MA}_\theta(v) = \mathrm{e}^{\lambda v} f\,\mathrm{d}V$ given by Theorem 14.2.1, and write $M = \sup_X v$ and $a = v - M \leq 0$. The rooftop envelope $p = P_\theta(a, \varphi)$ satisfies $\varphi - \|a\|_\infty \leq p \leq \varphi$, so $p \sim \varphi$. By the rooftop inequality of Proposition 13.1.3,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(p) \leq \mathbf{1}_{\{p = a \leq \varphi\}}\mathrm{MA}_\theta(a) + \mathbf{1}_{\{p = \varphi < a\}}\mathrm{MA}_\theta^{\mathrm{ext}}(\varphi).$$

The second term vanishes: by Proposition 13.1.4, the measure of φ is carried by $\{\varphi = 0\}$, whereas $\varphi < a \leq 0$ on the set in question. On the first contact set, $a = p$ and $\mathrm{MA}_\theta(a) = \mathrm{e}^{\lambda(a+M)} f\,\mathrm{d}V$. Thus $\mathrm{MA}_\theta^{\mathrm{ext}}(p) \leq \mathrm{e}^{\lambda(p+M)} f\,\mathrm{d}V$, and $w = p + M$ has the required properties. □

14.11.1 Existence for a positive exponent

We prove part (1) of Theorem 14.11.1 by maximizing a weighted mass. Among the potentials $z \sim \varphi$ whose weighted measure $\mathrm{e}^{-\lambda z}\mathrm{MA}_\theta(z)$ lies below $\mu = f\,\mathrm{d}V$, we find

one of maximal weighted mass; Theorem 14.11.2 provides the compactness needed for this. If its weighted measure were strictly smaller than μ, the addition theorem would produce a potential of larger weighted mass.

Proof (of Theorem 14.11.1, part (1)) *Step 1: a maximizing sequence.* Fix $\lambda > 0$. By Lemma 14.11.2, there is $w \sim \varphi$ such that

$$\nu_0 := \mathrm{e}^{-\lambda w}\mathrm{MA}_\theta^{\mathrm{ext}}(w) \le \mu = f\,\mathrm{d}V.$$

Consider all potentials $z \sim \varphi$ for which

$$\nu_0 \le \nu_z := \mathrm{e}^{-\lambda z}\mathrm{MA}_\theta^{\mathrm{ext}}(z) \le \mu,$$

and let B be the supremum of their weighted masses $\nu_z(X)$. This family is nonempty, since it contains w, and $B \le \mu(X) < +\infty$. Choose u_j in the family with $\nu_{u_j}(X) \to B$. Since $\nu_0 \le \nu_{u_j}$, Corollary 14.1.1 gives $u_j \le w$.

Step 2: uniform bounds. We need a lower bound for the suprema of the u_j. Put $\varphi_\varepsilon = P_{\varepsilon\theta}(\varphi) \le 0$, and let ψ be the bounded solution of

$$((1-\varepsilon)\theta + \mathrm{dd}^{\mathrm{c}}\psi)^n = \mathrm{e}^{\lambda\psi} f\,\mathrm{d}V$$

given by Theorem 14.2.1. For $h = \psi + \varphi_\varepsilon$, positivity of the splitting $\theta_h = (\varepsilon\theta + \mathrm{dd}^{\mathrm{c}}\varphi_\varepsilon) + ((1-\varepsilon)\theta + \mathrm{dd}^{\mathrm{c}}\psi)$ gives

$$\mathrm{e}^{-\lambda h}\mathrm{MA}_\theta^{\mathrm{ext}}(h) \ge \mathrm{e}^{-\lambda\varphi_\varepsilon} f\,\mathrm{d}V \ge \mu \ge \nu_{u_j}.$$

Here $h \preceq u_j$, because $h \preceq \varphi$ and $u_j \sim \varphi$, and each u_j admits a smaller-background envelope because $u_j \sim \varphi$. Corollary 14.1.1 therefore gives $u_j \ge h$. Consequently

$$\sup_X h \le M_j := \sup_X u_j \le \sup_X w,$$

and the lower bound is finite.

We now apply Theorem 14.11.2 to $v_j = u_j - M_j$. Their measures satisfy

$$\mathrm{MA}_\theta^{\mathrm{ext}}(v_j) = \mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \le \mathrm{e}^{\lambda \sup_X w} f\,\mathrm{d}V,$$

so $\varphi - C \le v_j \le \varphi$. Together with the bounds for M_j, this shows that all u_j lie within a fixed bounded distance of φ.

Step 3: the limit. Extract an L^1 limit u. By Corollary 14.8.1, applied with the dominating measure $\mathrm{e}^{\lambda \sup_X w}\mu$, the convergence holds in capacity, $u \sim \varphi$, and

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \rightharpoonup \mathrm{MA}_\theta^{\mathrm{ext}}(u).$$

After a further extraction we may also assume $\nu_{u_j} \rightharpoonup \nu$. Since $\nu_0 \le \nu_{u_j} \le \mu$, the limit satisfies the same inequalities. We claim that

$$\mathrm{e}^{\lambda u_j}\nu_{u_j} \rightharpoonup \mathrm{e}^{\lambda u}\nu.$$

Indeed, $e^{\lambda u_j} \to e^{\lambda u}$ in $L^1(\mu)$ by Lemma 1.23.1, and all the measures ν_{u_j} are at most μ; this controls the error caused by changing the weight. The fixed bounded weight $e^{\lambda u}$ can be approximated in $L^1(\mu)$ by continuous functions, and since both ν_{u_j} and ν are dominated by μ, this approximation is uniform in the integrals. The weak convergence $\nu_{u_j} \rightharpoonup \nu$ then gives the claim, and the same argument applies after multiplication by any continuous test function.

Since $e^{\lambda u_j}\nu_{u_j} = \mathrm{MA}_\theta^{\mathrm{ext}}(u_j)$, it follows that

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = e^{\lambda u}\nu, \qquad e^{-\lambda u}\mathrm{MA}_\theta^{\mathrm{ext}}(u) = \nu, \qquad \nu(X) = B.$$

The second identity holds off the pole set of u, which has zero μ-measure. Hence u belongs to the family and attains the supremum B. Write $\nu = g\,dV$, with $0 \le g \le f$.

Step 4: no deficit. Suppose that $g \neq f$ in $L^1(dV)$. Applying Lemma 14.11.2 to $f - g$, we find $v \sim \varphi$ with

$$\nu_v := e^{-\lambda v}\mathrm{MA}_\theta^{\mathrm{ext}}(v) \le (f - g)\,dV.$$

This measure is nonzero. In fact, no potential v admitting a smaller-background envelope has zero Monge–Ampère measure, since Theorem 14.1.1, applied with coefficient zero to v and $v + 1$, would give $v \ge v + 1$. Thus $\nu_v(X) > 0$.

The sum $\nu + \nu_v$ is finite, so Theorem 14.10.1 gives $a \sim \varphi$ with

$$e^{-\lambda a}\mathrm{MA}_\theta^{\mathrm{ext}}(a) = \nu + \nu_v.$$

This measure still lies between ν_0 and μ, but its mass is $B + \nu_v(X) > B$, a contradiction. Therefore $g = f$, and u solves the required equation. Uniqueness in the prescribed ordinary type follows from Corollary 14.1.1. □

14.11.2 The normalized equation

For the normalized equation we let the positive exponent tend to zero. Bounded comparison controls the normalizing constants from above, while the lower density estimate of Lemma 14.11.1 keeps them away from zero. The common barriers then give convergence of the Monge–Ampère measures and keep the limit in the prescribed type.

Proof (of Theorem 14.11.1, part (2)) For each $j \ge 1$, part (1) gives $u_j \sim \varphi$ with

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) = e^{u_j/j} f\,dV.$$

Write $M_j = \sup_X u_j$, $v_j = u_j - M_j$ and $c_j = e^{M_j/j}$. Let h be a bounded normalized solution of $\mathrm{MA}_\theta(h) = \alpha f\,dV$, with $\alpha > 0$, given by Theorem 14.2.2.

For $H_j = h + \|h\|_\infty + j \log \alpha$ we have

$$e^{-H_j/j} \mathrm{MA}_\theta(H_j) = e^{-(h+\|h\|_\infty)/j} f \, dV \le f \, dV = e^{-u_j/j} \mathrm{MA}_\theta^{\mathrm{ext}}(u_j).$$

The bounded function H_j admits a smaller-background envelope, and $u_j \preceq H_j$, so Corollary 14.1.1 gives $u_j \le H_j$. In particular,

$$0 < c_j \le \alpha \exp(2\|h\|_\infty / j).$$

The lower density bound of Lemma 14.11.1, applied to v_j with $q = p$, gives

$$b_p \le \|c_j e^{v_j/j} f\|_p \le c_j \|f\|_p,$$

so the c_j are also bounded away from zero.

Since $\sup_X v_j = 0$ and $\mathrm{MA}_\theta^{\mathrm{ext}}(v_j) = c_j e^{v_j/j} f \, dV \le C f \, dV$, Theorem 14.11.2 gives $\varphi - C' \le v_j \le \varphi$. Extract a subsequence with $v_j \to v$ in $L^1(X)$ and $c_j \to c > 0$. By Corollary 14.8.1, the convergence holds in capacity, $v \sim \varphi$, and the Monge–Ampère measures converge weakly. Meanwhile, Lemma 1.23.2 gives

$$\int_X |e^{v_j/j} - 1| f \, dV \longrightarrow 0.$$

Thus the right-hand sides converge in total variation to $c f \, dV$, and $\mathrm{MA}_\theta^{\mathrm{ext}}(v) = c f \, dV$.

For the uniqueness of the constant, suppose that $a, b \sim \varphi$ solve the normalized equation with constants $c_a < c_b$. For every real t,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(a) = \frac{c_a}{c_b} \mathrm{MA}_\theta^{\mathrm{ext}}(b + t),$$

so Theorem 14.1.1 gives $a \ge b + t$. This is impossible as $t \to +\infty$, at any point where both potentials are finite. Interchanging the roles of the two constants proves that c is unique. □

14.12 Comparison above a strict singular barrier

From now on, θ is an arbitrary smooth big real $(1,1)$-form. Then V_θ may be unbounded, and the smaller-background construction used above is no longer available. Its role is taken by a strict analytic barrier. When two potentials bounded below by the barrier are compared, adding a small multiple of the barrier forces a negative infimum of their difference to be attained away from its pole set, and there a local comparison principle rules it out.

Since θ is big, Theorem 1.15.2 provides $\rho \in \mathrm{PSH}(X, \theta)$ with analytic singularities and a smooth remainder after resolution such that $\theta_\rho \ge \kappa \omega$ for some $\kappa > 0$. Replacing ω by a small positive multiple and subtracting a constant from ρ, we fix such a ρ with $\rho \le 0$ and $\theta_\rho \ge \omega$. Put $Z = \{\rho = -\infty\}$ and $\Omega = X \setminus Z$. From now on until the end of

Section 14.17, these data remain fixed, and Ω always denotes this open set rather than an auxiliary Hermitian form. A potential bounded below by $\rho - C$ is locally bounded on Ω, and there its extended Monge–Ampère measure agrees with the local bounded product.

Lemma 14.12.1 *Let $B \Subset \Omega$ be a coordinate ball, and let u, v be bounded θ-plurisubharmonic functions on B. Assume*

$$\liminf_{x \to \partial B} (u - v)(x) \geq 0, \qquad \mathbf{1}_{\{u<v\}} \mathrm{MA}_\theta(u) \leq \mathbf{1}_{\{u<v\}} \mathrm{MA}_\theta(v).$$

Then $u \geq v$ on B.

Proof Fix $\varepsilon > 0$ and set $v_\varepsilon = \max(u, v - \varepsilon)$, which equals u near the boundary. We claim that

$$\mathrm{MA}_\theta(u) \leq \mathrm{MA}_\theta(v_\varepsilon)$$

throughout B. On $\{u > v - \varepsilon\}$ this follows from locality, since $v_\varepsilon = u$ there. On $\{u \leq v - \varepsilon\}$ it follows from ordered contact and from the assumed inequality, which applies because this set is contained in $\{u < v\}$.

Let q be the plurisubharmonic envelope on B of the obstacle $u - v_\varepsilon$, in the sense of (1.5). This obstacle is bounded, quasi-continuous and zero near the boundary. Hence it lies between Ah and zero for a sufficiently large A, where $h < 0$ is a smooth strictly plurisubharmonic defining function for the ball. Thus q tends to zero at the boundary, and (1.5) shows that $(\mathrm{dd}^{\mathrm{c}} q)^n$ is carried by $D = \{q = u - v_\varepsilon\}$.

Since $q \leq u - v_\varepsilon$ quasi-everywhere, the canonical representatives satisfy $q + v_\varepsilon \leq u$. Ordered contact, followed by the measure inequality above, yields

$$\mathbf{1}_D \mathrm{MA}_\theta(q + v_\varepsilon) \leq \mathbf{1}_D \mathrm{MA}_\theta(u) \leq \mathbf{1}_D \mathrm{MA}_\theta(v_\varepsilon).$$

The positive expansion of $(\theta_{v_\varepsilon} + \mathrm{dd}^{\mathrm{c}} q)^n$ contains both $\mathrm{MA}_\theta(v_\varepsilon)$ and $(\mathrm{dd}^{\mathrm{c}} q)^n$. Thus $\mathbf{1}_D (\mathrm{dd}^{\mathrm{c}} q)^n = 0$, and since $(\mathrm{dd}^{\mathrm{c}} q)^n$ is carried by D, we get $(\mathrm{dd}^{\mathrm{c}} q)^n = 0$. The classical Bedford–Taylor comparison principle for bounded plurisubharmonic functions with zero boundary values implies $q = 0$. Consequently $u \geq v_\varepsilon$, first quasi-everywhere and then everywhere. Finally let $\varepsilon \downarrow 0$. □

Theorem 14.12.1 *Suppose $u, v \in \mathrm{PSH}(X, \theta)$ satisfy, for constants $C_0, C_1 \geq 0$,*

$$\min(u, v) \geq \rho - C_0, \qquad v \leq u + C_1.$$

If, for some $0 \leq c < 1$,

$$\mathbf{1}_{\{u<v\}} \mathrm{MA}_\theta(u) \leq c\, \mathbf{1}_{\{u<v\}} \mathrm{MA}_\theta(v),$$

then $u \geq v$.

The measures in the theorem need not have finite total mass.

Proof We first modify the barrier. Let $r = a\rho - A$, where $a > 1$ is sufficiently close to one and A is sufficiently large. Since

$$\theta + \mathrm{dd}^{\mathrm{c}}(a\rho) = a\theta_\rho + (1-a)\theta,$$

we can arrange $\theta_r \geq \omega/2$ and $r - v \leq -1$, and moreover $u - r \to +\infty$ at Z, because $u - r \geq (a-1)(-\rho) + A - C_0$. When Z is empty, the last property is not needed.

Choose $0 < \delta < 1$ with $(1-\delta)^n > c$, and put $v_\delta = (1-\delta)v + \delta r$. Then

$$u - v_\delta \geq \delta(u - r) - (1-\delta)C_1.$$

Suppose that the infimum m of $u - v_\delta$ on Ω were negative. Since $u - v_\delta \to +\infty$ at Z, a sequence x_j along which $u - v_\delta$ tends to m has a subsequence converging to a point $x_0 \in \Omega$. Choose a coordinate ball $B \Subset \Omega$ centered at x_0, identify it with $\{|z| < 1\}$, and take

$$\eta(z) = b(1 - |z|^2), \qquad 0 < b < 1, \qquad \omega/2 + \mathrm{dd}^{\mathrm{c}}\eta \geq 0.$$

The function $w = v_\delta + \delta\eta + m$ is θ-plurisubharmonic on B, and $\liminf_{\partial B}(u - w) \geq 0$ because η vanishes on ∂B. Also

$$w - v = \delta(r - v + \eta) + m < 0.$$

Thus $\{u < w\} \subset \{u < v\}$, and positivity of mixed products gives on this set

$$\mathrm{MA}_\theta(u) \leq c\mathrm{MA}_\theta(v) \leq (1-\delta)^n \mathrm{MA}_\theta(v) \leq \mathrm{MA}_\theta(w).$$

By Lemma 14.12.1, $u \geq w$ on B. Evaluating at x_j gives $u(x_j) - v_\delta(x_j) \geq m + \delta\eta(x_j)$, which contradicts $\eta(x_0) > 0$ in the limit. Hence $u \geq v_\delta$ on Ω. Letting $\delta \downarrow 0$ along values with $(1-\delta)^n > c$, we obtain $u \geq v$ on Ω, and Lemma 1.3.3 extends this inequality to X. □

Corollary 14.12.1 *Let $u, v \in \mathrm{PSH}(X,\theta)$ satisfy $u, v \geq \rho - C$ for some $C \geq 0$ and $u \sim v$.*

(1) *If $\mathrm{MA}_\theta(u) \leq c\mathrm{MA}_\theta(v)$ for some $c \geq 0$, then $c \geq 1$.*
(2) *If $\mathrm{MA}_\theta(u) \leq \mathrm{e}^{\lambda(u-v)}\mathrm{MA}_\theta(v)$ for some $\lambda > 0$, then $u \geq v$.*

In particular, let μ be a positive measure. Among potentials bounded below by ρ minus a constant, each ordinary singularity type contains at most one solution of $\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u}\mu$, and the constant $c > 0$ in $\mathrm{MA}_\theta(u) = c\mu$ is uniquely determined within each type.

Proof If $c < 1$, apply the theorem to u and $v + A$ for every constant $A > 0$; the constants in its hypotheses may depend on A. The resulting inequality $u \geq v + A$ for all A is impossible. For the second assertion, fix $a > 0$ and restrict the measure inequality to $\{u < v - a\}$. There the factor is at most $\mathrm{e}^{-\lambda a} < 1$, so the theorem gives $u \geq v - a$; now let $a \downarrow 0$. For two solutions of the exponential equation, apply the second assertion in both orders; for two solutions of the normalized equation, apply the first. □

14.13 Subsolutions and the Gauduchon trace

The strict barrier also yields subsolutions within a bounded distance of any reference between ρ and zero. The curvature estimate comes from composing a convex function with the difference between the reference and a barrier-based subsolution, which produces a convex combination of positive currents. Pairing the equation with a Gauduchon metric then bounds the normalizing constants through a linear trace.

Lemma 14.13.1 *Fix $p > 1$ and $L > 0$. There is $m > 0$ such that, whenever*

$$\rho \leq \eta \leq 0, \quad \eta \in \mathrm{PSH}(X,\theta), \qquad g \geq 0, \quad \|g\|_{L^p(\mathrm{d}V)} \leq L,$$

there exists $v \in \mathrm{PSH}(X,\theta)$ with

$$\eta \leq v \leq \eta + 1, \qquad \mathrm{MA}_\theta(v) \geq mg\,\mathrm{d}V.$$

The constant m depends only on the fixed geometry and on ρ, p, L.

Proof Choose $1 < q < p$. By Hölder's inequality and the finiteness of all polynomial moments of the fixed quasi-plurisubharmonic function ρ, the functions $h = g(2-\rho)^{2n}$ have uniformly bounded L^q norms. Lemma 14.2.1, applied in the Hermitian background ω, gives $s \in \mathrm{PSH}(X,\omega)$ with $-1 \leq s \leq 0$ and

$$\omega_s^n \geq mh\,\mathrm{d}V$$

for a fixed $m > 0$. Put $u_1 = \rho + s$. Then $\theta_{u_1} \geq \omega_s$ and $u_1 \leq \rho \leq \eta$. On Ω define

$$t = 1 + \eta - u_1, \qquad v = \eta + t^{-1},$$

so that $1 \le t \le 2-\rho$. Lemma 1.7.6, applied on relatively compact subsets of Ω with $a = \eta$, $h = u_1$ and $\chi(x) = (1-x)^{-1}$, gives

$$\theta_v = (1-t^{-2})\theta_\eta + t^{-2}\theta_{u_1} + 2t^{-3}\,\mathrm{d}(\eta - u_1) \wedge \mathrm{d}^{\mathrm{c}}(\eta - u_1) \ge t^{-2}\theta_{u_1}.$$

Since $\eta \le v \le \eta + 1$, Lemma 1.3.7 extends v across Z, and the bounds extend by Lemma 1.3.3. On Ω, positivity of the local products gives

$$\mathrm{MA}_\theta(v) \ge t^{-2n}\theta_{u_1}^n \ge (2-\rho)^{-2n}\omega_s^n \ge mg\,\mathrm{d}V.$$

Neither side charges Z, so the inequality holds on X. □

Proposition 14.13.1 *Let γ be a Gauduchon metric on X, write $\gamma^n = G\,\mathrm{d}V$, and put*

$$T_\gamma = \int_X \theta \wedge \gamma^{n-1}.$$

Then $T_\gamma > 0$. If $u \in \mathrm{PSH}(X,\theta)$ satisfies $u \ge \rho - C$ and $\mathrm{MA}_\theta(u) \ge F\,\mathrm{d}V$ with $F \ge 0$, then

$$\int_X F^{1/n} G^{1-1/n}\,\mathrm{d}V \le T_\gamma. \tag{14.9}$$

Consequently, let $0 \le f \in L^p(\mathrm{d}V)$, $p > 1$, be nonzero, and let $\lambda > 0$. Every solution of $\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u} f\,\mathrm{d}V$ that is bounded below by ρ minus a constant satisfies $\sup_X u \le C'$, where C' depends only on θ, γ, f and λ. Moreover, if $v_j \in \mathrm{PSH}(X,\theta)$, $j \ge 1$, and constants $C_j \ge 0$ and $c_j > 0$ satisfy

$$\sup_X v_j = 0, \qquad \mathrm{MA}_\theta(v_j) = c_j \mathrm{e}^{v_j/j} f\,\mathrm{d}V, \qquad v_j \ge \rho - C_j,$$

then the constants c_j are uniformly bounded above.

Proof The current $\theta_u \wedge \gamma^{n-1}$ is linear in θ_u, so it is a globally defined positive current, even at Z. Since $\mathrm{dd}^{\mathrm{c}}\gamma^{n-1} = 0$, Stokes' theorem in the sense of currents gives

$$\int_X \theta_u \wedge \gamma^{n-1} = \int_X \theta \wedge \gamma^{n-1}.$$

Applied to ρ, this identity proves $T_\gamma \ge \int_X \omega \wedge \gamma^{n-1} > 0$.

On Ω, Lemma 1.7.3, applied to θ_u and γ, gives

$$\theta_u \wedge \gamma^{n-1} \ge F^{1/n} G^{1-1/n}\,\mathrm{d}V.$$

Exhausting Ω and using positivity of the global trace measure, we obtain (14.9), since the complement Z has zero volume.

For the exponential equation, write $a = \sup_X u$ and $w = u - a$. The estimate becomes

$$\mathrm{e}^{\lambda a/n} \int_X \mathrm{e}^{\lambda w/n} f^{1/n} G^{1-1/n} \, \mathrm{d}V \le T_\gamma .$$

The integral has a positive lower bound over all normalized $w \in \mathrm{PSH}(X, \theta)$. Otherwise, normalized compactness would give a sequence of such w with integrals tending to zero and converging almost everywhere to a θ-plurisubharmonic function; since $w \le 0$ and $f^{1/n} G^{1-1/n}$ is integrable, dominated convergence would give a strictly positive limit integral, a contradiction. This bounds a from above.

For the last assertion, the same estimate contains the factors $c_j^{1/n}$ and $\mathrm{e}^{v_j/(jn)}$. If the integrals $\int_X \mathrm{e}^{v_j/(jn)} f^{1/n} G^{1-1/n} \, \mathrm{d}V$ tended to zero along a subsequence with $j \to \infty$, normalized compactness and almost-everywhere convergence would give $v_j/j \to 0$ almost everywhere along a further subsequence. Dominated convergence would then give the positive limit $\int_X f^{1/n} G^{1-1/n} \, \mathrm{d}V$. This contradiction bounds c_j for all large j, and each of the finitely many remaining constants is finite. Neither argument uses the total Monge–Ampère mass. □

14.14 Stability above a strict barrier

The subsolutions of Lemma 14.13.1 stay within a bounded distance of a given reference. With them, the proof of Theorem 14.3.1 extends to unbounded potentials lying above ρ, and the resulting estimate is uniform over all references between ρ and zero. For a fixed reference, it upgrades L^1 compactness of solutions to uniform convergence of their differences on Ω.

Theorem 14.14.1 *Fix $C_0, L > 0$, $p > 1$, and*

$$0 < \gamma < \frac{p-1}{np + p - 1}.$$

Let $\eta \in \mathrm{PSH}(X, \theta)$ satisfy $\rho \le \eta \le 0$, and suppose that $u \in \mathrm{PSH}(X, \theta)$ satisfies

$$\eta - C_0 \le u \le \eta, \qquad \mathrm{MA}_\theta(u) = f \, \mathrm{d}V, \qquad 0 \le f \in L^p(\mathrm{d}V), \quad \|f\|_p \le L.$$

There is a constant C, depending only on the fixed geometry and on ρ, C_0, L, p, γ, such that every $v \in \mathrm{PSH}(X, \theta)$ with $v \le \eta$ satisfies

$$\sup_\Omega (v - u)_+ \le C \left(\int_\Omega (v - u)_+ \, \mathrm{d}V \right)^\gamma . \tag{14.10}$$

In particular, the constant does not depend on the reference η, and the comparison potential v need not have the ordinary singularity type of η. The difference $v - u$ is evaluated on Ω, where u and η are locally bounded; since Z has zero volume,

the integral is the same as over X. Since Z is pluripolar, the resulting inequality $v \le u + C\big(\int_\Omega (v-u)_+ \, \mathrm{d}V\big)^\gamma$ on Ω extends to the canonical representatives on all of X.

Proof Replacing v by $\max(v,u)$, we may assume $\eta - C_0 \le u \le v \le \eta$, so that $0 \le v - u \le C_0$ on Ω.

Fix $q \in (1,p)$ and $\delta > 0$, and put

$$E_\delta = \{u < v - \delta\} \cap \Omega, \qquad g_\delta = \mathbf{1}_{E_\delta} f, \qquad m_\delta = \|g_\delta\|_q.$$

When $m_\delta > 0$, Lemma 14.13.1, followed by subtracting one from its potential, gives $h \in \mathrm{PSH}(X,\theta)$ and a fixed $b > 0$ such that

$$\eta - 1 \le h \le \eta, \qquad \mathrm{MA}_\theta(h) \ge b\, g_\delta / m_\delta \, \mathrm{d}V.$$

The constant b is uniform in η, because the auxiliary density has L^q norm one and the strict barrier is fixed.

If $0 < m_\delta < b/2$, set

$$t = (2m_\delta/b)^{1/n}, \qquad w = (1-t)v + th - \delta - C_0 t.$$

Since $h - v \le C_0$, we have $w \le v - \delta$, so the set $\{u < w\} \cap \Omega$ is contained in E_δ. On this set the local expansion into positive mixed products gives $\mathrm{MA}_\theta(w) \ge t^n \mathrm{MA}_\theta(h) \ge 2\mathrm{MA}_\theta(u)$. Both potentials are bounded below by ρ minus a constant, and $w \le u + C_0$, so Theorem 14.12.1 applies and gives $u \ge w$. It follows that

$$v - u \le \delta + C_0 t + t(v-h) \le \delta + (C_0+1)t.$$

If $m_\delta = 0$, we apply the same domination theorem with coefficient zero to u and $v - \delta$. If $m_\delta \ge b/2$, we use $v - u \le C_0$. In all cases,

$$\sup_\Omega (v-u) \le \delta + C_1 m_\delta^{1/n}.$$

Write $I = \int_\Omega (v-u)\, \mathrm{d}V$. If $I = 0$, the canonical potentials agree. Otherwise Hölder's and Chebyshev's inequalities give

$$m_\delta \le L (I/\delta)^{(p-q)/(pq)}.$$

For $0 < I \le 1$, the choice $\delta = I^{(p-q)/(npq+p-q)}$ yields the exponent $\gamma_q = (p-q)/(npq+p-q)$. We choose $q > 1$ so close to one that $\gamma_q > \gamma$. The case $I > 1$ follows from the bound $v - u \le C_0$. This proves (14.10). □

Corollary 14.14.1 *Fix $\eta \in \mathrm{PSH}(X,\theta)$ with $\rho \le \eta \le 0$, constants $C_0, L > 0$, and $p > 1$. Consider the family of potentials $u \in \mathrm{PSH}(X,\theta)$ satisfying*

$$\eta - C_0 \le u \le \eta, \qquad \mathrm{MA}_\theta(u) = f_u \, \mathrm{d}V, \qquad 0 \le f_u \in L^p(\mathrm{d}V), \quad \|f_u\|_p \le L.$$

This family is compact for uniform convergence of differences on Ω. If u_j belong to the family and $u_j \to u$ in L^1, then u belongs to the family and

$$\sup_\Omega |u_j - u| \le C \|u_j - u\|^\gamma_{L^1(\mathrm{d}V)} \longrightarrow 0$$

for every exponent γ as in Theorem 14.14.1. Moreover, f_{u_j} converges weakly to f_u in L^p.

Proof Applying the theorem in both orders to u_j and u_k, with the common reference η, we see that an L^1-Cauchy sequence in the family is uniformly Cauchy in differences on Ω. Its uniform limit on Ω is locally θ-plurisubharmonic and agrees almost everywhere, hence everywhere for the canonical representatives, with the L^1 limit u. The bounds $\eta - C_0 \le u \le \eta$ hold on all of X. Letting $k \to \infty$ in the pairwise estimate proves the quantitative bound, before any equation for u is used.

The densities form a bounded set in the reflexive space L^p. Let f be the weak limit of a subsequence $f_{u_{j_k}}$. Since the potentials are locally bounded and converge locally uniformly on Ω, Bedford–Taylor continuity, which holds also for the smooth nonclosed background, gives $\mathrm{MA}_\theta(u) = f \, \mathrm{d}V$ on Ω. Neither measure charges the analytic set Z, so this equality holds on X. Positivity and weak lower semicontinuity of the norm give $f \ge 0$ and $\|f\|_p \le L$. Thus every weak cluster point equals the density f_u of $\mathrm{MA}_\theta(u)$, which proves weak convergence of the whole sequence. Finally, the common bounds by η and $\eta - C_0$ give L^1 compactness of the family, by the compactness of quasi-plurisubharmonic functions, and the preceding argument upgrades each convergent subsequence to uniform convergence of differences on Ω.□

For solutions with minimal singularities, normalized by $\sup_X u = 0$, we take $\eta = V_\theta$. Then $\rho \le V_\theta \le 0$, and every normalized comparison potential $v \in \mathrm{PSH}(X,\theta)$ satisfies $v \le V_\theta$, as the theorem requires.

14.15 Minimal singularities in an arbitrary big background

We now solve the equations in the ordinary singularity type of V_θ. Demailly's regularization approximates V_θ by strict potentials with analytic singularities. On a resolution of these singularities, the corresponding equations become equations in a semipositive big background, which we have already solved. The solutions satisfy bounds relative to the approximating singularities that are uniform in the approximation, and upper and lower envelopes then produce a solution with minimal singularities. For the normalized equation, the normalized exponential solutions lie

in a common interval below V_θ, so the compactness theorem of the preceding section applies directly.

Since $\rho \le 0$ is θ-plurisubharmonic, it is a competitor for V_θ, and hence $\rho \le V_\theta \le 0$. We use the analytic regularization of Theorem 1.15.2 in its resolved form.

Lemma 14.15.1 *Let $\psi \in \mathrm{PSH}(X,\theta)$ satisfy $\theta_\psi \ge a\omega$ for some $a > 0$, and suppose that ψ has a smooth remainder after resolution, as in Theorem 1.15.2. For every nonzero $0 \le f \in L^p(\mathrm{d}V)$, $p > 1$, and every $\lambda > 0$, there exists $u \in \mathrm{PSH}(X,\theta)$ with $u \sim \psi$ such that*

$$\mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u} f \, \mathrm{d}V.$$

Proof Let $\pi : Y \to X$ be a modification resolving the singularities of ψ. The pulled-back current has the form

$$\pi^*\theta + \mathrm{dd}^{\mathrm{c}}\pi^*\psi = \beta + [D],$$

where D is an effective real divisor, $[D]$ is its current of integration, and β is a smooth real $(1,1)$-form on Y. Off D we have $\beta \ge a\pi^*\omega$, and by continuity this inequality holds everywhere. In particular, β is semipositive.

We check that β is big. For a blowup with smooth center and exceptional divisor E, choose a metric on $\mathcal{O}(-E)$ whose curvature is positive in the directions tangent to the projective fibers. Along E, the pullback of a Hermitian metric is positive in the complementary directions. Consequently, its sum with a sufficiently small positive multiple of this curvature form is a Hermitian metric: positivity holds first along E, then on a neighborhood of E, and finally on the compact complement, where the pullback is already positive. Iterating over the blowups, we obtain an effective real exceptional divisor F, with logarithmic potential ζ, and a smooth Hermitian form κ such that

$$\pi^*\omega + \mathrm{dd}^{\mathrm{c}}\zeta = \kappa + [F].$$

At each step of the iteration, we pull back the smooth positive form obtained so far, apply the construction for one blowup, and add the pullback of the previous divisor to the new positive multiple of E. Hence $\beta + a\mathrm{dd}^{\mathrm{c}}\zeta \ge a\kappa$, so β is big. This argument only involves Hermitian metrics and never requires a closed positive form on Y.

Fix a smooth positive volume form $\mathrm{d}V_Y$ on Y, and write $\pi^*\mathrm{d}V = J\,\mathrm{d}V_Y$. The function J is smooth, nonnegative and bounded, and it is positive off the exceptional locus. Define

$$H = \mathrm{e}^{\lambda\pi^*\psi}(f \circ \pi)J.$$

This function is nonzero and belongs to $L^p(\mathrm{d}V_Y)$. Indeed, ψ is bounded above, and the change of variables formula gives

$$\int_Y |(f\circ\pi)J|^p \, \mathrm{d}V_Y \le \|J\|_\infty^{p-1} \int_X |f|^p \, \mathrm{d}V;$$

the analytic exceptional sets do not affect these integrals. Theorem 14.2.1, applied on Y in the semipositive big background β, gives a bounded $s \in \mathrm{PSH}(Y,\beta)$ with

$$\mathrm{MA}_\beta(s) = \mathrm{e}^{\lambda s} H \, \mathrm{d}V_Y .$$

The function $\pi^*\psi + s$ is $\pi^*\theta$-plurisubharmonic, because the corresponding current is $\beta_s + [D] \geq 0$, where $\beta_s = \beta + \mathrm{dd}^{\mathrm{c}} s$. By Theorem A.2.1 it descends to some $u \in \mathrm{PSH}(X, \theta)$, and $u \sim \psi$ because s is bounded. Off the exceptional set and the pole set of ψ, the change of variables formula gives the required equation. Neither the extended measure on the left nor the measure $\mathrm{e}^{\lambda u} f \, \mathrm{d}V$ on the right charges these analytic sets, so the equation holds on all of X. □

Theorem 14.15.1 *Let θ be any smooth big real $(1,1)$-form and let $0 \leq f \in L^p(\mathrm{d}V)$, $p > 1$, be nonzero. For every $\lambda > 0$ there is a unique $u \in \mathrm{PSH}(X, \theta)$ such that*

$$u \sim V_\theta, \qquad \mathrm{MA}_\theta(u) = \mathrm{e}^{\lambda u} f \, \mathrm{d}V .$$

Proof *Step 1: approximating singularity types.* Apply Theorem 1.15.2 to V_θ. Set $\delta_j = 2^{-j}$ and pass to a subsequence whose curvature errors are at most δ_j. Denote its potentials by $\widetilde{\psi}_j$; thus $\widetilde{\psi}_j \downarrow V_\theta$ and $\theta_{\widetilde{\psi}_j} \geq -\delta_j \omega$. Set

$$a_j = (1 - \delta_j) \sup_X \widetilde{\psi}_j \geq 0, \qquad \psi_j = (1 - \delta_j)\widetilde{\psi}_j + \delta_j \rho - a_j .$$

By Hartogs' lemma, $\sup_X \widetilde{\psi}_j \to \sup_X V_\theta = 0$, so $a_j \to 0$. A common resolution of the singularities of $\widetilde{\psi}_j$ and ρ shows that ψ_j has a smooth remainder after resolution. Moreover,

$$\theta_{\psi_j} \geq \delta_j^2 \omega, \qquad (1 - \delta_j) V_\theta + \delta_j \rho - a_j \leq \psi_j \leq V_\theta . \tag{14.11}$$

The upper inequality holds because ψ_j is θ-plurisubharmonic and nonpositive. Subtracting a_j explicitly keeps the normalization separate from the fixed barrier ρ.

Step 2: uniform bounds. By Lemma 14.15.1 there are $u_j \sim \psi_j$ satisfying

$$\mathrm{MA}_\theta(u_j) = \mathrm{e}^{\lambda u_j} f \, \mathrm{d}V .$$

Each u_j is bounded below by ρ minus a constant depending on j, so Proposition 14.13.1 gives a uniform upper bound for $\sup_X u_j$.

There is also a uniform lower bound. We apply Lemma 14.13.1 with the barrier ρ replaced by $\rho - 1 - \sup_j a_j$ and with the reference $\psi_j - 1$, which lies between this barrier and zero. The lemma gives v_j with $\psi_j - 1 \leq v_j \leq \psi_j \leq 0$ and $\mathrm{MA}_\theta(v_j) \geq m f \, \mathrm{d}V$, where $m > 0$ is independent of j. Put $w_j = v_j + \lambda^{-1} \log m$. Then

$$\mathrm{MA}_\theta(w_j) \geq \mathrm{e}^{\lambda w_j} f \, \mathrm{d}V, \qquad u_j \sim w_j \sim \psi_j ,$$

and the exponential order in Corollary 14.12.1 gives $u_j \geq w_j$. Thus, for a uniform constant C,

$$\psi_j - C \leq u_j \leq V_\theta + C . \tag{14.12}$$

After extraction, u_j converges in L^1 and almost everywhere to a θ-plurisubharmonic function u, and the preceding bounds give $V_\theta - C \leq u \leq V_\theta + C$.

Step 3: the equation for the limit. We identify the equation using envelopes. Put $A_j = \sup_{k\ge j} a_k$ and, for $N \ge j$, define

$$p_{j,N} = P_\theta(\min\{u_j, \dots, u_N\}), \qquad t_{j,N} = \max_{j\le k\le N} u_k.$$

Both functions lie above the θ-plurisubharmonic function

$$b_j = (1-\delta_j)V_\theta + \delta_j\rho - C - A_j,$$

which is a competitor for every $p_{j,N}$; in particular, no envelope is identically $-\infty$. All these functions are locally bounded on Ω, uniformly in j and N. Contact support (Theorem 14.7.2), together with a partition of the contact set according to the first index of contact, gives

$$\mathrm{MA}_\theta(p_{j,N}) \le \mathrm{e}^{\lambda p_{j,N}} f\,\mathrm{d}V.$$

No factor N appears here: on each piece the envelope equals a single u_k, and ordered contact bounds its measure by the measure of that u_k. Similarly, locality and ordered contact for a finite maximum give

$$\mathrm{MA}_\theta(t_{j,N}) \ge \mathrm{e}^{\lambda t_{j,N}} f\,\mathrm{d}V.$$

Now let $N \to \infty$, and set $p_j = \lim_N p_{j,N}$ and $t_j = (\lim_N t_{j,N})^*$. Continuity of local bounded products along monotone sequences passes both inequalities to these limits. Next, p_j increases to a regularized limit p, while t_j decreases to u by Hartogs' lemma. The bound by b_j gives $p \sim V_\theta$, and $p \le u$. A second application of the monotone continuity gives

$$\mathrm{MA}_\theta(p) \le \mathrm{e}^{\lambda p} f\,\mathrm{d}V, \qquad \mathrm{MA}_\theta(u) \ge \mathrm{e}^{\lambda u} f\,\mathrm{d}V.$$

These inequalities hold on Ω, and they extend across Z because no measure involved charges Z. Thus $\mathrm{MA}_\theta(p) \le \mathrm{e}^{\lambda(p-u)}\mathrm{MA}_\theta(u)$, and the exponential order in Corollary 14.12.1 gives $p \ge u$. Hence $p = u$, and the equation follows. Applying the same order in both directions proves uniqueness. Note that the Monge–Ampère operator was only ever applied along monotone sequences that are locally bounded on Ω. □

Lemma 14.15.2 *Under the hypotheses of Theorem 14.15.1, let u_λ be the solution given there, and put*

$$v_\lambda = u_\lambda - \sup_X u_\lambda, \qquad c_\lambda = \mathrm{e}^{\lambda \sup_X u_\lambda}.$$

There are constants $B, C, m > 0$, independent of $0 < \lambda \le 1$, such that

$$V_\theta - B \le v_\lambda \le V_\theta, \qquad m \le c_\lambda \le C. \tag{14.13}$$

Proof The normalized potential satisfies

$$\mathrm{MA}_\theta(v_\lambda) = c_\lambda \mathrm{e}^{\lambda v_\lambda} f\,\mathrm{d}V.$$

Fix a Gauduchon metric γ and write $\gamma^n = G\,\mathrm{d}V$. Since $v_\lambda \le 0$ and $0 < \lambda \le 1$, (14.9) gives

$$c_\lambda^{1/n} \int_X \mathrm{e}^{v_\lambda/n} f^{1/n} G^{1-1/n}\,\mathrm{d}V \le \int_X \theta \wedge \gamma^{n-1}.$$

The integrals on the left have a positive lower bound independent of λ. Otherwise, the compactness of normalized quasi-plurisubharmonic functions would give an almost everywhere convergent sequence of the normalized v_λ whose integrals tend to zero, with a θ-plurisubharmonic limit; since f is nonzero, dominated convergence would give a positive limit integral. Thus $c_\lambda \le C$.

To control the singularity type, we use uniform exponential integrability (Lemma 1.5.1) and Hölder's inequality to choose $\varepsilon > 0$ and $1 < q < p$ such that $\|\mathrm{e}^{-\varepsilon v_\lambda} f\|_q$ is uniformly bounded. Lemma 14.13.1, applied with the reference $V_\theta - 1$ and the barrier $\rho - 1$, gives $\eta_\lambda \in \mathrm{PSH}(X,\theta)$ with

$$V_\theta - 1 \le \eta_\lambda \le V_\theta, \qquad \mathrm{MA}_\theta(\eta_\lambda) \ge m\mathrm{e}^{-\varepsilon v_\lambda} f\,\mathrm{d}V \ge m f\,\mathrm{d}V$$

for a fixed $m > 0$. The scalar order in Corollary 14.12.1, together with $\mathrm{MA}_\theta(v_\lambda) \le c_\lambda f\,\mathrm{d}V$, gives $c_\lambda \ge m$. Set $D = \varepsilon^{-1}\max\{0, \log(C/m)\}$ and $w_\lambda = \eta_\lambda - D$. Then

$$\mathrm{e}^{\varepsilon(w_\lambda - v_\lambda)}\mathrm{MA}_\theta(v_\lambda) \le m\mathrm{e}^{-\varepsilon v_\lambda} f\,\mathrm{d}V \le \mathrm{MA}_\theta(w_\lambda),$$

since $\lambda v_\lambda \le 0$ and $\eta_\lambda \le 0$. The exponential order in Corollary 14.12.1 gives $v_\lambda \ge w_\lambda$, which proves the uniform bounds with $B = 1 + D$. □

Theorem 14.15.2 *Under the assumptions of Theorem 14.15.1, there are* $v \in \mathrm{PSH}(X,\theta)$*, a constant* $C > 0$ *and a uniquely determined* $c > 0$ *such that*

$$\sup_X v = 0, \qquad V_\theta - C \le v \le V_\theta, \qquad \mathrm{MA}_\theta(v) = c f\,\mathrm{d}V.$$

As in the semipositive case, only the constant c is asserted to be unique, not the normalized potential.

Proof Apply Lemma 14.15.2 with $\lambda = 1/j$, and write $v_j = v_{1/j}$ and $c_j = c_{1/j}$. Extract a subsequence with $v_j \to v$ in L^1 and almost everywhere, and with $c_j \to c \in [m, C]$. The limit is normalized, θ-plurisubharmonic, and has minimal singularities. The densities $c_j \mathrm{e}^{v_j/j} f$ have a common L^p bound. Hence Corollary 14.14.1, applied with the reference V_θ, upgrades the convergence to uniform convergence of differences on Ω and identifies the weak L^p limit of these densities with the density of $\mathrm{MA}_\theta(v)$.

At almost every point, v_j converges to a finite value, so $v_j/j \to 0$. Since $v_j \le 0$ and $c_j \le C$, dominated convergence gives $c_j \mathrm{e}^{v_j/j} f \to c f$ in L^p. Therefore $\mathrm{MA}_\theta(v) = c f\,\mathrm{d}V$. The uniqueness of the constant follows from Corollary 14.12.1. □

14.16 Local Hölder continuity in a big background

We now combine the stability estimate above ρ with the regularization of Lemma 1.21.7, whose curvature error is linear in the regularization parameter. As in the proof of Theorem 14.4.1, a small multiple of the strict barrier absorbs the curvature error of the transforms, and a lower bound for the minimizing radius converts the estimate for the transforms into an estimate for the smoothing on compact subsets of Ω. This gives a local Hölder modulus for solutions with minimal singularities.

Theorem 14.16.1 *Fix $C_0 > 0$. Let $u \in \mathrm{PSH}(X,\theta)$ satisfy*

$$\sup_X u = 0, \qquad V_\theta - C_0 \le u \le V_\theta, \qquad \mathrm{MA}_\theta(u) = f\,\mathrm{d}V,$$

where $0 \le f \in L^p(\mathrm{d}V)$ and $p > 1$. Then u is locally Hölder continuous on Ω, with every exponent

$$0 < \beta < \frac{2(p-1)}{np + 3(p-1)}.$$

For fixed bounds on C_0 and $\|f\|_p$, the Hölder constants are uniform on each fixed compact subset of Ω.

Proof Since $u \ge V_\theta - C_0 \ge \rho - C_0$, we may subtract a constant from the strict barrier so that $\rho \le u - 1$; it still satisfies $\theta + \mathrm{dd^c}\rho \ge \kappa\omega$ for a fixed $\kappa > 0$. Choose $0 < \gamma < (p-1)/(np+p-1)$ and set $\alpha = 2\gamma < 1$. Apply Lemma 1.21.7 with $a = u$, and let A, K, C and $\Phi_{c,\delta}$ be the constants and transforms given there. For small $\delta > 0$ set

$$c = \delta^\alpha, \qquad e = Ac + C\delta, \qquad s = e/\kappa, \qquad v_\delta = \frac{\Phi_{c,\delta} + s\rho}{1+s}.$$

By the curvature bound of Lemma 1.21.7, $v_\delta \in \mathrm{PSH}(X,\theta)$. The lower bound for $\Phi_{c,\delta}$ in that lemma implies $\rho \le \Phi_{c,\delta}$ when δ is small. Thus

$$v_\delta \le \Phi_{c,\delta} \le R_\delta u \le 0.$$

In particular $v_\delta \le V_\theta$, so Theorem 14.14.1 applies with the reference V_θ and the comparison potential v_δ. Together with the L^1 smoothing estimate, it gives

$$\sup_\Omega (v_\delta - u)_+ \le C\|(R_\delta u - u)_+\|_1^\gamma \le C\delta^\alpha.$$

Fix a compact subset of Ω on which $\rho \ge -M$. Since $s \le C\delta^\alpha$ and $u \le 0$, the identity

$$\Phi_{c,\delta} - u = (1+s)(v_\delta - u) + s(u - \rho)$$

gives $\Phi_{c,\delta} - u \le C_M\delta^\alpha$ there.

At a radius t where the infimum defining $\Phi_{c,\delta}$ is attained, the monotone lower bound yields

$$-c\log(t/\delta) \le \Phi_{c,\delta} - u + K(\delta^2 + \delta) \le C_M c.$$

Hence $t \geq a_M \delta$ for a fixed $a_M > 0$. As in the proof of Theorem 14.4.1, monotonicity of the smoothing now gives

$$R_{a_M \delta} u - u \leq C_M \delta^\alpha, \qquad R_{a_M \delta} u - u \geq -K(a_M \delta)^2$$

on the chosen compact set. Since every small radius has the form $a_M \delta$, we obtain $|R_t u - u| \leq C_M t^\alpha$ there for all small $t > 0$, with constants uniform on that compact set.

We apply this to a slightly larger compact neighborhood, on which also $\|\nabla R_t u\| \leq C_M / t$. For nearby points x, y at distance $d > 0$, the smooth function $R_t u$ and a short path in that neighborhood give

$$|u(x) - u(y)| \leq C_M (t^\alpha + d/t).$$

The choice $t = d^{1/(1+\alpha)}$ gives the exponent $\alpha/(1+\alpha)$, and letting γ approach its upper endpoint gives the asserted range. Pairs of points farther apart are handled by the boundedness of u on the compact neighborhood. □

It suffices that the equation hold on Ω. Suppose that $\mathrm{MA}_\theta(u) = c f \, \mathrm{d}V$ on Ω, where $c > 0$ and $0 \leq f \in L^p(X, \mathrm{d}V)$, and that u satisfies the same bounds as in the theorem. The lower bound $u \geq V_\theta - C_0 \geq \rho - C_0$ shows that u is locally bounded on Ω, so there $\mathrm{MA}_\theta(u)$ is the local bounded product. Since Z has zero volume and is not charged by $\mathrm{MA}_\theta(u)$, the equation holds on X, and the theorem applies with cf in place of f. The uniform estimates then depend on a bound for $\|cf\|_p$, which includes the constant c.

14.16.1 Limits of normalized exponential solutions

For the normalized exponential family (v_λ, c_λ) of Lemma 14.15.2, the reference interval $[V_\theta - B, V_\theta]$ is uniform in $0 < \lambda \leq 1$. Stability therefore controls differences on all of Ω, and the local Hölder estimates strengthen the convergence on compact subsets. We fix the nonzero density $0 \leq f \in L^p(\mathrm{d}V)$, $p > 1$, and use the constants B, C, m of that lemma.

Proposition 14.16.1 *For the family (v_λ, c_λ) of Lemma 14.15.2, the normalized potentials are relatively compact for uniform convergence of differences on Ω. As $\lambda \downarrow 0$, every cluster limit v is normalized, has minimal singularities, and satisfies*

$$\mathrm{MA}_\theta(v) = c f \, \mathrm{d}V,$$

where $c > 0$ is the unique constant of Theorem 14.15.2. Moreover,

$$c_\lambda \longrightarrow c, \qquad c_\lambda \mathrm{e}^{\lambda v_\lambda} f \longrightarrow c f \quad \text{in } L^p(\mathrm{d}V).$$

Every sequence of parameters in $(0, 1]$ has a subsequence for which the potentials converge in C^β on each compact subset of Ω, for all

$$0 < \beta < \frac{2(p-1)}{np + 3(p-1)}.$$

Proof By Lemma 14.15.2, all v_λ lie in a common reference interval, and their densities are bounded in L^p by $C\|f\|_p$. We may therefore apply Corollary 14.14.1 with $\eta = V_\theta$. Given any sequence $\lambda_j \downarrow 0$, we pass to a subsequence with $v_{\lambda_j} \to v$ uniformly in differences on Ω and in $L^1(X)$, and with $c_{\lambda_j} \to c_* \in [m, C]$. The limit satisfies the same reference bounds and is normalized. Off the pole set,

$$0 \le 1 - \mathrm{e}^{\lambda v_\lambda} \le 1 - \mathrm{e}^{\lambda(V_\theta - B)} \longrightarrow 0$$

as $\lambda \downarrow 0$. Multiplying by f and using dominated convergence, we obtain $\mathrm{e}^{\lambda v_\lambda} f \to f$ in L^p for the whole family. The compactness corollary therefore identifies the limit equation as $\mathrm{MA}_\theta(v) = c_* f \, \mathrm{d}V$, and the uniqueness of the constant gives $c_* = c$. Since every subsequential limit of c_λ as $\lambda \downarrow 0$ equals c, we conclude that $c_\lambda \to c$, and the stated convergence of the densities follows.

Finally, Theorem 14.16.1 gives uniform local C^α bounds for every α below its endpoint, and the uniform limit inherits these bounds by pointwise convergence. For $0 < \beta < \alpha$, uniform convergence and the elementary interpolation inequality on smaller coordinate balls give

$$[v_{\lambda_j} - v]_{C^\beta} \le C \|v_{\lambda_j} - v\|_\infty^{1-\beta/\alpha} [v_{\lambda_j} - v]_{C^\alpha}^{\beta/\alpha} \longrightarrow 0,$$

where the Hölder bounds are taken on slightly larger compact neighborhoods. The uniformly convergent subsequence given by compactness thus converges in C^β on every compact subset of Ω and for every exponent below the endpoint; no further extraction depending on the exponent is needed. □

Corollary 14.16.1 *Suppose a group G of biholomorphisms of X preserves θ and the measure $f \, \mathrm{d}V$. Then every v_λ and every cluster limit as $\lambda \downarrow 0$ is G-invariant. If the normalized zero-exponent equation has only one G-invariant solution with minimal singularities, then the whole family v_λ converges to it as $\lambda \downarrow 0$, uniformly in differences on Ω and in each local C^β topology of the proposition.*

Proof For $g \in G$, pullback by g preserves θ-plurisubharmonicity, and $V_\theta \circ g = V_\theta$ by the definition of the envelope. Pullback also preserves the positive-exponent equation, so its uniqueness gives $u_\lambda \circ g = u_\lambda$, and the normalization preserves this equality. Pullback by a fixed smooth biholomorphism is continuous on $L^1(X)$, since its Jacobian relative to the fixed smooth volume is bounded. Hence every cluster limit is invariant almost everywhere, and therefore everywhere for the canonical representatives. This argument does not require g to preserve the barrier ρ or the set Ω.

If the invariant solution is unique, every cluster limit is the same potential. Relative compactness then implies convergence of the whole family for uniform convergence of differences on Ω: a sequence staying at a fixed positive distance from that potential would have a convergent subsequence, a contradiction. The interpolation argument above upgrades this to the asserted local C^β convergence. □

The proposition gives compactness and identifies the equation of every cluster limit, and the symmetry criterion is one way to identify the limit itself. In general, Theorem 15.12.1 shows that the whole family converges, and it describes the limit through the greatest subsolution of the zero-exponent equation that satisfies a family of integral normalizations determined by how the constant c depends on the density. This holds even when the zero-exponent equation has several normalized solutions.

14.17 Interior smoothness on the regular locus

Throughout this section, θ is a smooth big real $(1,1)$-form, and ρ, $Z = \{\rho = -\infty\}$ and $\Omega = X \setminus Z$ are the strict analytic barrier and its regular locus fixed in Section 14.12. Thus $\rho \le 0$ has analytic singularities with smooth remainder, and $\theta + \mathrm{dd^c}\rho \ge \omega$. If $\varphi \in \mathrm{PSH}(X,\theta)$ has minimal singularities, then $\varphi \ge V_\theta - C \ge \rho - C$ for a constant C. Hence φ is locally bounded on Ω, and its Monge–Ampère measure there is the bounded-potential product.

For such a potential, Theorem 14.16.1 gives local Hölder continuity on Ω when the density belongs to L^p for some $p > 1$. We show that a smooth strictly positive density on the whole of Ω then makes the potential smooth on Ω. Local information alone cannot give this: Example 14.20.2 below is a locally Lipschitz plurisubharmonic function with constant Monge–Ampère density that is not C^1. The argument therefore uses the barrier globally. By the proper gap of Lemma 1.19.4, the difference between the solution and the barrier attains a minimum on the closed set where smoothness fails, and strict positivity of $\theta + \mathrm{dd^c}\rho$ turns this minimum into a quadratic separation. Near the minimum, smooth Dirichlet approximants have traces of polynomial growth; the separation improves this growth until a uniform trace bound yields elliptic regularity.

Theorem 14.17.1 *Suppose $\varphi \in \mathrm{PSH}(X,\theta)$ has minimal singularities and is locally Hölder continuous on Ω. Let $c > 0$ and let f be smooth and strictly positive on Ω. Assume*

$$(\theta + \mathrm{dd^c}\varphi)^n = c\, f\, \omega^n \quad \text{on } \Omega.$$

Then $\varphi \in C^\infty(\Omega)$ and $\theta + \mathrm{dd^c}\varphi > 0$ there.

The Hölder hypothesis holds when, in addition, $f \in L^p(X,\omega^n)$ for some $p > 1$, by Theorem 14.16.1; see Corollary 14.17.1. The theorem also applies when local Hölder continuity is obtained by another argument.

The proof is by contradiction and occupies the rest of the section. Let $\mathcal{S} \subset \Omega$ be the closed set of points near which φ is not smooth, suppose that $\mathcal{S} \neq \varnothing$, and let $p \in \mathcal{S}$ minimize $\varphi - \rho$ on $\mathcal{S}$. On a small ball centered at p the argument has four steps.

(1) A comparison principle for continuous solutions (Section 14.17.1) and the smooth Dirichlet problem give smooth solutions u_j of the equation that converge uniformly to φ at a polynomial rate in j, while the traces of $\theta + \mathrm{dd^c}u_j$, measured in Euclidean coordinates, grow at most polynomially in j (Section 14.17.3).
(2) Near p, the quadratic separation along $\mathcal{S}$, together with uniform trace bounds on compact sets where φ is already smooth, improves the trace growth to $O(j^\gamma)$ for every $\gamma > 0$. Interpolation with the convergence rate then gives uniform $C^{1,\alpha}$ bounds for every $\alpha < 1$ (Section 14.17.4).
(3) A third-order estimate whose constants depend polynomially on the ellipticity turns uniform $C^{1,\alpha}$ bounds, for α close to one, into a uniform trace bound (Section 14.17.5).
(4) A continuous solution with bounded trace is smooth (Section 14.17.2). Hence φ is smooth near p, contradicting $p \in \mathcal{S}$ (Section 14.17.6).

14.17.1 Local comparison

The comparison principle below, for continuous sub- and supersolutions on a bounded domain, identifies the given continuous potential with limits of smooth Dirichlet solutions. Since the background need not be closed, the classical Bedford–Taylor comparison does not apply directly. We freeze the background at a point, apply the closed-current comparison formula (1.4) to quadratic modifications, and control the error by the mixed inequalities of Lemmas 1.7.3 and 1.7.4.

The local arguments of this section take place in coordinate balls, always with compact closure in a larger coordinate chart. There we put $\beta = \mathrm{dd^c}|z|^2$, write $\partial_i = \partial/\partial z_i$ and $\partial_{\bar\imath} = \partial/\partial \bar z_i$, and take coefficient matrices of real $(1,1)$-forms relative to β. For such a form A, $\mathrm{tr}_\beta A$ and $\det_\beta A$ denote the trace and the determinant of its coefficient matrix, so that $A^n = (\det_\beta A)\beta^n$, and $\Delta_\beta = \mathrm{tr}_\beta\, \mathrm{dd^c}$. For a positive form T, tr_T is the trace computed with the inverse of the coefficient matrix of T. Indices run from 1 to n, repeated indices in tensor expressions are summed, and I denotes

the identity matrix. In local statements, ϑ denotes a smooth real $(1,1)$-form, not necessarily closed, which plays the role of θ.

Proposition 14.17.1 *Let $D \Subset \mathbb{C}^n$ be a bounded domain and let ϑ be a smooth real $(1,1)$-form near $\overline{D}$. Suppose $u, v \in C(\overline{D})$ are ϑ-plurisubharmonic,*

$$(\vartheta + \mathrm{dd^c} u)^n \geq F\beta^n, \qquad (\vartheta + \mathrm{dd^c} v)^n \leq F\beta^n,$$

where $F > 0$ is continuous on D. If $u \leq v$ on ∂D, then $u \leq v$ in D.

Proof *Step 1: v admits no strict smooth lower test.* Suppose, to the contrary, that a C^2 function q touches v from below at a point $p \in D$ and that, at p,

$$\vartheta + \mathrm{dd^c} q > 0, \qquad \det_{\beta}(\vartheta + \mathrm{dd^c} q) > F.$$

Choose a sufficiently small $a > 0$. After replacing q by $q - a|z-p|^2$, which makes the contact strict, and restricting to a small ball $B_r(p)$, there are fixed $\lambda, \eta > 0$ such that

$$A := \vartheta + \mathrm{dd^c} q \geq \lambda\beta, \qquad A^n \geq (F + \eta)\beta^n.$$

To compare with closed currents, freeze the background at p: put $\kappa = \sup_{B_r} \|\vartheta - \vartheta(p)\|_\beta$ and $B_0 = \vartheta(p) + \kappa\beta$. Then $S = B_0 - \vartheta$ satisfies $0 \leq S \leq 2\kappa\beta$. For small $s > 0$ the set $E = \{v < q + s\}$ is nonempty and relatively compact in B_r. If Q_0 is a quadratic potential for the constant form B_0, then

$$P = \mathrm{dd^c}(v + Q_0) = \vartheta + \mathrm{dd^c} v + S, \qquad Q = \mathrm{dd^c}(q + s + Q_0) = A + S \geq \lambda\beta$$

are closed positive Hessians. Applying (1.4), expanding P, and using $S \leq 2\kappa\beta \leq 2\kappa\lambda^{-1}Q$, we obtain

$$\int_E P^n \leq \int_E F\beta^n + e_\kappa \int_E P^n, \qquad e_\kappa = \left(1 + \frac{2\kappa}{\lambda}\right)^n - 1.$$

On the other hand, (1.4) with $j = n$ gives

$$\int_E P^n \geq \int_E Q^n \geq \int_E (F + \eta)\beta^n.$$

If M bounds F on the ball, the two estimates give $(1 - e_\kappa)\eta \leq e_\kappa M$. Since $\kappa \to 0$, and hence $e_\kappa \to 0$, as $r \downarrow 0$, this is impossible for small r. Thus no such lower test exists.

Step 2: comparison.

Suppose that $\max_D(u - v) > 0$. We regularize u to produce a forbidden lower test for v. Let χ_δ be a nonnegative smooth mollifier of mass one and radius $\delta > 0$. For small $t > 0$ and $C \geq \sup_D |z|^2$, set

$$u_t = u + t(|z|^2 - C).$$

Then $u_t \le v$ on ∂D, the positive maximum persists, and $T_t = \vartheta + \mathrm{dd^c} u_t \ge t\beta$. Lemma 1.7.3 gives

$$T_t^n \ge (F^{1/n} + t)^n \beta^n.$$

Choose a relatively compact neighborhood W of the positive maximum set. By Lemma 1.7.4,

$$(T_t * \chi_\delta)^n \ge \bigl((F^{1/n} + t) * \chi_\delta\bigr)^n \beta^n.$$

Since

$$\vartheta + \mathrm{dd^c}(u_t * \chi_\delta) = T_t * \chi_\delta + (\vartheta - \vartheta * \chi_\delta),$$

the convolution satisfies $T_t * \chi_\delta \ge t\beta$. If $\epsilon_\delta = \|\vartheta - \vartheta * \chi_\delta\|_{C^0(W)}$, then

$$\vartheta + \mathrm{dd^c}(u_t * \chi_\delta) \ge (1 - \epsilon_\delta/t)(T_t * \chi_\delta).$$

For fixed $t > 0$, uniform convergence of the convolved density and $\epsilon_\delta \to 0$ show that the left-hand side is positive and has determinant strictly larger than F on W for small δ. Since $u_t * \chi_\delta \to u_t$ uniformly on W, the difference $u_t * \chi_\delta - v$ still attains its maximum over $\overline{W}$ at an interior point of W for small δ. Subtracting this maximum from $u_t * \chi_\delta$ produces a smooth function touching v from below with the properties excluded in Step 1, a contradiction. □

14.17.2 Bounded traces and smoothness

We begin with the criterion used in the last step of the proof. A bounded trace of a positive current bounds all its coefficient measures, so a continuous solution with bounded trace is a strong solution with $W^{2,q}$ regularity for every finite q. The equation then bounds the eigenvalues from below, so it becomes uniformly elliptic. Since the solution is not yet known to be C^2, the Evans–Krylov theory is applied to it as a viscosity solution of a concave extension of the operator.

Proposition 14.17.2 *Let $B \subset \mathbb{C}^n$ be a coordinate ball, let ϑ be a smooth real $(1,1)$-form there and let $F \in C^\infty(B)$ be strictly positive. Suppose u is continuous, $T = \vartheta + \mathrm{dd^c} u \ge 0$, and*

$$T^n = F\beta^n. \tag{14.14}$$

For a point $p \in B$, the following conditions, each required on some neighborhood of p, are equivalent:

(1) *u is smooth;*
(2) *$T \ge \delta\beta$ for some $\delta > 0$;*
(3) *$\mathrm{tr}_\beta T$ has a locally bounded measure density.*

Proof Choose C so that $v = u + C|z|^2$ is plurisubharmonic, and use nonnegative radial mollifiers for which $v_\eta \downarrow v$. The smooth matrix convolutions $T_\eta = T * \chi_\eta$ can be written as

$$T_\eta = (\vartheta * \chi_\eta - C\beta) + \mathrm{dd^c} v_\eta.$$

Bedford–Taylor monotone continuity and smooth convergence of the background imply $T_\eta^k \to T^k$ for every k.

(2)⇒(3). Assume (2). For every Hermitian matrix $M \geq \delta I$,

$$\det M \geq \delta^{n-1}\bigl(\operatorname{tr} M - (n-1)\delta\bigr).$$

Apply this to the regularizations and pass to currents. Equation (14.14) gives

$$\operatorname{tr}_\beta T \leq \delta^{1-n} F + (n-1)\delta,$$

which is (3).

(3)⇒(1). Assume (3), say $\operatorname{tr}_\beta T \leq L$. Positivity makes every coefficient of the matrix-valued current T a bounded density. Hence the Euclidean Laplacian of u is locally bounded, and interior Poisson estimates give $u \in W^{2,q}_{\mathrm{loc}}$ for every finite q. Mollification converges in $W^{2,q}$; taking $q > 2n$ identifies the bounded-potential determinant with the ordinary almost-everywhere determinant. Thus $\det_\beta T = F$ almost everywhere. On a smaller ball with $F \geq m > 0$, all eigenvalues of T are at most L and their product is at least m, so

$$\frac{m}{L^{n-1}} I \leq T \leq L I$$

almost everywhere.

It remains to show that this strong solution is smooth. Let P be the real linear map from real symmetric $2n \times 2n$ Hessian matrices to Hermitian $n \times n$ matrices, sending $D^2 u$ to the coefficient matrix of $\mathrm{dd}^{\mathrm{c}} u$ relative to β, and let $\Theta(x)$ be the matrix of ϑ. With $\delta = mL^{1-n}$, define the concave extension

$$G(x, M) = \inf_{\delta I \leq A \leq L I} \Bigl\{ \log\det A + \operatorname{tr}\bigl[A^{-1}\bigl(\Theta(x) + P(M) - A\bigr)\bigr] \Bigr\} - \log F(x).$$

For fixed A, write $\mathcal{E}_A(x, M)$ for the expression in braces minus $\log F(x)$. The tangent-plane formula for $\log\det$ gives

$$G(x, D^2 u) = 0 \quad \text{almost everywhere.}$$

The operator G is concave and uniformly elliptic on real symmetric matrices. The affine operators $\mathcal{E}_A$ have constant principal matrices with eigenvalues bounded above and below in terms of δ and L. Their x-dependence is smooth uniformly in A, so G has a uniform local Lipschitz modulus in x.

We claim that u is a viscosity solution of $G(x, D^2 u) = 0$. Suppose that a smooth function ψ touches u from above at x_0 and that $G(x_0, D^2\psi) < 0$. Some fixed matrix A then satisfies $\mathcal{E}_A(x, D^2\psi) < -\eta$ on a small ball. Since $G(x, D^2 u) = 0$ almost everywhere, $\mathcal{E}_A(x, D^2 u) \geq 0$ there. Thus $u - \psi$ has an interior maximum and satisfies

$$\operatorname{tr}\Bigl(A^{-1} P\bigl(D^2(u - \psi)\bigr)\Bigr) \geq \eta \quad \text{almost everywhere.}$$

After a small quadratic perturbation makes the contact strict, this contradicts the Aleksandrov maximum principle [GT01, Chapter 9, Theorem 9.1]. If instead ψ touches u from below and $G(x_0, D^2\psi) > 0$, then $\mathcal{E}_A(x, D^2\psi) > \eta$ for every admissible A on a small ball. At almost every point choose an admissible $A(x)$ with $\mathcal{E}_{A(x)}(x, D^2u) < \eta/2$. A measurable choice is obtained by taking the first qualifying element of a countable dense family. The function $\psi - u$ then violates the same maximum principle for the measurable uniformly elliptic coefficients $A(x)^{-1}$. This proves the claim.

The classical variable-coefficient Evans–Krylov theorem gives $u \in C^{2,\alpha}_{\mathrm{loc}}$ for some $0 < \alpha < 1$. The original equation is now uniformly elliptic with smooth data. Difference quotients satisfy linear equations whose principal coefficients are averages of inverse matrices along positive definite segments. Interior Schauder estimates first give $u \in C^{3,\alpha}_{\mathrm{loc}}$ and then, by iteration, $u \in C^\infty$. This proves (3)$\Rightarrow$(1).

(1)$\Rightarrow$(2). If u is smooth, then T is a smooth semipositive form with determinant $F > 0$, so it is positive definite; on a smaller neighborhood this gives (2). □

14.17.3 Smooth exact approximants

We now construct the approximants of the first step. The smooth Dirichlet theorem, Lemma 14.6.1, applies to every smooth positive density F. Approximating the Hölder boundary values of φ by smooth functions therefore gives smooth solutions, and the point is to control them quantitatively. The estimates below bound the trace of a smooth solution by a power of the C^4 norm of its boundary value. The C^4 norms of the boundary approximations grow polynomially while their uniform errors decay polynomially, so both the convergence and the trace growth have polynomial rates.

In this subsection balls are centered at the origin. On the boundary sphere, ν is the outward Euclidean unit normal and $\nabla_{\tan}$ denotes tangential differentiation. For a positive form T, inner products $\langle \cdot, \cdot \rangle_T$ and norms $|\cdot|_T$ of $(1,0)$-covectors are computed with the inverse of the coefficient matrix of T.

Lemma 14.17.1 *Let B be a coordinate ball, let ϑ and $F > 0$ be smooth near $\overline{B}$, and let q be smooth with $R = \vartheta + \mathrm{dd^c} q \geq \varepsilon\beta$ for a fixed $\varepsilon > 0$. Fix a finite $L \geq 0$. If $u \in C^\infty(B)$ satisfies*

$$T = \vartheta + \mathrm{dd^c} u > 0, \qquad T^n = F\beta^n, \qquad |u - q| \leq L,$$

put $S = \mathrm{tr}_\beta T$ and $v = u - q$. For $A > 0$, define

$$Q_A = \log S - Av + \mathrm{e}^{-v}.$$

There are A_0, C, depending only on the fixed data and L, such that at every interior local maximum of Q_A, with $A \geq A_0$,

$$S \leq C\sqrt{A}. \tag{14.15}$$

The constants do not depend on any bound for the gradient of u.

Proof This is the maximum-principle computation behind the classical second-order estimate. The non-closedness of ϑ produces a first-order error term, which is absorbed by the convex term e^{-v}.

At the point in question make a constant unitary change of coordinates so that the matrix of T is diagonal, with eigenvalues λ_i. Write

$$\Delta_T = \sum_i \lambda_i^{-1} \partial_i \partial_{\bar{i}}, \qquad H = \mathrm{tr}_T \beta.$$

Differentiating $\log\det T = \log F$ and commuting derivatives gives

$$\Delta_T S = \Delta_\beta \log F + P + E_0, \quad P = \sum_{k,i,j} \frac{|\partial_k T_{i\bar{j}}|^2}{\lambda_i \lambda_j}, \quad |E_0| \leq C_0 H. \tag{14.16}$$

The non-closedness of ϑ enters through the bounded vector

$$E_p = \sum_k (\partial_p \vartheta_{k\bar{k}} - \partial_k \vartheta_{p\bar{k}}).$$

Since $\partial_p S - E_p = \sum_k \partial_k T_{p\bar{k}}$, weighted Cauchy–Schwarz gives $|\partial S - E|_T^2 \leq SP$. From (14.16),

$$\Delta_T \log S \geq -\frac{C_0(1+H)}{S} - \frac{2}{S}\,\mathrm{Re}\langle \partial \log S, E\rangle_T. \tag{14.17}$$

Set $g_A(s) = -As + \mathrm{e}^{-s}$. At a local maximum of Q_A, $\partial \log S = -g_A'(v)\partial v$ and $\Delta_T v = n - \mathrm{tr}_T R$. Combining these identities with (14.17), then completing the square in ∂v, yields

$$0 \geq \left[\varepsilon A - \frac{C_2}{S} - \frac{C_2(A+1)^2}{S^2}\right] H - C_3(A+1) - \frac{C_2}{S}. \tag{14.18}$$

Here $|E|_T^2 \le CH$ and the bounds for v have been used. If $S \ge K\sqrt{A}$ and K is large, the bracket is at least $\varepsilon A/2$. Thus $H \le C$ independently of A and u. The determinant upper bound then gives $S \le C'$. Enlarging K makes this incompatible with $S \ge K\sqrt{A}$, proving (14.15). □

We shall also use the following variant, in which a gradient bound replaces the convex term. If $|\nabla(u-q)|_\beta$ is bounded, then at an interior maximum of $\log S - A(u-q)$ the trace is bounded independently of A for all large A. Indeed, at the maximum $\partial \log S = A\partial(u-q)$, and (14.17) gives

$$0 \ge \left[A\varepsilon - \frac{C}{S} - \frac{CA}{S}\right] H - nA - \frac{C}{S}.$$

For S larger than a fixed constant the bracket is at least $A\varepsilon/2$; the determinant again controls S.

A polynomial boundary trace estimate

Proposition 14.17.3 *Let B be the unit ball. Fix smooth ϑ, smooth $F > 0$ near $\overline{B}$, and $M < \infty$. There are $C, N < \infty$, depending only on these fixed data, such that every smooth solution u with boundary value $g \in C^\infty(\partial B)$ of*

$$T = \vartheta + \mathrm{dd^c} u > 0, \qquad T^n = F\beta^n, \qquad \|u\|_{L^\infty(B)} \le M, \qquad u|_{\partial B} = g,$$

satisfies

$$\sup_{\overline{B}} \operatorname{tr}_\beta T \le C\big(1 + \|g\|_{C^4(\partial B)}\big)^N. \tag{14.19}$$

Proof We follow the classical boundary estimates for the Dirichlet problem on a ball and keep track of the dependence on $L = 1 + \|g\|_{C^4}$. Barriers bound the first derivatives, and differentiation along rotations bounds the mixed normal–tangential second derivatives on the boundary. A lower bound for the tangential block of T then bounds the double normal derivative through the equation, and Lemma 14.17.1 reduces the interior bound to the boundary bound.

Step 1: first derivatives. Fix a sufficiently large constant $K > 0$, depending only on the fixed data. Extend g to G on $\overline{B}$ with $\|G\|_{C^4} \le CL$. For $A = CL$ large enough,

$$\underline{u} = G + A(|z|^2 - 1), \qquad \underline{T} = \vartheta + \mathrm{dd^c}\underline{u} \ge K\beta, \qquad \underline{T}^n \ge F\beta^n.$$

Proposition 14.17.1 gives $\underline{u} \le u$. If h solves $\Delta_\beta h = -C_\vartheta$ with $h = g$ on ∂B and $C_\vartheta \ge \sup \operatorname{tr}_\beta \vartheta$, then $u \le h$. Boundary differentiation of these barriers gives

$$|\partial_\nu u| + |\nabla_{\tan} u| \le CL \quad \text{on } \partial B. \tag{14.20}$$

Let $H = \operatorname{tr}_T \beta$, $\mathcal{L} = \operatorname{tr}_T \mathrm{dd^c}$, and $w = u - \underline{u} \ge 0$, the linearized operator and the barrier function used below. Taking K fixed and sufficiently large gives

$$\mathcal{L}w = n - \operatorname{tr}_T \underline{T} \le -(1+H). \tag{14.21}$$

Let $E = \sum_k (z_k \partial_{z_k} + \bar{z}_k \partial_{\bar{z}_k})$ be the real radial field. Write Θ for the coefficient matrix of ϑ. Differentiating $\log\det T = \log F$ and commuting E with complex second derivatives yields

$$\mathcal{L}(Eu) = E(\log F) + 2n - \operatorname{tr}_T(E\Theta + 2\Theta).$$

Hence $|\mathcal{L}(Eu)| \le C(1+H)$. The same estimate holds for Zu when Z is an infinitesimal unitary rotation. Applying the minimum principle to $CL + C'w \pm Yu$, with $Y = E$ or Z, gives

$$|Eu| + |Zu| \le CL \quad \text{on } B. \tag{14.22}$$

Step 2: mixed second derivatives on the boundary. For a rotation Z, the function $R_Z = Z(u-G)$ vanishes on ∂B and satisfies $|\mathcal{L}R_Z| \le CL(1+H)$. The barriers $CLw \pm R_Z$ and (14.21) imply $|\partial_\nu R_Z| \le CL^2$ on the boundary. Rotations span the real tangent space of ∂B, so all real mixed normal–tangential second derivatives are $O(L^2)$. Pure tangential second derivatives are $O(L)$ by differentiating $u = g$ twice and using (14.20). Thus all complex Hessian entries except the complex normal–normal entry are $O(L^2)$.

Step 3: the double normal derivative. It remains to bound the tangential block of T from below. For $n \ge 2$, let

$$\lambda_0 = \min\{T_p(\xi,\bar\xi) : p \in \partial B,\ \xi \in T^{1,0}_p(\partial B),\ |\xi|_\beta = 1\}.$$

Choose a minimizing pair (p,ξ) and extend ξ to a smooth unit tangential field near p, with uniformly bounded derivatives. On the sphere, any smooth function vanishing there satisfies

$$\mathrm{dd}^{\mathrm{c}}(u-G)(\xi,\bar\xi) = \frac{1}{2}E(u-G).$$

Define

$$a(z) = (\vartheta + \mathrm{dd}^{\mathrm{c}}G)_z(\xi(z), \overline{\xi(z)}) - \frac{1}{2}EG(z), \qquad P = a + \frac{1}{2}Eu - \lambda_0.$$

Then $P \ge 0$ on the nearby spherical boundary and $P(p) = 0$. The boundary first-derivative bound also gives $\lambda_0 \le CL$ by the tangential identity above. Consequently

$$|P| \le CL, \qquad |\mathcal{L}P| \le CL(1+H).$$

On a fixed cap $D = B \cap B_r(p)$ consider

$$\Psi = P + C_1 Lw + C_2 L|z-p|^2.$$

Choose C_2 so that $\Psi \ge 0$ on the interior spherical part of ∂D, and then C_1 so that $\mathcal{L}\Psi \le 0$ by (14.21). The minimum principle yields $\Psi \ge 0$. At p the normal derivative of $|z-p|^2$ vanishes, and therefore

$$\partial_\nu P + C_1 L \partial_\nu w \le 0.$$

Equations (14.20)–(14.22) now give $D^2u(\nu,\nu)(p) \le CL^2$, hence $\operatorname{tr}_\beta T(p) \le CL^2$. Positivity and $\det_\beta T = F$ imply

$$\lambda_0 \ge cL^{-2(n-1)}. \tag{14.23}$$

At any boundary point write

$$T = \begin{pmatrix} B_0 & b \\ b^* & d \end{pmatrix}$$

in tangential–normal blocks, with B_0 an $(n-1)\times(n-1)$ Hermitian matrix, $b \in \mathbb{C}^{n-1}$ and $d \in \mathbb{R}$. We have $|b| \le CL^2$ and $B_0 \ge \lambda_0 I$. The determinant equation and the Schur complement give

$$d = \frac{F}{\det B_0} + b^* B_0^{-1} b \le (\sup F)\lambda_0^{-(n-1)} + CL^4\lambda_0^{-1},$$

which is polynomial in L. For $n = 1$, the trace is F and this argument is unnecessary.

Step 4: the interior. Choose a fixed quadratic q with $\vartheta + \mathrm{dd}^{\mathrm{c}} q \ge \varepsilon\beta$. Apply Lemma 14.17.1 with one fixed A. At an interior maximum of its auxiliary function the trace is uniformly bounded, while at a boundary maximum the preceding estimate applies. Since the remaining terms are uniformly bounded, (14.19) follows. □

Exact approximation

We apply these estimates to smooth approximations of the boundary values of φ on a ball in Ω. Recall that θ, ω, c and f are the data of Theorem 14.17.1.

Proposition 14.17.4 *Let $B \Subset \Omega$ be a coordinate ball, identified with $\{|z| < r_0\}$, with closure in a larger coordinate chart, and put*

$$F = \frac{c f \, \omega^n}{\beta^n}.$$

There are $a > 0$, $b, C < \infty$, and $u_j \in C^\infty(\overline{B})$ such that

$$\theta + \mathrm{dd^c} u_j > 0, \qquad (\theta + \mathrm{dd^c} u_j)^n = F\beta^n, \tag{14.24}$$

and

$$\|u_j - \varphi\|_{L^\infty(B)} \le C j^{-a}, \qquad \sup_{\overline{B}} \mathrm{tr}_\beta(\theta + \mathrm{dd^c} u_j) \le C j^b. \tag{14.25}$$

Proof Since φ is Hölder continuous near $\overline{B}$, mollification at scale $1/j$ gives smooth boundary approximations g_j with

$$\|g_j - \varphi\|_{L^\infty(\partial B)} \le C j^{-a}, \qquad \|g_j\|_{C^4(\partial B)} \le C j^4.$$

Choose a fixed quadratic q with $\eta = \theta + \mathrm{dd^c} q > 0$ near $\overline{B}$. Extend g_j smoothly to G_j. For a sufficiently large, polynomially bounded A_j, the function

$$\underline{w}_j = G_j - q + A_j(|z|^2 - r_0^2)$$

has boundary value $g_j - q$ and satisfies

$$\eta + \mathrm{dd^c} \underline{w}_j = \theta + \mathrm{dd^c} G_j + A_j \beta > 0, \qquad (\eta + \mathrm{dd^c} \underline{w}_j)^n \ge F\beta^n.$$

Apply the smooth Dirichlet theorem recalled at the beginning of this subsection, with density $H = F\beta^n/\eta^n$ to obtain a solution w_j for the Hermitian background η; put $u_j = w_j + q$. Comparing u_j with $\varphi \pm \|g_j - \varphi\|_\infty$ by Proposition 14.17.1 proves the first bound in (14.25). The functions u_j are therefore uniformly bounded. Proposition 14.17.3 and the polynomial C^4 boundary norm give the second bound.□

14.17.4 Localization near the nonregular set

In the auxiliary function of Lemma 14.17.1, the term $-A(u_j - q)$ penalizes points where $u_j - q$ is large. A quadratic gap of $u - q$ along the nonregular set therefore suppresses the contribution of the boundary of a neighborhood of that set. Taking A proportional to $\log j$ makes this suppression beat the polynomial growth of the

boundary trace, and near the point of minimal $u - q$ the trace then grows more slowly than every positive power of j. Interpolation with the polynomial approximation rate gives uniform $C^{1,\alpha}$ bounds.

Distances and norms below are Euclidean. By a smooth exact solution for (ϑ, F) we mean a smooth function u_j with $\vartheta + \mathrm{dd^c} u_j > 0$ and $(\vartheta + \mathrm{dd^c} u_j)^n = F\beta^n$.

Proposition 14.17.5 *For $R > 0$, let $B = B_R(0)$, let ϑ and $F > 0$ be smooth near $\overline{B}$, and let $u \in C(\overline{B})$. Suppose q is smooth and $\vartheta + \mathrm{dd^c} q \geq \varepsilon\beta$ for some $\varepsilon > 0$. Put $v = u - q$ and $m = v(0)$, and fix $\kappa > 0$. Let $\mathcal{S} \subset \overline{B}$ be closed, contain 0, and satisfy*

$$v(0) = m, \qquad v(z) \geq m + \kappa|z|^2 \quad (z \in \mathcal{S}). \tag{14.26}$$

Assume that smooth exact solutions u_j, $j \geq 2$, satisfy, for fixed constants $a > 0$, $b \geq 0$ and $C > 0$,

$$\|u_j - u\|_\infty \leq C j^{-a}, \tag{14.27}$$

$$\sup_{\overline{B}} \mathrm{tr}_\beta(\vartheta + \mathrm{dd^c} u_j) \leq C j^b, \tag{14.28}$$

$$\sup_j \sup_K \mathrm{tr}_\beta(\vartheta + \mathrm{dd^c} u_j) < \infty \quad \textit{for every } K \Subset \overline{B} \setminus \mathcal{S}. \tag{14.29}$$

Then for every $\gamma > 0$ there are a neighborhood U_γ of 0 and C_γ such that

$$\mathrm{tr}_\beta(\vartheta + \mathrm{dd^c} u_j) \leq C_\gamma j^\gamma \quad \textit{on } U_\gamma. \tag{14.30}$$

For every $0 < \alpha < 1$, there is also a neighborhood U of 0 on which $u_j \to u$ in $C^{1,\alpha}$. In particular the approximants are uniformly bounded in that norm and $u \in C^{1,\alpha}(U)$.

Proof *Step 1: the trace bound* (14.30). Write $e_j = Cj^{-a}$, fix $d = \kappa R^2/2$, and choose $D > (b+1)/d$. Choose $\eta > 0$ so that $2D\eta < \gamma/2$. For small $\delta > 0$, the neighborhood

$$W_\delta = \{z \in B : \mathrm{dist}(z, \mathcal{S}) < \delta\}$$

contains 0, has $v \geq m - \eta$ on its closure, and satisfies $v \geq m + d$ on $\partial B \cap \overline{W}_\delta$ with the fixed d above. These properties follow from (14.26), continuity, and compactness. The remaining part of the boundary of W_δ is a compact subset of $\overline{B} \setminus \mathcal{S}$, where (14.29) applies.

Set $A_j = D \log j$. Apply the maximum principle on $\overline{W}_\delta$ to

$$Q_j = \log \mathrm{tr}_\beta(\vartheta + \mathrm{dd^c} u_j) - A_j(u_j - q) + \mathrm{e}^{-(u_j - q)}.$$

At an interior maximum, Lemma 14.17.1 gives $\log \mathrm{tr}_\beta(\vartheta + \mathrm{dd^c} u_j) \leq C + \frac{1}{2}\log A_j$. On the part of ∂W_δ inside B, which stays away from $\mathcal{S}$, the trace has a bound independent of j. On the outer part $\partial B \cap \overline{W}_\delta$, (14.28) and the gap d give

$$Q_j \leq C + b \log j - A_j(m + d - e_j),$$

and the choice $Dd > b + 1$ makes this smaller than the bound below for large j. Hence throughout W_δ,

$$Q_j \le C_\delta + \tfrac{1}{2}\log A_j - A_j(m - \eta - e_j).$$

On a small ball about 0 where $v \le m + \eta$, this implies

$$\log \operatorname{tr}_\beta(\vartheta + \mathrm{dd}^{\mathrm{c}} u_j) \le C_\delta + \tfrac{1}{2}\log A_j + A_j(2\eta + 2e_j).$$

By the choice of η, the logarithmic factor and $A_j e_j$ are absorbed into the remaining power. This proves (14.30).

Step 2: $C^{1,\alpha}$ convergence. On a smaller ball, the real Laplacian of u_j is bounded by Cj^γ. Interior Poisson estimates give a W^{2,q_0} bound for every finite q_0, and Sobolev embedding with q_0 large then gives, for every $\sigma < 1$,

$$\|u_j\|_{W^{2,q_0}} + \|u_j\|_{C^{1,\sigma}} \le Cj^\gamma.$$

For $d_k = u_{2^{k+1}} - u_{2^k}$,

$$\|d_k\|_\infty \le C2^{-ka}, \qquad \|d_k\|_{C^{1,\sigma}} \le C2^{k\gamma}.$$

If $\alpha < \sigma$ and $t = (1 + \alpha)/(1 + \sigma)$, Hölder interpolation gives

$$\|d_k\|_{C^{1,\alpha}} \le C2^{k[-a(1-t)+\gamma t]}.$$

Since γ may be arbitrarily small, the exponent can be made negative. The dyadic series converges in $C^{1,\alpha}$ to its uniform limit u. If $2^k \le j < 2^{k+1}$, interpolation applied to $u_j - u_{2^k}$ gives the same decaying bound. Hence the full sequence converges to u in $C^{1,\alpha}$ on a smaller ball. □

Proposition 14.17.6 *Suppose u_j solve the same smooth equation as in Proposition 14.17.5, satisfy (14.27)–(14.28), and u is smooth with $\vartheta + \mathrm{dd}^{\mathrm{c}} u > 0$ on an open set $O \subset B$. Then, for every $K \Subset O$,*

$$\sup_j \sup_K \operatorname{tr}_\beta(\vartheta + \mathrm{dd}^{\mathrm{c}} u_j) < \infty. \tag{14.31}$$

Proof Where u is smooth and strictly ϑ-plurisubharmonic, it provides its own quadratic separation, so the argument of Proposition 14.17.5 applies around every point of O. A first application gives trace growth of order $\sqrt{\log j}$; the resulting gradient convergence then allows the variant of Lemma 14.17.1 with a gradient bound, which removes this growth.

For p in a fixed compact subset of O, take a uniformly sized ball $B_r(p) \Subset O$ and set

$$q_p(z) = u(z) - \kappa|z - p|^2$$

with $\kappa > 0$ small, so $\vartheta + \mathrm{dd}^{\mathrm{c}} q_p \ge \varepsilon\beta$. If $e_j = Cj^{-a}$ and $v_{j,p} = u_j - q_p$, then

$$v_{j,p} \ge -e_j, \quad v_{j,p}(p) \le e_j, \quad v_{j,p} \ge \kappa r^2 - e_j \text{ on } \partial B_r(p).$$

With $A_j = D \log j$ and $D\kappa r^2 > b + 1$, the same maximum argument as above gives

$$\operatorname{tr}_\beta(\vartheta + \mathrm{dd}^{\mathrm{c}} u_j)(p) \le C\sqrt{\log j}. \tag{14.32}$$

The constants are uniform on compact subsets of O.

Put $T_j = \vartheta + \mathrm{dd}^{\mathrm{c}} u_j$ and $w_j = u_j - u$. On slightly larger compact sets, (14.32) bounds $|\Delta w_j|$ by $C\sqrt{\log j}$. Poisson estimates and Sobolev embedding give

$$\|w_j\|_{C^{1,\sigma}} \le C_\sigma \sqrt{\log j}, \qquad \sigma < 1.$$

Interpolating with $\|w_j\|_\infty \le C j^{-a}$ shows $\nabla w_j \to 0$ uniformly on smaller compact sets. The gradients of $v_{j,p}$ are therefore uniformly bounded. Repeat the maximum argument with $\log \operatorname{tr}_\beta T_j - A_j v_{j,p}$, now using the variant of Lemma 14.17.1 with a gradient bound. Its interior trace bound is now independent of A_j, while the boundary term is suppressed as before. Evaluation at p gives

$$\operatorname{tr}_\beta T_j(p) \le C \exp(2A_j e_j) \le C,$$

proving (14.31). □

14.17.5 Derivative estimates and bounded traces

Uniform $C^{1,\alpha}$ bounds control averages of the trace $\operatorname{tr}_\beta(\vartheta + \mathrm{dd}^{\mathrm{c}} u_j) = \operatorname{tr}_\beta \vartheta + \Delta_\beta u_j$ over small balls. To pass from averages to pointwise values we need a bound for the gradient of the trace, that is, a third-order estimate, whose dependence on the ellipticity constants is polynomial. We prove it by Calabi's maximum-principle argument, computed with the Chern connection of the solution so that the torsion of the nonclosed background appears explicitly. The resulting averaging inequality is nonlinear in the trace, and it closes under iteration when α is sufficiently close to one.

In this subsection B is the unit ball and $B_r(p)$ is the Euclidean ball of radius r centered at p. For a Hermitian metric g, ∂g denotes the ordinary coordinate derivatives of its coefficient matrix, while tensor derivatives in the proofs are taken with respect to the Chern connection of g.

Proposition 14.17.7 *Fix smooth ϑ and smooth $F > 0$ near the closed unit ball. There are $C, N < \infty$, depending only on finitely many derivatives of the fixed data, such that any smooth solution*

$$g = \vartheta + \mathrm{dd}^{\mathrm{c}} u, \qquad g^n = F\beta^n, \qquad M^{-1}\beta \le g \le M\beta, \qquad M \ge 1,$$

satisfies

$$\sup_{B_{1/2}} |\partial g|_\beta \le C M^N. \tag{14.33}$$

If only $\sup_B \operatorname{tr}_\beta g \le L$ *is given, the same bound holds with a fixed power of* $1+L$*. On a ball of radius* $r \le 1$*,*

$$\sup_{B_{r/2}} |\nabla \operatorname{tr}_\beta g|_\beta \le C r^{-1} (1+L)^N. \tag{14.34}$$

Proof The quantity $\mathcal{R}$ below is the squared norm of the difference between the Chern connection of g and the flat connection. We derive a differential inequality for $\mathcal{R}$ in which the torsion enters through fixed derivatives of ϑ, and combine it with the trace in a maximum principle; every constant is kept a power of M.

We compare the flat connection of β with the Chern connection ∇ of g. Write $g^{k\bar\ell}$ for the coefficients of the inverse matrix and $\bar\nabla$ for covariant differentiation in $(0,1)$ directions; tensor norms and inner products without subscript are computed with g. The difference of the two connections and its squared norm are

$$\Psi^k_{ij} = g^{k\bar\ell}\partial_i g_{j\bar\ell}, \qquad \mathcal{R} = |\Psi|^2_g.$$

The torsion of ∇ is determined by the fixed background, because the third derivatives of u cancel in it. Its lowered and raised components are

$$C_{ij\bar\ell} = \partial_i \vartheta_{j\bar\ell} - \partial_j \vartheta_{i\bar\ell}, \qquad \mathcal{T}^k_{ij} = g^{k\bar\ell} C_{ij\bar\ell}. \tag{14.35}$$

Consequently, for a fixed integer N,

$$\begin{aligned} |\mathcal{T}| &\le C M^N, \\ |\nabla \mathcal{T}| + |\bar\nabla \mathcal{T}| &\le C M^N (1+\sqrt{\mathcal{R}}), \\ |\nabla^2 \mathcal{T}| + |\nabla\bar\nabla \mathcal{T}| + |\bar\nabla^2 \mathcal{T}| &\le C M^N (1 + \mathcal{R} + |\nabla\Psi| + |\bar\nabla\Psi|). \end{aligned} \tag{14.36}$$

Every factor here is either a fixed derivative of ϑ, a connection factor Ψ, or a factor of $g^{\pm 1}$; this explains the polynomial dependence.

For tensor fields, use $\Delta_g = g^{p\bar q}\nabla_p \nabla_{\bar q}$. We need the following curvature identities. With

$$\operatorname{Rm}^k{}_{i\bar j l} = -\partial_{\bar j}\Psi^k_{il}, \qquad \operatorname{Rm}_{i\bar j l\bar k} = g_{m\bar k}\operatorname{Rm}^m{}_{i\bar j l},$$

set

$$\operatorname{Ric}^{(2)}_{l\bar k} = g^{i\bar j}\operatorname{Rm}_{i\bar j l\bar k}, \qquad \operatorname{Ric}^{(1)}_{l\bar k} = g^{i\bar j}\operatorname{Rm}_{l\bar k i\bar j} = -\partial_l\partial_{\bar k}\log F.$$

The two curvature interchanges are

$$\begin{aligned} \operatorname{Rm}_{i\bar j l\bar k} - \operatorname{Rm}_{l\bar j i\bar k} &= -\nabla_{\bar j} C_{il\bar k}, \\ \operatorname{Rm}_{i\bar j l\bar k} - \operatorname{Rm}_{i\bar k l\bar j} &= -\nabla_i \overline{C}_{\bar j\bar k l}. \end{aligned}$$

They follow by differentiating the torsion identity and its conjugate. Successive interchange and contraction give

$$\operatorname{Ric}^{(2)}_{l\bar k} = \operatorname{Ric}^{(1)}_{l\bar k} - g^{i\bar j}\big(\nabla_l \overline{C}_{\bar j\bar k i} + \nabla_{\bar j} C_{il\bar k}\big). \tag{14.37}$$

Metric compatibility, (14.36), and the fixed smooth formula for $\mathrm{Ric}^{(1)}$ imply

$$|\mathrm{Ric}^{(2)}| \le CM^N(1+\sqrt{\mathcal{R}}), \qquad |\nabla \mathrm{Ric}^{(2)}| \le CM^N(1+\mathcal{R}+|\nabla\Psi|+|\bar\nabla\Psi|). \tag{14.38}$$

Moreover,

$$\nabla_{\bar q}\Psi^k_{ij} = -\mathrm{Rm}^k{}_{i\bar q j},$$

and the Chern–Bianchi identity, including its torsion term, is

$$\nabla_p \mathrm{Rm}^k{}_{i\bar q j} - \nabla_i \mathrm{Rm}^k{}_{p\bar q j} = -\mathcal{T}^r_{pi}\,\mathrm{Rm}^k{}_{r\bar q j}.$$

Consequently,

$$\Delta_g \Psi^k_{ij} = -\nabla_i(\mathrm{Ric}^{(2)})^k{}_j + g^{p\bar q}\mathcal{T}^r_{pi}\,\mathrm{Rm}^k{}_{r\bar q j}. \tag{14.39}$$

If $A^k{}_l = (\mathrm{Ric}^{(2)})^k{}_l$, define its action on a tensor of type $(1,2)$ by

$$(A\cdot\Psi)^k_{ij} = A^k{}_l\Psi^l_{ij} - A^l{}_i\Psi^k_{lj} - A^l{}_j\Psi^k_{il}.$$

Differentiating the squared norm and using metric compatibility gives

$$\Delta_g\mathcal{R} = |\nabla\Psi|^2 + |\bar\nabla\Psi|^2 + 2\,\mathrm{Re}\langle\Delta_g\Psi,\Psi\rangle - \mathrm{Re}\langle A\cdot\Psi,\Psi\rangle. \tag{14.40}$$

There is no mixed torsion term because the Chern torsion has type $(2,0)$. Using (14.36), (14.38), and (14.39) in (14.40), Young's inequality absorbs the products of $\sqrt{\mathcal{R}}$ with $|\nabla\Psi| + |\bar\nabla\Psi|$. We obtain

$$\Delta_g\mathcal{R} \ge -CM^N(\mathcal{R}^{3/2}+1). \tag{14.41}$$

Let $s = \mathrm{tr}_\beta\, g$. Direct differentiation as in (14.16) gives

$$\Delta_g s \ge M^{-1}\mathcal{R} - CM, \qquad |\partial s|^2_g \le nM^2\mathcal{R}. \tag{14.42}$$

Take a cutoff ζ supported in B, equal to one on $B_{1/2}$, set $\eta = \zeta^2$ and $h = 2nM - s$, so $nM \le h \le 2nM$, and maximize

$$Q = \frac{\eta\mathcal{R}}{h}.$$

At a positive interior maximum of Q, the identity $\partial\mathcal{R}/\mathcal{R} = \partial h/h - \partial\eta/\eta$ gives

$$0 \ge \frac{\Delta_g Q}{Q} = \frac{\Delta_g\mathcal{R}}{\mathcal{R}} + \frac{\Delta_g\eta}{\eta} - \frac{\Delta_g h}{h} - \frac{2|\partial\eta|^2_g}{\eta^2} + \frac{2\,\mathrm{Re}\langle\partial\eta,\partial h\rangle_g}{\eta h}.$$

We have $|\partial\eta|^2_g \le CM\eta$, $|\Delta_g\eta| \le CM$ and $|\partial h|_g \le \sqrt{n}M\sqrt{\mathcal{R}}$. Insert (14.41) and (14.42) and multiply by ηQ. The positive term is $M^{-1}Q^2$. The two terms involving $\sqrt{\mathcal{R}}$ are bounded in absolute value by a fixed power of M times $Q^{3/2}$, since $\mathcal{R} = hQ/\eta$ and $h \le 2nM$. The remaining cutoff terms are bounded by $CM^N(Q+1)$. Therefore

$$0 \ge M^{-1}Q^2 - CM^N(Q^{3/2}+Q+1).$$

Thus Q, and then $\mathcal{R}$ on $B_{1/2}$, are bounded by a fixed polynomial in M. Since $|\partial g|^2_\beta \le M^3\mathcal{R}$, this proves (14.33).

If $s \le L$, the determinant lower bound gives $\lambda_{\min}(g) \ge (\inf F)L^{1-n}$, so M is a fixed power of $1+L$. For a ball $B_r(p)$, set $u_r(z) = r^{-2}u(p+rz)$ and use the coefficient matrices $\vartheta_r(z) = \vartheta(p+rz)$, $g_r(z) = g(p+rz)$ and $F_r(z) = F(p+rz)$. Then $g_r = \vartheta_r + \mathrm{dd^c}u_r$ in the unit coordinates and $\det g_r = F_r$. For $r \le 1$ the derivatives of the fixed data remain uniformly bounded. The unit-ball estimate for the ordinary coefficient derivatives ∂g_r and their conjugates gives the factor r^{-1} in (14.34). □

Proposition 14.17.8 *There is $\alpha_* < 1$, depending only on n and the exponent N in Proposition 14.17.7, with the following property. Let B_0 be a Euclidean ball, fix a smooth real $(1,1)$-form ϑ and a smooth function $F > 0$ near $\overline{B_0}$, and let u_j be smooth exact solutions of $(\vartheta + \mathrm{dd^c}u_j)^n = F\beta^n$ with $\vartheta + \mathrm{dd^c}u_j > 0$. If*

$$\sup_j \|u_j\|_{C^{1,\alpha}(B_0)} < \infty \qquad \text{for some } \alpha_* < \alpha < 1,$$

then $\mathrm{tr}_\beta(\vartheta + \mathrm{dd^c}u_j)$ is uniformly bounded on every smaller ball.

Proof Fix a center for concentric balls $B_r \Subset B_0$, put $s_j = \mathrm{tr}_\beta(\vartheta + \mathrm{dd^c}u_j)$, and set

$$M_j(r) = 1 + \sup_{B_r} s_j.$$

For concentric balls $B_r \Subset B_R \Subset B_0$, $d = R - r \le 1$, Proposition 14.17.7 gives

$$|\nabla s_j| \le Cd^{-1}M_j(R)^N \quad \text{on } B_{r+d/2}. \tag{14.43}$$

Fix $p \in B_r$ and let χ_h be a nonnegative mollifier of radius $h \le d/4$. Since

$$s_j = \mathrm{tr}_\beta\,\vartheta + \Delta_\beta u_j,$$

integration by parts, after subtracting the constant vector $\nabla u_j(p)$, and the uniform $C^{1,\alpha}$ bound give

$$(s_j * \chi_h)(p) \le C(1 + h^{\alpha-1}).$$

Equation (14.43) gives

$$|s_j(p) - (s_j * \chi_h)(p)| \le Cd^{-1}M_j(R)^N h.$$

Choose

$$h = \frac{d}{4}M_j(R)^{-N/(2-\alpha)}.$$

Taking the supremum over $p \in B_r$ and absorbing fixed powers of d^{-1}, we obtain

$$M_j(r) \le Cd^{-1}M_j(R)^q, \qquad q = \frac{N(1-\alpha)}{2-\alpha}. \tag{14.44}$$

Choose α_* so close to one that $q < 1$ for $\alpha > \alpha_*$. Choose $0 < r_0 < R_0$ with $B_{R_0} \Subset B_0$. Let $r_k \uparrow R_0$ with $r_{k+1} - r_k = (R_0 - r_0)2^{-k-1}$. Iterating (14.44) gives

$$M_j(r_0) \le \prod_{k=0}^{m-1} \left[C(r_{k+1} - r_k)^{-1}\right]^{q^k} M_j(r_m)^{q^m}.$$

The infinite product converges because $\sum q^k(1+k) < \infty$. For each fixed j, the final factor tends to one as $m \to \infty$. The resulting bound is independent of j. □

14.17.6 Proof of the main theorem

We now assemble the four steps outlined after Theorem 14.17.1. The barrier enters only once, but globally: it locates a point of the nonsmooth set at which the quadratic separation required in Proposition 14.17.5 holds.

Proof (of Theorem 14.17.1) If $n = 1$, the equation is the linear identity

$$\mathrm{dd^c}\varphi = c f\, \omega - \theta \quad \text{on } \Omega.$$

Its right-hand side is smooth, so interior elliptic regularity gives $\varphi \in C^\infty(\Omega)$, and the original equation gives $\theta + \mathrm{dd^c}\varphi = c f\, \omega > 0$. We henceforth assume $n \ge 2$.

Let

$$\mathcal{S} = \{p \in \Omega : \varphi \text{ is not smooth on any neighborhood of } p\}.$$

This is closed in Ω. Suppose $\mathcal{S} \neq \varnothing$. By Lemma 1.19.4, the restriction of $\varphi - \rho$ to $\mathcal{S}$ attains its minimum m at some $p \in \mathcal{S}$.

Choose nested coordinate balls

$$B \Subset B_0 \Subset \Omega$$

centered at p. On B_0, Proposition 14.17.4 gives smooth exact Dirichlet solutions u_j converging uniformly to φ at a polynomial rate and having polynomial global trace growth.

On the open set $\Omega \setminus \mathcal{S}$ the function φ is smooth, and $\theta + \mathrm{dd^c}\varphi$ is semipositive with positive determinant, hence positive definite. Proposition 14.17.6 therefore gives a uniform trace bound for the u_j on every compact subset of $B_0 \setminus \mathcal{S}$.

In coordinates centered at p, take $\kappa > 0$ small and set

$$q(z) = \rho(z) - \kappa|z|^2.$$

After shrinking B, the lower bound $\theta + \mathrm{dd^c}\rho \ge \omega$ gives $\theta + \mathrm{dd^c}q > 0$ on $\overline{B}$. If $v = \varphi - q$, then the minimizing property of p gives

$$v(p) = m, \qquad v(z) = (\varphi - \rho)(z) + \kappa|z|^2 \ge m + \kappa|z|^2 \quad (z \in \mathcal{S} \cap \overline{B}).$$

Thus Proposition 14.17.5 applies on B with the closed set $\mathcal{S} \cap \overline{B}$: the approximation rate and global polynomial trace bound come from Proposition 14.17.4, and the bound away from $\mathcal{S}$ comes from Proposition 14.17.6. Its second assertion gives, for every $0 < \alpha < 1$, a neighborhood of p on which the approximants have a uniform $C^{1,\alpha}$ bound.

Choose $\alpha > \alpha_*$ as in Proposition 14.17.8, and apply that proposition on a ball centered at p inside this neighborhood. It yields

$$\sup_j \operatorname{tr}_\beta(\theta + \mathrm{dd^c} u_j) < \infty$$

on a still smaller neighborhood of p. Since $u_j \to \varphi$ uniformly, $\mathrm{dd^c} u_j \to \mathrm{dd^c}\varphi$ as currents. The trace bound passes to the limit, so $\operatorname{tr}_\beta(\theta + \mathrm{dd^c}\varphi)$ has a bounded density near p. Proposition 14.17.2 now implies that φ is smooth near p, contradicting $p \in \mathcal{S}$.

Hence $\mathcal{S} = \varnothing$ and $\varphi \in C^\infty(\Omega)$. The form $\theta + \mathrm{dd^c}\varphi$ is smooth and semipositive there, while

$$(\theta + \mathrm{dd^c}\varphi)^n = c f \, \omega^n > 0.$$

Its nonnegative eigenvalues have positive product, so every eigenvalue is positive. Therefore $\theta + \mathrm{dd^c}\varphi > 0$ on Ω. □

Corollary 14.17.1 *Let $0 \le f \in L^p(X, \omega^n)$, $p > 1$, be smooth and strictly positive on Ω. Every minimal-singularity solution of $(\theta + \mathrm{dd^c}\varphi)^n = c f \, \omega^n$, $c > 0$, is smooth and strictly θ-plurisubharmonic on Ω.*

Proof The analytic complement of Ω has zero mass for both measures, so it suffices to know the equation in the bounded-potential sense on Ω. Apply Theorem 14.16.1 with density $c f$ to obtain local Hölder continuity. All hypotheses of Theorem 14.17.1 are now satisfied. □

By Theorem 14.15.2, such a solution exists, with a uniquely determined $c > 0$. For a smooth closed big representative on a compact Kähler manifold, Theorem 28.10.1 applies this conclusion to the classical full-mass solution and identifies the regular open set with the ample locus.

14.18 Degenerating semipositive backgrounds

Adding a small multiple of a Hermitian form makes a semipositive background strictly positive, and the smooth theory then solves the normalized equation with a smooth positive density. We study these smooth solutions as the added multiple tends to zero. Bounded subsolutions give uniform bounds for the potentials and the normalizing constants, and a strict analytic barrier gives uniform bounds for the trace on compact sets away from its poles. Smooth local convergence then identifies the limiting equation, without any global continuity property of the Monge–Ampère operator.

The main example is a small resolution of a threefold with nodes (Section 14.18.1). There the background is the pullback of a positive form from the singular threefold, and it degenerates exactly along the exceptional curves. When this background is closed, the limit is unique and the whole family converges smoothly away from the exceptional curves. Convergence of the associated metric spaces then reduces to controlling the diameters of neighborhoods of these curves, in the limiting metric and in the approximating metrics (Section 14.18.3).

Throughout this section $n \geq 2$. The background θ, the barrier ρ and its pole set Z are new data, independent of those fixed in Section 14.12. Let $\theta \geq 0$ be a smooth real $(1,1)$-form, and fix a Hermitian form η and a smooth positive probability volume form μ on X. Suppose that there are $\delta > 0$ and $\rho \in \mathrm{PSH}(X,\theta)$ with analytic singularities such that

$$\theta + \mathrm{dd^c}\rho \geq \delta\eta, \qquad \sup_X \rho = 0. \tag{14.45}$$

Write $Z = \{\rho = -\infty\}$ and assume that ρ is smooth on $X \setminus Z$. For $0 < \varepsilon \leq 1$, the form $\theta + \varepsilon\eta$ is Hermitian, and Theorem 9.1.1 gives $u_\varepsilon \in C^\infty(X)$ and $c_\varepsilon > 0$ with

$$\omega_\varepsilon := \theta + \varepsilon\eta + \mathrm{dd^c}u_\varepsilon > 0, \qquad \omega_\varepsilon^n = c_\varepsilon\mu, \qquad \sup_X u_\varepsilon = 0. \tag{14.46}$$

Lemma 14.18.1 *There are constants $b, B, C > 0$, independent of ε, such that*

$$b \leq c_\varepsilon \leq B, \qquad -C \leq u_\varepsilon \leq 0.$$

Proof Write $\mu = f\,\mathrm{d}V$, where f is smooth and positive. The strict barrier makes θ big. By Lemma 14.2.1, there is a bounded $s \in \mathrm{PSH}(X,\theta)$ with $-1 \leq s \leq 0$ and $\mathrm{MA}_\theta(s) \geq b\mu$ for some fixed $b > 0$. If $c_\varepsilon < b$, positivity gives

$$\mathrm{MA}_{\theta+\varepsilon\eta}(u_\varepsilon) \leq (c_\varepsilon/b)\mathrm{MA}_{\theta+\varepsilon\eta}(s + A)$$

for every constant A. Strict bounded domination would imply $u_\varepsilon \geq s + A$ for every A, which is absurd. Hence $c_\varepsilon \geq b$.

For an upper bound, choose a fixed Gauduchon form γ. The arithmetic–geometric mean inequality and Stokes give

$$c_\varepsilon^{1/n} \int_X \left(\frac{\mu}{\gamma^n}\right)^{1/n} \gamma^n \leq \int_X \omega_\varepsilon \wedge \gamma^{n-1} = \int_X (\theta + \varepsilon\eta) \wedge \gamma^{n-1} \leq \int_X (\theta + \eta) \wedge \gamma^{n-1}.$$

The first integral is fixed and positive, giving $c_\varepsilon \leq B$.

For the lower bound on u_ε, note that all u_ε are normalized $(\theta+\eta)$-plurisubharmonic functions. Uniform exponential integrability, Lemma 1.5.1, gives $a > 0$ such that $g_\varepsilon = \mathrm{e}^{-au_\varepsilon} f$ has a common L^2 bound. Also $g_\varepsilon \geq f$. By Theorem 14.2.1, the solutions

$$w_\varepsilon \in \mathrm{PSH}(X,\theta), \qquad \mathrm{MA}_\theta(w_\varepsilon) = \mathrm{e}^{aw_\varepsilon} g_\varepsilon\,\mathrm{d}V$$

are uniformly bounded. Put $B_0 = \max\{1, B\}$ and $z_\varepsilon = w_\varepsilon - a^{-1}\log B_0$. Then

$$\mathrm{MA}_{\theta+\varepsilon\eta}(z_\varepsilon) \geq \mathrm{e}^{a z_\varepsilon} c_\varepsilon g_\varepsilon \, \mathrm{d}V, \qquad \mathrm{MA}_{\theta+\varepsilon\eta}(u_\varepsilon) = \mathrm{e}^{a u_\varepsilon} c_\varepsilon g_\varepsilon \, \mathrm{d}V.$$

The comparison principle for the exponential equation in the background $\theta + \varepsilon\eta$ gives $z_\varepsilon \leq u_\varepsilon \leq 0$, and z_ε is bounded below uniformly in ε. □

Since θ may degenerate along Z, we do not estimate the trace by local arguments. Instead we apply the maximum principle on all of $X \setminus Z$ to the logarithm of the trace minus a multiple of $u_\varepsilon - \rho$. This function tends to $-\infty$ at Z, so its maximum is attained off Z, where $\theta + \mathrm{dd^c}\rho \geq \delta\eta$ provides positivity. An additional logarithmic term in the weight absorbs the torsion term without a gradient bound for ρ.

Lemma 14.18.2 *For every compact $K \Subset X \setminus Z$, there is $C_K > 1$, independent of ε, such that*

$$C_K^{-1}\eta \leq \omega_\varepsilon \leq C_K \eta \quad \text{on } K.$$

Proof For the differentiated calculation write $U = u_\varepsilon/(2\pi)$ and $P = \rho/(2\pi)$, so that $\mathrm{dd^c} u_\varepsilon = \mathrm{i}\partial\bar\partial U$. Put

$$S = \mathrm{tr}_\eta \, \omega_\varepsilon, \quad R = \mathrm{tr}_{\omega_\varepsilon} \eta, \quad D = \omega_\varepsilon^n/\eta^n.$$

The previous lemma and the smooth positive density give $0 < d_1 \leq D \leq d_2$. Choose a fixed C_0 so that $v = U - P + C_0 > 1$, and set

$$H = \log S - \gamma(v), \qquad \gamma(v) = Av + \log v,$$

where A will be fixed below. For each ε, S is smooth on X and v tends to infinity at Z. Thus $H \to -\infty$ there, and H attains its maximum on $X \setminus Z$. We bound this maximum independently of ε.

In local holomorphic coordinates, h and g denote the coefficient matrices of η and ω_ε with respect to $\mathrm{i}\,\mathrm{d}z_j \wedge \mathrm{d}\bar z_k$, and commas denote coordinate derivatives, as in $h_{i\bar j,k} = \partial_k h_{i\bar j}$ and $h_{i\bar j,\bar k} = \partial_{\bar k} h_{i\bar j}$. At a maximum point choose holomorphic coordinates in which

$$h_{i\bar j} = \delta_{ij}, \qquad h_{i\bar i,k} = 0, \qquad g_{i\bar j} = \lambda_i \delta_{ij}.$$

A linear change first normalizes h and diagonalizes g. In these coordinates, the quadratic change $z_i = w_i + \frac{1}{2}\sum_{j,k} a^i_{jk} w_j w_k$, with symmetric coefficients chosen so that $a^i_{ik} = -h_{i\bar i,k}$, then kills $h_{i\bar i,k}$. Its coefficients are uniformly bounded on a fixed finite cover. Write

$$\Delta_g = \sum_i \lambda_i^{-1} \partial_i \partial_{\bar i}, \quad T_{ij\bar k} = g_{j\bar k,i} - g_{i\bar k,j}, \quad E_i = \sum_j T_{ij\bar j}.$$

The lowered torsion coefficients $T_{ij\bar k}$ and their first derivatives are uniformly bounded: the potential Hessian cancels, leaving only derivatives of $\theta + \varepsilon\eta$.

Let μ_{loc} be the density of μ with respect to the coordinate volume form. Differentiating $S = h^{k\bar\ell} g_{k\bar\ell}$ and the equation $\log\det g = \log c_\varepsilon + \log \mu_{\mathrm{loc}}$ gives

$$\Delta_g S \geq Q - CRS - CR, \qquad Q = \sum_{i,j} \frac{|g_{i\bar{j},j}|^2}{\lambda_i \lambda_j}. \tag{14.47}$$

The second derivatives of g contribute $\sum_{i,j,k} |g_{i\bar{j},k}|^2/(\lambda_i\lambda_j)$, up to $-CR - C$, by commuting the potential derivatives. The first derivatives of h contribute $-2\,\mathrm{Re}\sum_{i,j,k} \lambda_i^{-1} h_{j\bar{k},\bar{i}} g_{k\bar{j},i}$. Its terms with $j = k$ vanish. Replace $g_{k\bar{j},i}$ by $g_{i\bar{j},k} + T_{ik\bar{j}}$ and apply weighted Cauchy–Schwarz. This consumes exactly the terms of the preceding square with $j \neq k$ and costs at most $CRS + CR$. The second derivatives of h^{-1} cost CRS. Finally the fixed density term $-C$ is absorbed using $SR \geq n^2$.

Since $\partial_i S = \sum_j g_{i\bar{j},j} + E_i$ at the maximum point, weighted Cauchy–Schwarz also gives

$$|\partial S|_g^2 \leq SQ + 2\,\mathrm{Re}\langle E, \partial S\rangle_g.$$

Indeed expand around $\partial S - E$ and discard the resulting term $-|E|_g^2$. Combining with (14.47) yields

$$\Delta_g \log S \geq -CR - CR/S - \frac{2}{S}\,\mathrm{Re}\langle E, \partial \log S\rangle_g.$$

At the maximum, $\partial \log S = \gamma' \partial v$. Moreover (14.45) gives $\Delta_g v \leq n - \delta R$, and $|E|_g^2 \leq CR$. Young's inequality with the positive coefficient $-\gamma'' = v^{-2}$ therefore gives

$$0 \geq \Delta_g H \geq (\delta\gamma' - C)R - n\gamma' - CR/S - \frac{CR}{S^2}\frac{\gamma'^2}{-\gamma''}.$$

Since $\gamma' = A + v^{-1}$, choose A with $\delta A - C \geq 1$. The resulting inequality is

$$0 \geq R - C\left(1 + \frac{R}{S} + \frac{R(1+v^2)}{S^2}\right). \tag{14.48}$$

All constants are independent of ε.

If the maxima of H were unbounded, then at a sequence of maximizing points

$$\log(S/v) = H + Av \longrightarrow +\infty.$$

Thus $S/v \to \infty$ and $S \to \infty$. Inequality (14.48) would imply $R \leq 2C$ along this sequence. But

$$S = D\sum_i \prod_{j\neq i} \lambda_j^{-1} \leq nDR^{n-1} \leq nd_2(2C)^{n-1},$$

a contradiction. Hence H is uniformly bounded. On K, both U and P are bounded, so $S \leq C_K$. The determinant lower bound then gives $\lambda_i \geq d_1/C_K^{n-1}$, completing the proof. □

Theorem 14.18.1 *In the preceding setting, c_ε decreases to a positive number c_0 as $\varepsilon \downarrow 0$. This number is independent of the perturbing Hermitian form η. For every sequence $\varepsilon_j \downarrow 0$, a subsequence satisfies*

$$u_{\varepsilon_j} \longrightarrow u_0 \quad \text{in } L^1(X) \cap C^\infty_{\mathrm{loc}}(X \setminus Z),$$

where $u_0 \in \mathrm{PSH}(X,\theta) \cap L^\infty(X)$, $\sup_X u_0 = 0$, and

$$\mathrm{MA}_\theta(u_0) = c_0 \mu.$$

If θ is closed, then $c_0 = \int_X \theta^n$.

Proof *Monotonicity of the constants.* Let $\alpha \le \beta$ be Hermitian forms, and let (u_α, c_α) and (u_β, c_β) be the normalized smooth solutions of $(\alpha + \mathrm{dd^c} u_\alpha)^n = c_\alpha \mu$ and $(\beta + \mathrm{dd^c} u_\beta)^n = c_\beta \mu$. At a maximum point of $u_\alpha - u_\beta$,

$$\alpha + \mathrm{dd^c} u_\alpha \le \beta + \mathrm{dd^c} u_\beta,$$

so $c_\alpha \le c_\beta$. Hence c_ε decreases as $\varepsilon \downarrow 0$, and Lemma 14.18.1 gives $c_0 \ge b > 0$. Write $c_\eta(\varepsilon)$ for the constant c_ε defined with the perturbation η. For two perturbations with $M^{-1}\eta_1 \le \eta_2 \le M\eta_1$, the same comparison gives

$$c_{\eta_1}(\varepsilon/M) \le c_{\eta_2}(\varepsilon) \le c_{\eta_1}(M\varepsilon).$$

Letting $\varepsilon \downarrow 0$ shows that c_0 does not depend on η.

Local estimates. The trace bound of Lemma 14.18.2 gives uniform ellipticity on compact subsets of $X \setminus Z$. The smooth coefficients of $\theta + \varepsilon\eta$ and all derivatives of $\log \mu_{\mathrm{loc}}$ have common bounds there. Interior complex Evans–Krylov and Schauder estimates, as in the ellipticity argument of Proposition 14.17.2, give uniform C^k bounds on smaller compact subsets for every k.

Convergence and the limiting equation. Normalized compactness in the fixed background $\theta + \eta$, followed by a diagonal extraction over an exhaustion of $X \setminus Z$, gives the stated convergence. The uniform bound $-C \le u_\varepsilon \le 0$ passes to the canonical limit, and normalized compactness preserves the supremum zero. Current convergence gives $\theta + \mathrm{dd^c} u_0 \ge 0$, and smooth convergence identifies the equation on $X \setminus Z$. The bounded non-pluripolar measure $\mathrm{MA}_\theta(u_0)$ and the smooth measure μ both vanish on the analytic set Z. This proves the equation on all of X. For closed θ, bounded closed-background Stokes gives $\int_X \mathrm{MA}_\theta(u_0) = \int_X \theta^n$, proving the last assertion. □

Since $\theta \ge 0$ is nef, Theorem 26.10.1 identifies c_0 with the Gauduchon variational volume $\mathcal{V}_\mu(\theta)$. The proof uses no bound on Monge–Ampère masses: all estimates concern the solutions for the fixed smooth density μ. If the bounded normalized limiting equation has a unique solution, all cluster limits coincide, and the whole family converges in $L^1(X) \cap C^\infty_{\mathrm{loc}}(X \setminus Z)$.

14.18.1 Small resolutions of nodes

The pullback of a positive form from a singular space loses positivity along the contracted curves. In the standard small resolution of a node, the logarithm of the norm in the normal bundle of the exceptional curve provides the missing curvature along the curve. Cutting this logarithm off where the pullback is already positive gives a global strict barrier, so the results above apply.

Assume now $n = 3$. Let Y be a connected compact normal complex threefold, smooth outside a finite set Σ of nodes. A node is locally the hypersurface

$$\{x_1x_4 - x_2x_3 = 0\} \subset \mathbb{C}^4.$$

Let $\pi : X \to Y$ be a proper holomorphic map that is biholomorphic over $Y \setminus \Sigma$. Assume each local resolution is the standard small resolution: a neighborhood of its exceptional curve is identified with a neighborhood of the zero section of

$$\mathcal{O}_{\mathbb{P}^1}(-1) \oplus \mathcal{O}_{\mathbb{P}^1}(-1),$$

and the contraction, in bundle coordinates (z, y_1, y_2), is

$$\pi(z, y_1, y_2) = (y_1, zy_1, y_2, zy_2). \tag{14.49}$$

Interchanging the two rulings gives the other standard model. Write $E = \pi^{-1}(\Sigma)$; its components E_j are disjoint copies of $\mathbb{P}^1$.

Fix a positive form ω_Y on Y in the local embedding sense: in each ambient chart it is induced by a smooth strictly positive real $(1,1)$-form. Set $\theta = \pi^*\omega_Y$, and let η be an arbitrary Hermitian form on X.

Lemma 14.18.3 *The form θ is smooth and semipositive, positive on $X \setminus E$. There are $\delta > 0$ and $\rho \in \mathrm{PSH}(X, \theta)$ with analytic poles precisely on E, smooth on $X \setminus E$, such that*

$$\sup_X \rho = 0, \qquad \theta + \mathrm{dd}^{\mathrm{c}}\rho \geq \delta\eta.$$

Proof Smoothness and positivity off E follow from the pullback and the biholomorphism. In one standard model put

$$r^2 = (1 + |z|^2)(|y_1|^2 + |y_2|^2), \qquad b = \mathrm{dd}^{\mathrm{c}} \log(1 + |z|^2).$$

The function r^2 is the sum of the squared absolute values of the four contracted coordinates. It is therefore globally defined on the bundle; b is the pullback of the Fubini–Study form from its base. In the chart (14.49),

$$\mathrm{dd}^{\mathrm{c}} \log r^2 = b + \mathrm{dd}^{\mathrm{c}} \log(|y_1|^2 + |y_2|^2) \geq b. \tag{14.50}$$

This is an inequality of currents across the zero section as well as a smooth inequality off it.

Ambient positivity gives $\theta \geq c\mathrm{dd}^{\mathrm{c}} r^2$ on a sufficiently small tube, for some $c > 0$. The smooth form $\mathrm{dd}^{\mathrm{c}} r^2 + b$ is positive definite there. Indeed the contraction is an immersion off the zero section, and on that section $\mathrm{dd}^{\mathrm{c}} r^2$ is positive in both fiber directions while b is positive along the base. Compactness of the zero section and a smaller closed tube give a uniform lower bound by a positive multiple of η. Thus, for every fixed $a > 0$,

$$\theta + a\mathrm{dd}^{\mathrm{c}} \log r^2 \geq c\mathrm{dd}^{\mathrm{c}} r^2 + ab \geq \delta_a \eta$$

near the zero section, with $\delta_a > 0$.

Choose disjoint model tubes with nonempty complement and numbers $0 < t_1 < t_2 < 1$ in each. Let $0 \leq \chi \leq 1$ be a smooth cutoff of r^2, equal to one for $r^2 \leq t_1$ and zero for $r^2 \geq t_2$. Extend $\chi(r^2) \log r^2$ by zero outside its tube. On the compact transition annuli, the pullback θ is uniformly positive and the second derivatives of this cutoff potential are bounded. A sufficiently small positive rational a therefore makes

$$\rho = a \sum_j \chi_j(r_j^2) \log r_j^2$$

satisfy $\theta + \mathrm{dd}^{\mathrm{c}} \rho \geq \delta\eta$ there and near every E_j. On the remaining compact set, $\rho = 0$ and θ is positive, so decreasing δ proves the global inequality. Near E_j the function is $a \log(|y_1|^2 + |y_2|^2) + a \log(1 + |z|^2)$, hence has analytic singularities with rational coefficient and pole set exactly E_j. It is smooth elsewhere and nonpositive; its zero extension gives supremum zero. If E is empty, take $\rho = 0$ and use the positivity of θ on compact X. □

Corollary 14.18.1 *For the preceding geometric data and every smooth positive probability volume form μ on X, the solutions of* (14.46) *have the bounds and subsequential convergence of Theorem 14.18.1, with $Z = E$. Moreover, for each exceptional curve,*

$$\int_{E_j} \omega_\varepsilon = \varepsilon \int_{E_j} \eta \longrightarrow 0.$$

Proof Apply the theorem using Lemma 14.18.3. Since π contracts E_j, the restriction of θ to it is zero. Stokes on the compact smooth curve gives $\int_{E_j} \mathrm{dd}^{\mathrm{c}} u_\varepsilon = 0$, proving the area identity. □

When K_X is torsion, the density can be chosen so that these metrics are Chern–Ricci flat. Recall that the Chern–Ricci form $\mathrm{Ric}^{\mathrm{Ch}}(\omega)$ of a Hermitian metric ω is $-\mathrm{i}\partial\bar{\partial}$ of the logarithm of the density of ω^n with respect to a coordinate volume form. Choose a nowhere vanishing holomorphic section of $K_X^{\otimes m}$ for some $m \geq 1$. If its local expression is $f(\mathrm{d}z_1 \wedge \mathrm{d}z_2 \wedge \mathrm{d}z_3)^{\otimes m}$, use $|f|^{2/m}$ as the density relative to the standard coordinate volume form. The coordinate Jacobians cancel, so this defines a smooth positive volume form on X; normalize it to total mass one and take it as μ. Its logarithmic density is pluriharmonic. Applying $-\mathrm{i}\partial\bar{\partial}$ log to $\omega_\varepsilon^3 = c_\varepsilon \mu$ therefore gives $\mathrm{Ric}^{\mathrm{Ch}}(\omega_\varepsilon) = 0$, and the same holds for the smooth limiting metric on $X \setminus E$.

14.18.2 Measures and bounded potentials at a node

We keep the standard small resolution $\pi : X \to Y$ and a smooth positive probability volume form μ on X. Write $\mu_Y = \pi_*\mu$, and let ν_Y be ω_Y^3 on the regular locus, extended by zero at the nodes. The pullback of the ambient volume form ω_Y^3 vanishes along the exceptional curves, and its order of vanishing determines the integrability of the density of μ_Y with respect to ν_Y.

Lemma 14.18.4 *The measures μ_Y and ν_Y are finite and give the nodes zero mass. There is a positive density F with $\mu_Y = F\nu_Y$. If Σ is nonempty, then for $1 \le p < \infty$,*

$$F \in L^p(Y, \nu_Y) \quad \Longleftrightarrow \quad p < 3.$$

At each node, F is comparable to r^{-2}, where $r^2 = \sum_{j=1}^4 |x_j|^2$ in the local model $\{x_1x_4 - x_2x_3 = 0\}$ of the node. There are $c, C, T_0 > 0$ such that

$$cT^{-3} \le \nu_Y(\{F > T\}) \le CT^{-3} \qquad (T \ge T_0).$$

Thus the endpoint is weak L^3, with $F \notin L^3$. If Σ is empty, F is smooth and bounded.

Proof The map is biholomorphic off E, and both smooth measures μ and θ^3 give E zero mass. Hence $\nu_Y = \pi_*\theta^3$ is finite, μ_Y has no node atom, and on the regular locus

$$F \circ \pi = \mu/\theta^3.$$

In the chart (14.49), put $h = 1 + |z|^2$ and $s = |y_1|^2 + |y_2|^2$, so $r^2 = hs$. The fiber block of the complex Hessian of r^2 is h times the identity, and its Schur complement is s/h. Consequently

$$\det\big((r^2)_{j\bar{k}}\big) = hs = r^2, \qquad \frac{(\mathrm{dd^c} r^2)^3}{3!} = \frac{r^2}{\pi^3}\,\mathrm{d}\lambda_6, \tag{14.51}$$

where λ_6 is Euclidean volume in (z, y_1, y_2). Ambient positivity bounds θ above and below by positive multiples of $\mathrm{dd^c} r^2$ on a smaller tube. The smooth density of μ is bounded above and below there. On compact subcharts covering the base $\mathbb{P}^1$, it follows that

$$\theta^3 \asymp r^2\,\mathrm{d}\lambda_6, \qquad F \circ \pi \asymp r^{-2}.$$

The other bundle chart gives the same comparison, since r is the norm of the contracted coordinates.

On each bounded base subchart, r is comparable to the Euclidean radius R in the two complex fiber variables. Up to fixed positive constants, the contribution to $\int F^p\,\mathrm{d}\nu_Y$ is therefore

$$\int_0^{R_0} R^{2-2p} R^3\,\mathrm{d}R = \int_0^{R_0} R^{5-2p}\,\mathrm{d}R.$$

Two compact base subcharts give the upper estimate; a fixed open base subchart gives the lower estimate. The integral is finite precisely when $p < 3$, and diverges logarithmically at $p = 3$. Away from the finitely many nodes the density is smooth. The same comparisons give $\nu_Y(\{r < t\}) \asymp t^6$ near a node. The two bounds for F sandwich $\{F > T\}$ between such tubes of radii comparable to $T^{-1/2}$, proving the endpoint estimate. □

The descent theorem Theorem A.2.1 applies to the normal space Y and its resolution π, also when the ambient background is not closed. Every bounded θ-plurisubharmonic function is therefore constant on each exceptional curve and is the pullback of a unique bounded ω_Y-plurisubharmonic function. In particular each cluster limit has the form $u_0 = \psi_0 \circ \pi$, with $\sup_Y \psi_0 = 0$. Let $\mathrm{MA}^{\mathrm{ext}}_{Y,\omega_Y}$ be the extended Monge–Ampère measure on Y, defined in (A.7) as the pushforward of the extended measure of the pullback to a resolution; it does not depend on the resolution. Then

$$\mathrm{MA}^{\mathrm{ext}}_{Y,\omega_Y}(\psi_0) = c_0\mu_Y = c_0 F \nu_Y. \tag{14.52}$$

The equality holds also at the nodes, since both measures give them zero mass. Thus ψ_0 is a bounded solution of an equation on the singular space; nothing is claimed about its continuity at a node.

Theorem 14.18.2 *Suppose additionally that θ is closed. The equation*

$$\mathrm{MA}_\theta(u) = c\mu, \qquad u \in \mathrm{PSH}(X,\theta) \cap L^\infty(X), \qquad \sup_X u = 0,$$

has a unique pair (c, u) with $c > 0$. Its scalar is $c = c_0 = \int_X \theta^3$. The entire family u_ε converges to u in $L^1(X)$ and smoothly on compact subsets of $X \setminus E$. The limit is independent of η, and its descended potential is the unique bounded normalized solution of (14.52).

Proof Existence follows from Corollary 14.18.1. For uniqueness we use an energy identity, which is available because θ is closed. Fix one cluster limit u_0 and put $A = \theta + \mathrm{dd^c} u_0$. This is a positive closed current with bounded local potentials, smooth and strictly positive on $X \setminus E$ by the trace bounds. If v is another bounded solution with scalar c, bounded closed-background Stokes gives $c = \int_X \theta^3 = c_0$. Put $B = \theta + \mathrm{dd^c} v$ and $w = v - u_0$. The bounded integration-by-parts calculus of Section 1.6 gives

$$0 = \int_X w(B^3 - A^3) = -\sum_{j=0}^{2} \int_X \mathrm{d}w \wedge \mathrm{d^c} w \wedge B^j \wedge A^{2-j}.$$

All three energies are nonnegative, so each of them vanishes, in particular the one with A^2. On every relatively compact chart of $X \setminus E$, the smooth positive factor A^2 controls the weak gradient of w, so $\mathrm{d}w = 0$ there. The complement of a proper complex analytic subset in the connected manifold X is connected. Thus w is constant almost everywhere off E. Since E has ordinary volume zero, canonical almost-everywhere

equality of quasi-plurisubharmonic functions, Lemma 1.3.3, gives $v = u_0 + C$ on all of X. Normalization fixes $C = 0$.

The compactness and smooth local estimates of Theorem 14.18.1 now make every subsequential limit equal to u_0, proving convergence of the whole family. The equation and its unique normalized solution do not depend on η. Descent and the zero exceptional mass identify bounded solutions upstairs and downstairs, proving the final assertion. □

14.18.3 Distances across finitely many contracting regions

On the small resolutions above, the potential limit for a closed background gives smooth convergence of the metrics away from the exceptional curves. Global distances, however, are also affected by paths through neighborhoods of these curves, so their convergence requires control of the diameters of such neighborhoods. The criterion of Proposition 14.18.1 separates the two controls: uniform convergence on compact subsets of the regular part, and small diameters of neighborhoods of the contracted sets, in the limiting metric and uniformly in the approximating metrics. We first recall the Gromov–Hausdorff distance.

Definition 14.18.1 For nonempty subsets E, F of a metric space (W, d_W), their Hausdorff distance is

$$d_{\mathrm{H}}^{W}(E,F) = \max\left\{ \sup_{x\in E}\inf_{y\in F} d_W(x,y), \sup_{y\in F}\inf_{x\in E} d_W(x,y) \right\}.$$

For nonempty bounded metric spaces E, F, put

$$d_{\mathrm{GH}}(E,F) = \inf_{W,\iota,\jmath} d_{\mathrm{H}}^{W}(\iota(E),\jmath(F)),$$

where $\iota, \jmath$ are isometric embeddings into a common metric space W. A correspondence is a subset $R \subset E \times F$ whose two coordinate projections are surjective. Its distortion is

$$\operatorname{dis} R = \sup_{(x,y),(x',y')\in R} |d_E(x,x') - d_F(y,y')|.$$

Lemma 14.18.5 *For any correspondence R between nonempty bounded metric spaces,*

$$\frac{1}{2}|\operatorname{diam} E - \operatorname{diam} F| \le d_{\mathrm{GH}}(E,F) \le \frac{1}{2}\operatorname{dis} R.$$

Proof Choose $\varepsilon > 0$ with $2\varepsilon \ge \operatorname{dis} R$. Give the disjoint union $E \sqcup F$ its original distances within each space, and use the symmetric cross distance

$$D(x,y) = \inf_{(x_0,y_0)\in R}\bigl(d_E(x,x_0) + \varepsilon + d_F(y_0,y)\bigr), \qquad x \in E,\ y \in F.$$

It is finite and at least ε. The triangle inequalities involving one cross distance follow from the triangle inequality within the corresponding space and the infimum. For two cross distances, take $(x_0,y_0), (x_1,y_1) \in R$. The distortion bound gives

$$\begin{aligned} d_E(x,x') &\le d_E(x,x_0) + d_F(y_0,y_1) + 2\varepsilon + d_E(x_1,x') \\ &\le d_E(x,x_0) + d_F(y_0,y) + \varepsilon + \varepsilon + d_F(y,y_1) + d_E(x_1,x'). \end{aligned}$$

Taking the two infima gives $d_E(x,x') \le D(x,y) + D(y,x')$. The same argument with E, F exchanged treats the other case. Hence D is a metric extending both metrics. Each point has a correspondent at cross distance ε, so the Hausdorff distance between E and F in $(E \sqcup F, D)$ is at most ε. Letting ε decrease to half the distortion proves the upper bound, including zero distortion.

For the lower bound, suppose two isometric images have Hausdorff distance h. For every $\delta > 0$, two points in the first image have points in the second within $h + \delta$. Their distance is at most $\operatorname{diam} F + 2h + 2\delta$. Taking the supremum and then $\delta \downarrow 0$ gives $\operatorname{diam} E \le \operatorname{diam} F + 2h$. Exchanging the images and taking the infimum over embeddings proves the lower bound. □

We now work in a purely metric setting, which contains the nodal one. Let Y be a compact metrizable space and let $S = \{s_1, \dots, s_N\} \subset Y$ be finite. Assume $Y^\circ = Y \setminus S$ is a dense connected smooth manifold. Let g_0 be a smooth Riemannian metric on Y°, and denote its intrinsic length distance by d_0.

Lemma 14.18.6 *Suppose every s_a has a neighborhood basis of open sets $V_{a,r}$ such that*

$$\lim_{r\downarrow 0} \operatorname{diam}_{d_0}(V_{a,r} \setminus S) = 0.$$

Then the metric completion $(\widehat{Y}, \widehat{d_0})$ of (Y°, d_0) is compact, and the identity on Y° extends to a homeomorphism $\iota : Y \to \widehat{Y}$.

Proof The neighborhoods can be chosen nested, with closures avoiding the other points of S. Every sequence of regular points converging to s_a is d_0-Cauchy: its tail lies in each prescribed neighborhood, whose punctured diameter tends to zero. Interleaving two such sequences shows that they define the same completion point, denoted by $\widehat{s}_a$. Density of Y° guarantees the existence of these sequences.

For each prescribed positive diameter, remove sufficiently small neighborhoods of all the points of S. Their complement is a compact subset of Y° and hence is totally

bounded for d_0. The removed punctured neighborhoods each have the prescribed small diameter. Thus Y° is totally bounded, and its completion is compact.

The points $\widehat{s}_a$ are distinct from one another and from the regular points. To see this, fix s_a and a different point $y \in Y$. Choose an open neighborhood V of s_a whose closure avoids y and $S \setminus \{s_a\}$, and choose $W \Subset V$ containing s_a. There is a smooth function χ on Y°, equal to one on $W \setminus S$ and zero outside V, whose derivative has compact support in Y°. Indeed the transition takes place in the compact regular set $\overline{V} \setminus W$, where smooth cutoffs exist. Therefore $|\mathrm{d}\chi|_{g_0} \le C$ for some finite C. Integration along curves gives

$$|\chi(p) - \chi(q)| \le C d_0(p,q), \qquad p, q \in Y^\circ.$$

The Lipschitz extension of χ to the completion has value one at $\widehat{s}_a$ and zero at the regular point y, or at $\widehat{s}_b$ if $y = s_b$. This proves the assertion.

Define ι by the identity on the regular locus and by $\iota(s_a) = \widehat{s}_a$. The intrinsic distance induces the smooth topology at each regular point. At s_a, adjoining $\widehat{s}_a$ to a punctured neighborhood does not increase its diameter, so the diameter hypothesis proves continuity of ι. Every completion point is represented by a Cauchy sequence in Y°. Compact metrizability of Y gives a subsequence converging topologically either to a regular point or to some s_a; the preceding arguments give its metric limit. Hence ι is surjective as well as injective. A continuous bijection from compact Y to Hausdorff $\widehat{Y}$ is a homeomorphism. □

Let X be a compact connected smooth manifold and let $\pi : X \to Y$ be a continuous surjection, with $E = \pi^{-1}(S)$ and with $\pi : X \setminus E \to Y^\circ$ a diffeomorphism. Assume that the identity of Y° extends to a homeomorphism $\iota : Y \to \widehat{Y}$, for instance under the hypothesis of Lemma 14.18.6, and write $G = \iota \circ \pi$. For a smooth Riemannian metric g on X and an open subset U, let $\operatorname{diam}^{\mathrm{int}}(U, g)$ denote the intrinsic diameter of U, computed with the lengths of piecewise smooth curves contained in U.

Proposition 14.18.1 *Let g_j be smooth Riemannian metrics on X such that $g_j \to \pi^* g_0$ uniformly on every compact subset of $X \setminus E$. Suppose each s_a has a nested neighborhood basis $V_{a,r}$, with $U_{a,r} = \pi^{-1}(V_{a,r})$, satisfying*

$$\lim_{r \downarrow 0} \operatorname{diam}_{\widehat{d}_0}(\iota(V_{a,r})) = 0, \qquad \lim_{r \downarrow 0} \limsup_{j \to \infty} \operatorname{diam}^{\mathrm{int}}(U_{a,r}, g_j) = 0.$$

Then, for the global length distances d_j of g_j,

$$\lim_{j \to \infty} \sup_{x, x' \in X} |d_j(x,x') - \widehat{d}_0(G(x), G(x'))| = 0.$$

Consequently (X, d_j) converges to $(\widehat{Y}, \widehat{d}_0)$ in Gromov–Hausdorff distance.

Proof If S is empty, uniform metric comparison on compact X proves the distance convergence. Assume $N \ge 1$. Fix $\tau > 0$. Choose pairwise disjoint neighborhoods V_a from the specified bases with

$$\operatorname{diam}_{\widehat{d}_0}(\iota(V_a)) < \tau, \qquad \operatorname{diam}^{\mathrm{int}}(U_a, g_j) < \tau$$

for all sufficiently large j, where $U_a = \pi^{-1}(V_a)$. Pick $q_a \in V_a \setminus S$, and then choose open neighborhoods W_a of s_a with $\overline{W}_a \subset V_a$ and $q_a \notin \overline{W}_a$. The regular cores

$$K_Y = Y \setminus \bigcup_a W_a, \qquad K_X = \pi^{-1}(K_Y)$$

are compact and identified by π. Uniform convergence and positivity of g_0 on this core give numbers $A_j \geq 1$, with $A_j \to 1$, such that lengths of curves contained in the cores compare in both directions by the factor A_j.

Consider a piecewise smooth path in Y° joining two points of K_Y. The preimages of the closed sets $\overline{W}_a$ are compact subsets of its parameter interval. At its first visit to any such set, delete the portion from that visit through its last visit to the same set. Resume with the remaining tail. That set is never visited again; thus there are at most N deleted portions. Each retained segment lies in K_Y, and each deleted portion has endpoints in a single $\overline{W}_a \subset V_a$. The lifts of those endpoints can be joined in U_a with g_j-length less than τ, up to an arbitrarily small error. Applying this procedure to almost minimizing paths, comparing retained lengths, and letting the errors tend to zero gives, for $x, x' \in K_X$,

$$d_j(x, x') \leq A_j \widehat{d}_0(G(x), G(x')) + N\tau.$$

Conversely start with an almost minimizing g_j-path in X and apply the same deletion procedure to the closed sets $\pi^{-1}(\overline{W}_a)$. Project its retained segments, which avoid E, to K_Y. The two images of each deleted portion have completion distance less than τ. The triangle inequality in $\widehat{Y}$ therefore gives

$$\widehat{d}_0(G(x), G(x')) \leq A_j d_j(x, x') + N\tau, \qquad x, x' \in K_X.$$

For any $x \notin K_X$ with $\pi(x) \in W_a$, replace x by $p = \pi^{-1}(q_a) \in U_a \cap K_X$. Then $d_j(x, p) < \tau$ and $\widehat{d}_0(G(x), G(p)) < \tau$. Leave points of K_X fixed. Replacing both endpoints extends the two inequalities to all $x, x' \in X$, with the same error

$$C_j = (N + 2 + 2A_j)\tau.$$

If $D = \operatorname{diam}(\widehat{Y}, \widehat{d}_0)$, the first inequality gives $\operatorname{diam}(X, d_j) \leq A_j D + C_j$. The positive and negative distance errors are consequently bounded by

$$(A_j - 1)D + C_j, \qquad (A_j - 1)(A_j D + C_j) + C_j,$$

respectively. Their upper limits are at most $(N + 4)\tau$. Letting $\tau \downarrow 0$ proves uniform convergence.

The graph of G is a correspondence between X and $\widehat{Y}$, and its distortion b_j for the distances d_j and $\widehat{d}_0$ is the supremum in the statement. By Lemma 14.18.5,

$$d_{\mathrm{GH}}((X,d_j),(\widehat{Y},\widehat{d}_0)) \le b_j/2 \longrightarrow 0.$$

For the standard nodal small resolutions of Section 14.18.1 with closed θ, the smooth convergence of the whole family off E in Theorem 14.18.2 gives the uniform convergence on compact subsets of $X \setminus E$ required in Proposition 14.18.1. What remains are the two conditions on the diameters of neighborhoods. The next estimates control the approximating neighborhoods by metric bounds along and normal to the exceptional curves.

14.18.3.1 Curve areas and radial tube lengths

The approximating metrics give each exceptional curve an area tending to zero, by Corollary 14.18.1. Along the curve, small area forces small diameter as long as the metrics are bounded above; in the normal directions, an integrable bound for the speed of radial rays has the same effect.

Let C be a connected compact Riemann surface. Fix a smooth Hermitian metric h of area one on C, and use the associated Riemannian metrics for lengths and areas.

Lemma 14.18.7 *There is $K_h > 0$ such that every smooth Hermitian metric $g \le Mh$, with $M > 0$ and $A = \mathrm{Area}_g(C)$, satisfies*

$$\mathrm{diam}(C,g) \le K_h\sqrt{A\big(1+\log(M/A)\big)}.$$

Here $0 < A \le M$. In particular, for a fixed upper bound M, area tending to zero implies diameter tending to zero.

Proof Replace g by g/M. Its area is $a = A/M \le 1$, and it is bounded above by h. We prove the estimate for this normalized metric.

Choose a finite cover by holomorphic coordinate disks U_i represented by $\{|z| < 1\}$, with each coordinate defined on the larger disk $\{|z| < 2\}$. Write $g = \rho_i|\mathrm{d}z|^2$ there. There is a common $L > 0$ such that $0 < \rho_i \le L$ on all the closed unit disks, and

$$\int_{U_i} \rho_i \,\mathrm{d}\lambda_2 \le a,$$

where λ_2 is Euclidean area. For $p, z \in U_i$, let $\ell_p(z)$ be the g-length of their straight coordinate segment, which stays in U_i. Polar coordinates about p and Fubini give

$$\int_{U_i} \ell_p(z)\,\mathrm{d}\lambda_2(z) \le 2\int_{U_i} \frac{\sqrt{\rho_i(w)}}{|w-p|}\,\mathrm{d}\lambda_2(w).$$

Indeed each ray meets the convex unit disk in an interval of length $R \le 2$. Interchanging the radial integrals multiplies the length integrand at radius s by $(R^2 - s^2)/2 \le 2$.

For $0 < a \le 1/4$, put $t = \sqrt{a}$. The integral on the right, without its factor two, is bounded by

$$\sqrt{L}\int_{\{|w-p|<t\}}\frac{\mathrm{d}\lambda_2(w)}{|w-p|}+\left(\int_{U_i}\rho_i\,\mathrm{d}\lambda_2\right)^{1/2}\left(\int_{\{t<|w-p|<2\}}\frac{\mathrm{d}\lambda_2(w)}{|w-p|^2}\right)^{1/2}$$
$$\le 2\pi\sqrt{L}\,t+\sqrt{2\pi a\log(2/t)}\le K\sqrt{a\bigl(1+\log(1/a)\bigr)}.$$

Thus for any $p,q\in U_i$, averaging $\ell_p(z)+\ell_q(z)$ over $z\in U_i$ gives a two-segment path of length at most $K\sqrt{a(1+\log(1/a))}$. The constant is common to the finite cover.

The overlap graph of this cover is connected because C is connected. Choose points in consecutive overlaps along a simple path in this finite graph. The local estimates join any two points of C through at most the number of covering disks, proving the global bound for $a\le 1/4$. For $1/4\le a\le 1$, the comparison $g\le h$ gives $\operatorname{diam}(C,g)\le\operatorname{diam}(C,h)$, and increasing K_h gives the same estimate. Restoring the factor M scales lengths by $\sqrt{M}$ and proves the assertion. □

Example 14.18.1 On every such (C,h) there are smooth Hermitian metrics $g_\varepsilon\le h$, for $\varepsilon\downarrow 0$, such that

$$A_\varepsilon:=\operatorname{Area}_{g_\varepsilon}(C)\asymp\varepsilon^2\log(1/\varepsilon),$$
$$\operatorname{diam}(C,g_\varepsilon)\asymp\varepsilon\log(1/\varepsilon).$$

Consequently the preceding diameter bound has sharp order under its uniform upper bound. Without that bound, area can tend to zero while diameter stays bounded below by a positive constant.

Proof Choose a coordinate disk $\{|z|<R\}$ with $0<R<1$, on whose closure $h=\lambda(z)|\mathrm{d}z|^2$ with $\lambda>0$ smooth. Choose a smooth cutoff $0\le\chi\le 1$, supported in this disk and equal to one for $|z|\le R/2$, and a constant $c>0$ with $c\le\min\lambda$. For sufficiently small $\varepsilon>0$, set

$$g_\varepsilon=\left(\chi\frac{c\varepsilon^2}{\lambda(z)(\varepsilon^2+|z|^2)}+(1-\chi)\varepsilon^2\right)h$$

in the disk, and set $g_\varepsilon=\varepsilon^2 h$ outside it. The cutoff makes this a smooth positive metric, and both coefficients in its convex combination are at most one.

On $|z|\le R/2$ its metric density is $c\varepsilon^2/(\varepsilon^2+|z|^2)$, whose area is

$$\pi c\varepsilon^2\log\left(1+\frac{R^2}{4\varepsilon^2}\right).$$

The remaining area is $O(\varepsilon^2)$, proving the asserted area comparison. Any path from the origin to a point outside this smaller disk must first cross its boundary. Radial variation is bounded by Euclidean speed, so that initial portion has length at least

$$\sqrt{c}\,\varepsilon\int_0^{R/2}\frac{\mathrm{d}r}{\sqrt{\varepsilon^2+r^2}}=\sqrt{c}\,\varepsilon\operatorname{arsinh}(R/(2\varepsilon))\asymp\varepsilon\log(1/\varepsilon).$$

This gives the diameter lower bound. The upper bound follows from Lemma 14.18.7, since $A_\varepsilon(1+\log(1/A_\varepsilon))\asymp\varepsilon^2\log^2(1/\varepsilon)$. Finally rescale by

$$\widetilde{g}_\varepsilon = \frac{g_\varepsilon}{\varepsilon^2 \log^2(1/\varepsilon)}.$$

Its area is comparable to $1/\log(1/\varepsilon)$ and tends to zero, whereas its diameter is comparable to one. At the origin its ratio to h tends to infinity, so it has no uniform upper bound. □

Let $V \to C$ be a holomorphic vector bundle of positive rank with a fixed smooth Hermitian fiber norm. Write $U_\delta = \{v \in V : |v| < \delta\}$ and identify its zero section with C.

Proposition 14.18.2 *Let g_j be smooth Hermitian metrics on U_{δ_0}. Suppose their restrictions to C satisfy*

$$g_j|_C \le Mh, \qquad A_j = \operatorname{Area}_{g_j|_C}(C) \longrightarrow 0$$

for a fixed $M > 0$. Suppose also that there are $B > 0$ and $0 < \alpha \le 1$ such that, for every unit fiber vector v over any $x \in C$, the ray $\gamma_{x,v}(s) = sv$ satisfies

$$g_j(\gamma'_{x,v}(s), \gamma'_{x,v}(s)) \le Bs^{2\alpha-2}, \qquad 0 < s < \delta_0,$$

uniformly in j, x, v. Then

$$\operatorname{diam}^{\mathrm{int}}(U_\delta, g_j) \le \frac{2\sqrt{B}}{\alpha}\delta^\alpha + K_h\sqrt{A_j\big(1 + \log(M/A_j)\big)}, \qquad 0 < \delta < \delta_0.$$

In particular,

$$\lim_{\delta \downarrow 0} \limsup_{j \to \infty} \operatorname{diam}^{\mathrm{int}}(U_\delta, g_j) = 0.$$

Proof A point of fiber radius $r < \delta$ joins its base point on the zero section along the radial segment, entirely inside U_δ. Its length is at most

$$\sqrt{B}\int_0^r s^{\alpha-1}\,\mathrm{d}s = \frac{\sqrt{B}}{\alpha}r^\alpha.$$

The metric is smooth at the zero section for each j; the integrable uniform bound controls the whole segment. Join the two base points by an almost minimizing path in $(C, g_j|_C)$. This path also lies in U_δ, and up to an arbitrarily small excess its length is bounded by Lemma 14.18.7. Together with the two radial segments, this gives the asserted bound for the intrinsic diameter. Since $A_j(1 + \log(M/A_j)) \to 0$, taking $j \to \infty$ and then $\delta \downarrow 0$ proves the final assertion. □

Return to the standard nodal small resolutions of Section 14.18.1. On a nodal tube put $r^2 = \sum_{k=1}^4 |x_k \circ \pi|^2$, the squared bundle norm used in Lemma 14.18.3. Let $V_\delta \subset Y$ be the nodal coordinate ball $\sum_k |x_k|^2 < \delta^2$. For sufficiently small δ, properness gives $\pi^{-1}(V_\delta) = \{r < \delta\}$. Write g_ε for the Riemannian metric associated to ω_ε. Its area on E_a is $\varepsilon\int_{E_a}\eta$ by Corollary 14.18.1. Fix an area-one Hermitian metric h_a on E_a.

If $g_\varepsilon|_{E_a} \le M h_a$ uniformly and the radial bound of Proposition 14.18.2 holds with $\alpha = 1/2$, substitution in that proposition gives

$$\operatorname{diam}^{\mathrm{int}}(\{r < \delta\}, g_\varepsilon) \le K\delta^{1/2} + K\sqrt{\varepsilon\big(1 + \log(1/\varepsilon)\big)}$$

for sufficiently small ε and δ, with K independent of both. Under these two pointwise metric bounds, the condition on approximating neighborhoods in Proposition 14.18.1 therefore holds. The condition on punctured neighborhoods in the limiting metric does not follow from it, as the next example shows.

In the following surface example the volume form is fixed and the approximating tubes shrink, but the punctured neighborhoods of the contracted point keep a positive diameter in the limiting metric.

Example 14.18.2 There are a compact complex surface X, a holomorphic map $\pi : X \to Y = \mathbb{P}^2$ contracting a curve E to a point p, and smooth Hermitian metrics g_j, g_* on X with the following properties. The map is biholomorphic from $X \setminus E$ to $Y \setminus \{p\}$, and $g_j = g_*$ eventually on each compact subset of $X \setminus E$. Their associated Hermitian forms satisfy

$$\omega_j^2 = \omega_*^2.$$

The curve areas tend to zero, and the metrics have a uniform integrable radial bound near E. For a neighborhood basis V_δ of p, with $U_\delta = \pi^{-1}(V_\delta)$,

$$\lim_{\delta \downarrow 0} \limsup_{j \to \infty} \operatorname{diam}^{\mathrm{int}}(U_\delta, g_j) = 0.$$

Nevertheless, for the intrinsic distance d_0 of $g_0 = (\pi^{-1})^* g_*$ on $Y \setminus \{p\}$, there is $c > 0$ such that

$$\operatorname{diam}_{d_0}(V_\delta \setminus \{p\}) \ge c$$

for every sufficiently small δ.

Proof Put $p = [1 : 0 : 0]$ and take the incidence surface

$$X = \big\{([z_0 : z_1 : z_2], [u : v]) \in \mathbb{P}^2 \times \mathbb{P}^1 : z_1 v = z_2 u\big\},$$
$$\pi([z], [u : v]) = [z].$$

Off p, the second coordinate is $[z_1 : z_2]$, so π is biholomorphic there. Its exceptional curve is $E = \{p\} \times \mathbb{P}^1$. In the affine chart $z_0 = 1$, a chart of X is

$$(t, w) \longmapsto ([1 : w : tw], [1 : t]).$$

The other chart is $([1 : t'w' : w'], [t' : 1])$, with $t' = 1/t$ and $w' = tw$ on their overlap. These are the charts of the tautological line bundle $L = \mathcal{O}_{\mathbb{P}^1}(-1)$. They also show smoothness along E; smoothness elsewhere follows from the biholomorphism. Thus X is a compact smooth complex surface. Its connected dense complement $X \setminus E$ makes it connected.

Let $q : L \to \mathbb{P}^1$ be the bundle projection. Give L the norm induced by its tautological inclusion into $\mathbb{P}^1 \times \mathbb{C}^2$. In the first chart its squared norm is

$$r^2 = (1 + |t|^2)|w|^2 = |z_1|^2 + |z_2|^2.$$

Fix an area-one Hermitian metric h on $\mathbb{P}^1$. The Chern connection of the fiber norm defines a smooth semipositive Hermitian tensor k on L by the squared norm of the covariant fiber differential. Explicitly, with $\lambda = 1 + |t|^2$,

$$k = \lambda \, |\mathrm{d}w + w\partial \log \lambda|^2 \, .$$

Under $t' = 1/t$, $w' = tw$, the differential in this formula multiplies by t and λ divides by $|t|^2$, so the tensor is globally defined. It has complex rank one, is positive on nonzero vertical tangent vectors, and restricts to zero on TE. Consequently $q^*h + k$ is a smooth positive Hermitian metric on L.

Choose $0 < \delta_0 < 1$ and extend this metric from $U_{\delta_0} = \{r < \delta_0\}$ to a smooth Hermitian metric g_* on X. Such an extension follows by a smooth cutoff supported in a slightly larger bundle tube and a convex combination with any global Hermitian metric. It agrees exactly with $q^*h + k$ on U_{δ_0}.

Choose $0 < \varepsilon_j < 1$ tending to zero, with $2\varepsilon_j^2 < \delta_0$, and a smooth function $0 \le \chi \le 1$ on $[0, \infty)$, equal to zero on $[0, 1]$ and to one on $[4, \infty)$. Set

$$\begin{aligned} f_j(r) &= \varepsilon_j^2 + (1 - \varepsilon_j^2)\chi(r^2/\varepsilon_j^4), \\ g_j &= f_j q^*h + f_j^{-1} k, \end{aligned}$$

on U_{δ_0}, and set $g_j = g_*$ elsewhere. The function f_j is smooth at E, is at least ε_j^2, and equals one for $r \ge 2\varepsilon_j^2$. Hence the metrics glue smoothly and are positive. They equal g_* eventually on every compact subset of $X \setminus E$.

Let β, κ be the Hermitian forms of q^*h, k. Their complex rank one gives $\beta^2 = \kappa^2 = 0$. On the tube,

$$(f_j\beta + f_j^{-1}\kappa)^2 = 2\beta \wedge \kappa = (\beta + \kappa)^2.$$

Outside it the metrics coincide. This proves the global volume identity. On E, the restriction is $g_j|_E = \varepsilon_j^2 h$, so its area is ε_j^2.

For any unit fiber vector a, a radial ray $\gamma(s) = sa$ has k-squared speed one and zero base component. Thus its g_j-squared speed is $f_j(s)^{-1}$. If $s < 2\varepsilon_j^2$, this is at most $\varepsilon_j^{-2} \le 2/s$; otherwise it is one, still at most $2/s$ for $s < \delta_0$. This is the uniform integrable radial bound with exponent $1/2$.

A radial segment of radius $r < \delta$ has length at most $r + 2\varepsilon_j$: its portion below $2\varepsilon_j^2$ has speed at most ε_j^{-1} and length at most $2\varepsilon_j$, and its remaining speed is one. Connect two points by their radial segments and an almost minimizing path on E. All three segments stay inside U_δ, giving

$$\operatorname{diam}^{\mathrm{int}}(U_\delta, g_j) \le 2\delta + \varepsilon_j\big(4 + \operatorname{diam}(\mathbb{P}^1, h)\big).$$

Taking $j \to \infty$ before $\delta \downarrow 0$ proves the asserted shrinking condition. The affine balls

$$V_\delta = \{[1 : z_1 : z_2] : |z_1|^2 + |z_2|^2 < \delta^2\}$$

have precisely these tubes as their preimages.

Let d_* be the global distance of the fixed smooth metric g_*. Choose distinct points $a, b \in E$, and put $c = d_*(a, b) > 0$. Choose points a_r, b_r of fiber norm $r > 0$ over these base points. They tend to a, b as $r \downarrow 0$. Every path in $Y \setminus \{p\}$ lifts to a path in $X \setminus E$ with the same g_0-length as its g_*-length. Therefore

$$d_0(\pi(a_r), \pi(b_r)) \geq d_*(a_r, b_r) \longrightarrow c.$$

For any fixed $\delta > 0$, these two images lie in V_δ when $r < \delta$. Taking the supremum and then $r \downarrow 0$ gives its punctured diameter at least c. □

14.19 Symmetry and the selected projective limit

Let ω be a Hermitian form and $0 \leq f \in L^p(\mathrm{d}V)$, $p > 1$, a nonzero density. When the normalized equation $\mathrm{MA}_\omega(u) = c f \,\mathrm{d}V$ has several solutions, the positive-exponent equations $\mathrm{MA}_\omega(u) = \mathrm{e}^{\lambda u} f \,\mathrm{d}V$ still have unique solutions, and their normalized limits as $\lambda \downarrow 0$ single out particular solutions of the normalized equation. We study this selection in the projective example of Theorem 11.6.1, whose density vanishes on an open band. The starting point is a general observation: uniqueness at positive exponent preserves the symmetries of the data, and uniform compactness carries them to every normalized cluster limit. For the projective data this already gives a solution distinct from the two smooth solutions exchanged by the involution. The radial form of the equation then identifies the selected limit (Theorem 14.19.1) and shows that the positive-exponent solutions fail to be C^2 along the same hypersurfaces (Proposition 14.19.2).

Proposition 14.19.1 *Let ω be a Hermitian form on X, let $\mathrm{d}V$ be a smooth positive volume form, and let $0 \leq f \in L^p(\mathrm{d}V)$, $p > 1$, be nonzero. Let $c > 0$ be the unique scalar for the bounded equation $\mathrm{MA}_\omega(u) = c f \,\mathrm{d}V$ (Theorem 10.1.1). For $\lambda > 0$ denote by u_λ the unique bounded solution of*

$$\mathrm{MA}_\omega(u_\lambda) = \mathrm{e}^{\lambda u_\lambda} f \,\mathrm{d}V, \qquad a_\lambda = u_\lambda - \sup_X u_\lambda.$$

The family $\{a_\lambda : 0 < \lambda \leq 1\}$ is relatively compact in $C(X)$. Every cluster limit as $\lambda \downarrow 0$ is a normalized bounded solution of $\mathrm{MA}_\omega(a) = c f \,\mathrm{d}V$.

Suppose a group G of biholomorphisms of X preserves ω and the measure $f \,\mathrm{d}V$. Then every a_λ and every such cluster limit is G-invariant. In particular, the zero-exponent equation has a G-invariant normalized solution.

Proof The barriers of Proposition 10.6.1 give a uniform oscillation bound for u_λ and uniform convergence $\mathrm{e}^{\lambda u_\lambda} \to c$. Thus the equation densities are uniformly bounded

in L^p for $0 < \lambda \le 1$ and tend to cf in L^p as $\lambda \downarrow 0$. Apply Theorem 10.3.2 to obtain relative compactness of a_λ in $C(X)$ and the asserted equation for every cluster limit.

For each $g \in G$, pullback of the positive-exponent equation shows that $u_\lambda \circ g$ solves the same equation. Its uniqueness gives $u_\lambda \circ g = u_\lambda$. Surjectivity of g preserves the supremum, so $a_\lambda \circ g = a_\lambda$. Uniform convergence preserves these equalities for every g. Compactness gives at least one cluster limit as $\lambda \downarrow 0$, yielding the invariant solution. □

Corollary 14.19.1 *On $\mathbb{P}(\mathbb{C}^2 \oplus \mathbb{C}^2)$, with block homogeneous coordinates $[A : B]$, the data in Theorem 11.6.1 can be chosen so that the same zero-exponent equation has at least three distinct normalized bounded solutions. Two are smooth, and a third is Hölder continuous and fixed by the involution $\iota[A : B] = [B : A]$.*

Proof Use the radial coordinate r, rank-one forms P, Q, R, Fubini–Study form ω_X, and scalar functions F, x, y, z from Sections 11.6.1 and 11.6.2. Set $w = F(r)$, $\omega_0 = xP + yQ + zR$, $H = \mathrm{dd^c} w/2$, $A_0 = \omega_0 - H$ and $B_0 = \omega_0 + H$ as in Section 11.6.3. The Hermitian form is $\omega = \omega_0 + \mathrm{dd^c}\rho$, with $\rho = \varepsilon(r^2 - 1)\kappa(r)$ from Section 11.6.4. Choose the cutoff κ even; all its required support and plateau properties are preserved by this choice. Then ρ is even, while $w = F(r)$ is odd. The involution sends r to $-r$, interchanges P, Q, and fixes R. The coefficient identities $x(-r) = y(r)$ and $z(-r) = z(r)$ show that $\iota^*\omega_0 = \omega_0$. Thus $\iota^*\omega = \omega$, and $\iota^*\omega_X = \omega_X$.

Since $\iota^* H = -H$, the involution interchanges A_0 and B_0. Their cubes are equal, so $f\omega_X^3$ is invariant. It also interchanges $\widetilde{u} = -w/2 - \rho$ and $\widetilde{v} = w/2 - \rho$. These functions therefore have the same supremum, and the normalized solutions u, v are interchanged. They are distinct, so neither is invariant.

Apply Proposition 14.19.1 to the group generated by ι. Here $c = 1$, as the two constructed solutions already have that scalar. An invariant cluster solution a cannot equal either u or v. Its bounded equation with smooth density gives Hölder regularity by Theorem 14.4.1. This gives a third solution. Its regularity is determined in Sections 14.19.1 and 14.19.2: it is $C^{1,1}$ but not C^2. □

To identify the whole normalized limit for these symmetric data, we now use the radial form of the equation. It determines the invariant solution even among bounded potentials whose differentiability is not known in advance.

14.19.1 The invariant projective solution

We keep the symmetric projective data of Corollary 14.19.1. Thus $X = \mathbb{P}^3$ with block coordinates $[A : B]$ and Fubini–Study form ω_X; on $U = \{A \neq 0,\ B \neq 0\}$ we use the radial coordinate r, the rank-one forms P, Q, R and the coefficients x, y, z, p, z_0 of Sections 11.6.1 and 11.6.2. The function $\rho(r)$ is the even correction of Section 11.6.4, not a barrier, and $\omega = \omega_0 + \mathrm{dd^c}\rho$ is the resulting Hermitian form, with $\omega_0 = xP + yQ + zR$; the density f is that of Theorem 11.6.1. Let K be the group generated by the block unitary group $U(2) \times U(2)$ and the exchange $\iota[A : B] = [B : A]$. Both preserve ω and $f\omega_X^3$. Denote by u_* the normalized ι-invariant solution of Proposition 11.6.1, given by the symmetric transition pair $(-t_*, t_*)$.

Theorem 14.19.1 *For the symmetric projective data, u_* is the unique normalized bounded K-invariant solution of*

$$\mathrm{MA}_\omega(u) = f\omega_X^3.$$

If u_λ is the unique solution of

$$\mathrm{MA}_\omega(u_\lambda) = \mathrm{e}^{\lambda u_\lambda} f\omega_X^3, \qquad \lambda > 0,$$

then

$$u_\lambda - \sup_X u_\lambda \longrightarrow u_* \quad \textit{uniformly as } \lambda \downarrow 0.$$

The selected limit u_* is $C^{1,1}$.

Uniqueness holds only within the K-invariant class: by Proposition 11.6.1, the same equation has uncountably many normalized solutions. Since a cluster limit is a priori only bounded, the proof needs the radial form of the equation for bounded invariant solutions, which we derive first. For a real scalar s, define the coefficient polynomial $A(r, s)$ and its primitive $\Phi(r, s)$ by

$$A(r, s) = (x(r) + s)(y(r) - s), \qquad \Phi(r, s) = \int_0^s A(r, t)\,\mathrm{d}t.$$

Partial derivatives of Φ with respect to r below keep s fixed.

Lemma 14.19.1 *Suppose u is a bounded block-unitary-invariant solution of the zero-exponent equation. On U write $u + \rho = G(r)$. Then G is locally Lipschitz, its derivative $h = G'$ has locally bounded variation, and its one-sided representatives satisfy*

$$-x(r) \le h(r\pm) \le y(r), \qquad \mathrm{d}h + z\,\mathrm{d}r \ge 0.$$

In fact h is continuous. With

$$k(r) = \begin{cases} 0, & |r| \le 1, \\ x(r)y(r)z(r), & |r| > 1, \end{cases}$$

it satisfies the distributional identity on $\mathbb{R}$

$$\mathrm{d}\big(\Phi(r, h(r))\big) = \big(k(r) - A(r, h(r))z(r) + \partial_r \Phi(r, h(r))\big)\,\mathrm{d}r. \tag{14.53}$$

On every open interval where $A(r, h(r)) > 0$, h is smooth and

$$h' = \frac{k(r)}{A(r, h)} - z.$$

Proof *Reduction to one variable.* Block-unitary orbits in U are exactly the level sets of r: normalize the sum of the squared norms of the two coordinate blocks, and map the two vectors of the same respective lengths by their unitary groups. Thus invariance gives a function G of one real variable.

On a compact r-interval, the radial direction annihilates P, Q, while R is strictly positive in that direction. Testing positivity of $\omega_0 + \mathrm{dd}^{\mathrm{c}} G(r)$ in this direction gives $G'' + z \ge 0$ as a one-dimensional distribution. One may obtain this first by smooth approximation of the scalar distribution and then by testing with nonnegative functions. Adding a twice integrated primitive of z makes G convex. A finite bounded convex function on an interval is locally Lipschitz, and its derivative is locally of bounded variation. The quasi-plurisubharmonic representative is the corresponding continuous representative. The horizontal directions give $x + h \ge 0$, $y - h \ge 0$ almost everywhere. Continuity of x, y and the one-sided limits of a function of bounded variation give these bounds for both one-sided representatives. The radial inequality is precisely $\mathrm{d}h + z\,\mathrm{d}r \ge 0$; in particular jumps of h can only be upward.

The radial form of the measure. We next justify the formula for the measure, including possible jumps. Identify U smoothly with $\mathbb{R} \times Y$, where $Y = \{r = 0\}$, by real scaling of one block. The forms P, Q are independent of r in this identification. So is $\mathrm{d}^{\mathrm{c}} r$: in local coordinates it is the angular differential of the relative complex scale plus fixed base terms. Therefore

$$P \wedge Q \wedge R = \mathrm{d}r \wedge \nu,$$

where ν is a fixed smooth positive volume form on the compact orbit Y, with the orientation chosen by this equality.

For smooth G, the rank-one wedge formula gives the radial coefficient of its Monge–Ampère measure, after dividing by 6ν, as

$$A(r,h)(z+h')\,\mathrm{d}r = A(r,h)z\,\mathrm{d}r + \mathrm{d}\big(\Phi(r,h)\big) - \partial_r\Phi(r,h)\,\mathrm{d}r.$$

This identity passes to a locally Lipschitz G with the preceding lower Hessian bound. Indeed, convolve G on a slightly larger compact interval. The derivatives h_ϵ are uniformly bounded and converge to h almost everywhere and in every finite L^q space. Their second derivatives have a uniform lower bound. Consequently the functions $G_\epsilon(r)$ have a common quasi-plurisubharmonic lower Hessian bound on compact subsets of U, and converge uniformly to $G(r)$. A fixed smooth local correction and bounded Bedford–Taylor continuity give convergence of their signed products. On the right-hand side of the formula, the two ordinary terms converge in L^1, and $\Phi(r,h_\epsilon)\to\Phi(r,h)$ in L^1, giving distributional convergence of its derivative. This proves the same formula for the bounded product of G.

Continuity of h. After the same division by 6ν, the right-hand side $f\omega_X^3$ has radial coefficient $k(r)\,\mathrm{d}r$. This gives (14.53), initially for the almost-everywhere representative of h. If h jumped at r_0, the atom of its left side would be

$$\Phi(r_0,h(r_0+)) - \Phi(r_0,h(r_0-)) = \int_{h(r_0-)}^{h(r_0+)} (x(r_0)+s)(y(r_0)-s)\,\mathrm{d}s.$$

The right side has no atom. An upward jump of positive size lies in $[-x(r_0),y(r_0)]$, where the integrand is strictly positive in the interior. Since $x+y>0$ everywhere, such an integral is strictly positive. Thus there are no jumps. A locally bounded-variation function whose jumps all vanish has a continuous representative here: its distributional derivative consists of an absolutely continuous measure and a nonnegative singular measure, so its one-sided representatives coincide at every point. We henceforth use this representative. In particular G is C^1 and $G'=h$ everywhere.

All coefficients on the right of (14.53) are now continuous, so $\Phi(r,h(r))$ is C^1. Where $\partial_s\Phi = A > 0$, the implicit function theorem gives $h\in C^1$ and the stated ordinary differential equation. Smoothness then follows by the smooth coefficients of that equation. The function k is smooth, since the original density and its flat joins are smooth. □

Proof (of Theorem 14.19.1) We first show that a normalized bounded K-invariant solution u coincides with u_*, by computing its slope h on the band $|r|\le 1$ and outside it. Apply Lemma 14.19.1. Because ρ and u are invariant under block exchange, G is even, so h is odd and $h(0)=0$.

The slope on the band. On $0<r<1$ we have $x=p>0$ and $y=p+b\ge p>0$. Starting from zero, as long as $-p<h<y$, the equation is $h'=-z_0$. Thus $h(r) = -\int_0^r z_0(s)\,\mathrm{d}s$. This decreasing function cannot meet the positive upper boundary y. Its first meeting with the lower boundary $-p$ occurs at the unique $t_*\in(0,1)$ satisfying

$$\int_0^{t_*} z_0(s)\,\mathrm{d}s = p(t_*),$$

whose existence and uniqueness were proved in Proposition 11.6.1.

After that meeting, h must stay on $-p$ until $r=1$. To prove it, suppose a connected component (a_0,b_0) of $\{h+p>0\}$ lies to its right. Its left endpoint has $a_0\ge t_*$ and

$h(a_0) = -p(a_0) < 0$. Near that endpoint, $h < 0 < y$; hence on the component the interior equation applies for as long as $h < 0$. It forces $h' = -z_0 < 0$, so h cannot first reach zero. The equation therefore holds throughout the component. But then

$$(h + p)' = p' - z_0 < 0,$$

contradicting positivity of $h + p$ immediately to the right of its zero at a_0. Thus $h = -p$ on $[t_*, 1]$. Oddness determines the entire negative half of the band. The slope on $[-1, 1]$ is exactly that of the symmetric explicit solution.

The slope outside the band. Here boundedness of u at the projective ends matters. On $r > 1$, $k = xyz > 0$. Neither horizontal coefficient can vanish at a finite point of this interval. For the lower one define

$$\Psi(r) = \int_{-x(r)}^{h(r)} A(r, s)\, \mathrm{d}s \geq 0.$$

Equation (14.53) and the smooth lower endpoint show that Ψ is C^1. If $h(r_0) = -x(r_0)$, its derivative at that point is $k(r_0) > 0$: the Az term vanishes, and the two partial-r terms agree at the common endpoint. This contradicts that the nonnegative C^1 function Ψ has an interior minimum zero there. The upper-endpoint integral $\int_{h(r)}^{y(r)} A(r, s)\, \mathrm{d}s$ gives the same contradiction, with derivative $-k(r_0)$, when $h = y$. Thus $-x < h < y$ everywhere on $r > 1$, and the smooth ordinary differential equation of the lemma applies.

For $r \geq 2$ the background is Fubini–Study:

$$x = \sigma, \qquad y = 1 - \sigma, \qquad z = \sigma', \qquad \sigma = \frac{\mathrm{e}^r}{1 + \mathrm{e}^r}.$$

Set $a = \sigma + h \in (0, 1)$. Its equation is

$$a(1 - a)a' = \sigma(1 - \sigma)\sigma' > 0.$$

Hence a is increasing and has a limit in $(0, 1]$ at $+\infty$. If that limit were less than one, $h = a - \sigma$ would approach a negative constant and its primitive G would be unbounded below, contrary to boundedness of u and ρ. The limit is therefore one. Integrating the equation gives

$$\frac{a^2}{2} - \frac{a^3}{3} = \frac{\sigma^2}{2} - \frac{\sigma^3}{3} + C.$$

Taking the limit at infinity gives $C = 0$. The scalar function $s^2/2 - s^3/3$ is strictly increasing on $(0, 1)$, so $a = \sigma$ and $h = 0$ for $r \geq 2$. Ordinary uniqueness propagates this zero solution throughout $r > 1$, since the coefficients are smooth and the two horizontal coefficients stay positive there. Oddness gives $h = 0$ on $r < -1$ as well.

We have proved that G' agrees everywhere with the symmetric explicit slope. Thus u differs from u_* by a constant on U. The two quasi-plurisubharmonic functions then agree up to that constant on X by their canonical representatives. Their supremum

normalization removes the constant. This proves uniqueness within the bounded K-invariant class.

Convergence. Finally Proposition 14.19.1 gives uniform precompactness of the normalized positive-exponent family. Every cluster limit solves the zero-exponent equation and is K-invariant, because the data are K-invariant. The scalar is one for these data. The uniqueness just proved identifies every cluster limit with u_*. If convergence of the whole family failed, a sequence staying a fixed positive uniform distance from u_* would have a convergent subsequence, contradicting that identification. This proves uniform convergence and the asserted $C^{1,1}$ regularity of the limit. □

14.19.2 Second derivatives at positive exponent

On the band where the density vanishes, the exponential factor plays no role, and the radial equation determines the slope of the solution independently of the exponent. Consequently the positive-exponent solutions have the same failure of second differentiability as the selected limit u_*. We keep the notation A, Φ, k and the transition radius t_* of Section 14.19.1.

Proposition 14.19.2 *For the symmetric projective data of Theorem 14.19.1, let u_λ solve*

$$\mathrm{MA}_\omega(u_\lambda) = \mathrm{e}^{\lambda u_\lambda} f \omega_X^3, \qquad \lambda > 0.$$

On the open band $\{-1 < r < 1\}$, $u_\lambda - u_*$ is constant. Both potentials are $C^{1,1}$ there and fail to be C^2 at every point of the two hypersurfaces $r = \pm t_*$. In particular, none of these positive-exponent solutions is a globally C^2 potential.

Proof Uniqueness and invariance of the data imply that u_λ is K-invariant. Write $u_\lambda + \rho = G_\lambda(r)$ on U. The positivity argument in Lemma 14.19.1 uses only boundedness and invariance, so G_λ is locally Lipschitz and $h_\lambda = G_\lambda'$ is locally of bounded variation, with

$$-x \le h_\lambda(r\pm) \le y, \qquad \mathrm{d}h_\lambda + z\,\mathrm{d}r \ge 0.$$

Its weak flux equation is the same one, with the prescribed coefficient replaced by

$$k_\lambda(r) = \mathrm{e}^{\lambda(G_\lambda(r) - \rho(r))} k(r).$$

Indeed, the scalar convolution and signed-product argument of that lemma is unchanged, and k_λ is exactly the radial coefficient of the right-hand measure. Since G_λ is bounded on compact r-intervals, k_λ is locally bounded. Hence the right side of the flux equation has no atoms. The same strictly positive jump integral eliminates every jump of h_λ. Thus h_λ is continuous and G_λ is C^1. The coefficient k_λ is consequently continuous. Where $A(r, h_\lambda) > 0$, inversion of the C^1 flux gives

$$h'_\lambda = \frac{k_\lambda(r)}{A(r, h_\lambda)} - z.$$

On $-1 < r < 1$ the coefficient k_λ is identically zero. Exchange invariance gives $h_\lambda(0) = 0$ and oddness. On the positive half-band, the first-contact and no-departure arguments in the proof of Theorem 14.19.1 apply verbatim: the first branch solves $h' = -z_0$, reaches $-p$ at t_*, and cannot leave that lower boundary to its right because $(h + p)' = p' - z_0 < 0$ on every proposed departure interval. Therefore

$$h_\lambda(r) = \begin{cases} p(r), & -1 < r \le -t_*, \\ -\displaystyle\int_0^r z_0(s)\,\mathrm{d}s, & -t_* \le r \le t_*, \\ -p(r), & t_* \le r < 1. \end{cases}$$

This is the derivative of $u_* + \rho$. Its primitive differs from G_λ by one constant on the connected band. The claimed local $C^{1,1}$ regularity follows from the explicit slope.

At $t_* \in (0, 1)$ the two one-sided derivatives of this slope are

$$h'_\lambda(t_*-) = -z_0(t_*) < 0, \qquad h'_\lambda(t_*+) = -p'(t_*) > 0.$$

These unequal derivatives prevent the scalar primitive from having a second derivative at t_*. Through every point of that level set, the submersion r provides a smooth curve parametrized by r, transferring the failure to u_λ. Smooth ρ cannot cancel the jump. Oddness gives the conclusion at $-t_*$, and the identical slope proves it for u_*. □

The zero set of f contains the whole band. This example therefore does not concern the smooth strictly positive densities in the Hermitian Calabi–Yau theorem. It does show why smoothness of a nonnegative density alone is insufficient for second-order regularity, even when the equation includes a strictly increasing exponential factor.

14.20 Local density and boundary control

Theorem 14.17.1 requires a smooth positive density on the whole regular locus of a global strict barrier, and the global minimum of the difference between the solution and the barrier drives its proof. If the density is smooth and positive only on a smaller open set, smoothness can fail there. A bounded solution with minimal singularities can be discontinuous on a ball where its density is constant (Theorem 14.20.2), and a locally Lipschitz plurisubharmonic function with constant density need not be C^1 (Example 14.20.2). Boundary data give a different route to regularity: if the solution has smooth boundary values on small balls, uniqueness for the bounded Dirichlet problem identifies it with the smooth Dirichlet solution.

In this section θ is a smooth real $(1, 1)$-form on X, and $\rho \in \mathrm{PSH}(X, \theta)$ satisfies $\theta + \mathrm{dd}^{\mathrm{c}}\rho \ge \varepsilon\omega$ for some $\varepsilon > 0$; in particular θ is big. We fix an open set $\Omega \subset X$ on which ρ is smooth and $\mathrm{d}\theta = 0$.

14.20.1 Smooth boundary traces

Let $B \Subset \Omega$ be a coordinate ball. A function u on B has *boundary trace* g, a function on ∂B, if $u(z) \to g(\xi)$ as $B \ni z \to \xi$, for every $\xi \in \partial B$.

Theorem 14.20.1 *Suppose that $u \in \mathrm{PSH}(X, \theta)$ has minimal ordinary singularities and*

$$\mathrm{MA}_\theta(u) = f \, \mathrm{d}V \quad \text{on } \Omega, \qquad f \in C^\infty(\Omega), \quad f > 0.$$

Assume that Ω is covered by coordinate Euclidean balls $B_j \Subset \Omega$ such that θ has a smooth local potential near $\overline{B_j}$ and u has a smooth boundary trace on ∂B_j. Then $u \in C^\infty(\Omega)$ and $\theta + \mathrm{dd^c} u > 0$ there.

Proof Since $\rho - \sup_X \rho \le V_\theta$, minimal singularities give $u \ge \rho - C$ for a constant C. Thus u is locally bounded on Ω. Fix one of the balls, write it as $B = B_R(z_0)$, let g be the boundary trace of u on ∂B, and choose a smooth function h near $\overline{B}$ with $\mathrm{dd^c} h = \theta$. By Proposition 1.7.1, the bounded plurisubharmonic function $v = u + h$ has Bedford–Taylor measure $f \, \mathrm{d}V$ and smooth boundary trace $\varphi = g + h|_{\partial B}$.

For a smooth function V and the Euclidean volume $\mathrm{d}\Lambda$,

$$(\mathrm{dd^c} V)^n = \frac{n!}{\pi^n} \det(V_{j\bar{k}}) \, \mathrm{d}\Lambda. \tag{14.54}$$

The smooth Dirichlet theorem recalled in Section 14.17.3, with zero background and density $f \, \mathrm{d}V$, gives a smooth strictly plurisubharmonic V on $\overline{B}$ with $(\mathrm{dd^c} V)^n = f \, \mathrm{d}V$ and boundary value φ; a smooth extension Φ of φ gives the required strict subsolution $\Phi + A(|z - z_0|^2 - R^2)$ for large A. In dimension one this is the Dirichlet problem for the Poisson equation.

The difference $v - V$ tends to zero at every boundary point. Compactness of ∂B makes this convergence uniform near the boundary: otherwise a sequence approaching the boundary with difference bounded away from zero would have a subsequence approaching one fixed boundary point. Uniqueness for the bounded Dirichlet problem, that is, the Bedford–Taylor comparison principle, gives $v = V$. Therefore $u = V - h$ is smooth on B, and $\theta + \mathrm{dd^c} u = \mathrm{dd^c} V > 0$ there. Since the balls cover Ω, the theorem follows. □

The proof uses minimal singularities only to obtain the local lower bound by ρ. Consequently the same conclusion holds for any solution already known to be locally bounded on Ω and satisfying the same trace condition. Closedness of θ on Ω provides the local potentials h once the coordinate balls are small enough; the background may be nonclosed elsewhere.

Example 14.20.1 For every $n \ge 1$, the trace criterion applies to a bounded continuous solution whose global density belongs to L^1 but to no L^p with $p > 1$, and which is not Hölder continuous at the points of $X \setminus \Omega$.

Let $E = \mathbb{C}/(\mathbb{Z} + \mathrm{i}\mathbb{Z})$, $X = E^n$, and

$$\omega_j = \frac{\mathrm{i}}{2\pi}\,\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_j, \qquad \theta = \sum_{j=1}^{n} \omega_j, \qquad D = \{0\} \times E^{n-1}.$$

Take $\mathrm{d}V = \theta^n$ and $\rho = 0$. Choose a nonnegative smooth cutoff χ supported in a coordinate disk $|z| < r_0 < 1$ of E and equal to one near zero. For $\beta > 0$, define

$$\psi(z) = \chi(z)(-\log|z|^2)^{-\beta} \quad (z \neq 0), \qquad \psi(0) = 0,$$

and extend by zero. On the smaller punctured disk put $t = |z|^2$ and $L = -\log t$. Differentiation gives

$$\psi_{z\bar{z}} = \frac{\beta(\beta+1)}{tL^{\beta+2}}, \qquad t\frac{\mathrm{d}}{\mathrm{d}t}L^{-\beta} = \beta L^{-\beta-1} \longrightarrow 0. \tag{14.55}$$

The first expression is integrable and the second is the radial flux. Integration by parts on punctured disks, using also $\psi \to 0$, shows that the distributional Hessian has no atom at zero. On the cutoff annulus its negative part is bounded. Hence, for a sufficiently small fixed $\eta > 0$, $u = \eta\psi(z_1)$ satisfies $\theta + \mathrm{dd}^{\mathrm{c}}u \geq \theta/2$.

Only one coordinate contributes to $\mathrm{dd}^{\mathrm{c}}u$. Locally approximate the bounded subharmonic potential in that coordinate from above and use Theorem 1.6.1; the smooth diagonal determinant identity passes to the limit and yields

$$\mathrm{MA}_\theta(u) = f\theta^n, \qquad f = 1 + \eta\psi_{z\bar{z}}(z_1).$$

Give f any positive value on the null set D. It is smooth and positive on $\Omega = X \setminus D$, where u is smooth and has smooth traces on all relatively compact coordinate balls. Near D its singular term is comparable to $|z_1|^{-2}(-\log|z_1|^2)^{-\beta-2}$. Its radial L^1 integral converges, whereas

$$\int_0^{r_0} s^{1-2p}(-\log s^2)^{-p(\beta+2)}\,\mathrm{d}s = +\infty \qquad (p > 1).$$

Also $(-\log|z|^2)^{-\beta}/|z|^\alpha \to +\infty$ for every $\alpha > 0$, so u is not Hölder at D. Finally, boundedness gives minimal ordinary singularities, since every global θ-plurisubharmonic competitor is bounded above.

14.20.2 A bounded discontinuous potential

We construct a bounded plurisubharmonic function on a bidisk whose Monge–Ampère measure is a constant multiple of Lebesgue measure, but which is discontinuous. The construction places logarithmic poles with summable weights at points accumulating at the origin; the resulting weight b vanishes at the poles but not at their limit. It is the local model for Theorem 14.20.2.

Let $U = W = \{|z| < 1/4\} \subset \mathbb{C}$, with coordinates z and w on the two factors. Write $\mathrm{d}A$ for planar Lebesgue measure and set

$$a_k = \alpha_k = 2^{-k-4}, \qquad A = \sum_{k\ge 1} \alpha_k = \frac{1}{16}, \qquad S = \{0\} \cup \{a_k : k \ge 1\}.$$

Define on U

$$h(z) = \sum_{k\ge 1} \alpha_k \log |z - a_k|^2, \qquad b(z) = \mathrm{e}^{h(z)}, \tag{14.56}$$

with $b = 0$ where $h = -\infty$.

Lemma 14.20.1 *The function*

$$a(z) = \frac{1}{\pi} \int_U \log |z - \zeta|^2 \, b(\zeta)^{-1} \, \mathrm{d}A(\zeta)$$

is bounded and continuous on U. The bounded function

$$P(z, w) = a(z) + b(z)|w|^2$$

is plurisubharmonic on $U \times W$, is smooth off $S \times W$, and satisfies

$$(\mathrm{dd^c} P)^2 = \frac{2}{\pi^2} \, \mathrm{d}A(z) \, \mathrm{d}A(w). \tag{14.57}$$

It is discontinuous at every $(0, w_0)$ with $w_0 \neq 0$.

Proof The summands defining h are negative on U, so their partial sums decrease. Since $h(0) = 2 \sum_k \alpha_k \log a_k > -\infty$, the limit is subharmonic. On compact subsets of $U \setminus S$, the series and its derivatives converge uniformly, making h harmonic there. Moreover $0 \le b \le 1$, $b(a_k) = 0$, and $b(0) > 0$.

Weighted arithmetic–geometric mean gives, almost everywhere,

$$b(z)^{-2} \le \sum_{k\ge 1} \frac{\alpha_k}{A} |z - a_k|^{-4A}. \tag{14.58}$$

For the countable inequality, first use the first N weights and assign the remaining weight to the factor 1; then let N increase. Since $4A = 1/4 < 2$, the integrals of the terms $|z - a_k|^{-4A}$ on U are bounded uniformly in k. Thus $b^{-1} \in L^2(U)$.

The logarithmic kernel has uniformly bounded L^2 norm on the translates of U that occur in the definition of a. Cauchy–Schwarz bounds a uniformly. Choose a compactly supported $L^2(\mathbb{C})$ kernel agreeing with $\log |z|^2$ on $U - U$. Translation continuity in L^2, paired with $b^{-1}\mathbf{1}_U \in L^2$, proves continuity of a. The distribution identity $\partial_z \partial_{\bar z} \log |z|^2 = \pi \delta_0$ gives $a_{z\bar z} = b^{-1}$. In particular a is subharmonic and, by local elliptic regularity, smooth off S.

The second summand of P is $\exp(h(z) + \log |w|^2)$, a convex increasing composition of a plurisubharmonic function, extended by zero at its poles. Thus P is bounded and plurisubharmonic. At smooth points the harmonicity of $h = \log b$ gives $b b_{z\bar z} = |b_z|^2$, and hence

$$\det(P_{j\bar k}) = b a_{z\bar z} + |w|^2 \big(b b_{z\bar z} - |b_z|^2 \big) = 1.$$

The set $S \times W$ is contained in the pole set of $h(z) + \log|z|$, a plurisubharmonic function not identically $-\infty$. It is also Lebesgue-null. Pluripolar nullity in Theorem 1.6.1 and (14.54) prove (14.57) throughout the bidisk. Finally,

$$P(a_k, w_0) = a(a_k) \longrightarrow a(0) < a(0) + b(0)|w_0|^2 = P(0, w_0)$$

when $w_0 \neq 0$. □

14.20.3 Compact gluing

We now glue the local example into a compact torus by a regularized maximum with a quadratic function. The result is a bounded solution with minimal singularities whose density is constant on a ball, where the solution is discontinuous; in the transition region the density acquires singularities that destroy every L^p bound with $p > 1$.

We work on the flat complex torus $X = (\mathbb{C}/(\mathbb{Z} + i\mathbb{Z}))^2$, identifying a small coordinate ball with a ball in $U \times W$. For a smooth function v on the ball write $H_v = (v_{j\bar{k}})$ for its complex Hessian and I for the two-dimensional identity matrix.

Theorem 14.20.2 *There are a positive flat Kähler form θ on X, a bounded $u \in \mathrm{PSH}(X, \theta)$ with minimal ordinary singularities, and a density $F > 0$ almost everywhere such that*

$$\mathrm{MA}_\theta(u) = F\theta^2, \qquad F \in L^1(X, \theta^2), \qquad F \notin L^p(X, \theta^2) \quad (p > 1).$$

On an open coordinate ball Ω, F is a positive constant and u is discontinuous. The constant function $\rho = 0$ is a smooth strict barrier on X.

Proof Set $R = 1/8$ and choose M so that $P_0 = P + M$ satisfies $0 \le P_0 \le L$ on $B_R \Subset U \times W$ for some finite L. Choose $C > 0$ with

$$\frac{3CR^2}{16} \ge 2, \qquad \frac{5CR^2}{16} > L + 2, \tag{14.59}$$

and put $Q(Z) = C(|Z|^2 - R^2/4)$ for $Z = (z, w)$. Let χ be the convolution of $|t|$ with an even nonnegative smooth probability kernel supported in $(-1, 1)$. Then χ is smooth and convex, $|\chi'| \le 1$, $\chi'(0) = 0$, and $\chi(t) = |t|$ for $|t| \ge 1$. The function

$$m(s, t) = \frac{s + t + \chi(s - t)}{2}, \qquad v = m(P_0, Q)$$

is bounded and plurisubharmonic, because m is convex and nondecreasing in each variable. The collar inequalities imply

$$v = P_0 \quad \text{on } B_{R/4}, \qquad v = Q \quad \text{when } 3R/4 \le |Z| < R.$$

Indeed, $Q \le -2 \le P_0 - 2$ on the first ball and $Q > L + 2 \ge P_0 + 2$ on the collar. Define

$$\theta = \frac{\mathrm{i}C}{2\pi}(\mathrm{d}z \wedge \mathrm{d}\bar z + \mathrm{d}w \wedge \mathrm{d}\bar w), \qquad u = \begin{cases} v - Q & \text{on } B_R, \\ 0 & \text{outside } B_R. \end{cases}$$

The collar identity makes u identically zero near ∂B_R and gives a global bounded potential with $\theta + \mathrm{dd}^{\mathrm{c}} u = \mathrm{dd}^{\mathrm{c}} v$ on the ball and $\theta + \mathrm{dd}^{\mathrm{c}} u = \theta$ outside. Thus u is admissible and has minimal ordinary singularities.

Outside the pluripolar set $(S \times W) \cap B_R$, set $\lambda = (1 + \chi'(P_0 - Q))/2$. Differentiating the regularized maximum gives

$$H_v = \lambda H_P + (1-\lambda) CI + \frac{\chi''(P_0 - Q)}{2} \partial(P_0 - Q) \otimes \overline{\partial(P_0 - Q)}. \tag{14.60}$$

Both H_P and CI are positive definite there; the final term is positive semidefinite. Hence the classical density is positive. Bounded products charge no pluripolar sets, so there is no further measure on the exceptional set. Their mass on compact X is finite by Proposition 1.7.1. This proves $\mathrm{MA}_\theta(u) = F\theta^2$ for an almost-everywhere positive $F \in L^1$. On $\Omega = B_{R/4}$, (14.57) gives the representative $F = C^{-2}$. There $u = P + M - Q$ is discontinuous at $(0, w_0)$ for $0 < |w_0| < R/4$.

We prove failure of every global L^p directly in the transition region. For large k, set

$$m_k = a(a_k) + M \in [0, L], \qquad w_k = \left(R^2/4 + m_k/C - |a_k|^2\right)^{1/2}, \qquad Z_k = (a_k, w_k).$$

Then $w_k > 0$, $P_0(Z_k) = Q(Z_k) = m_k$, and (14.59) gives $|Z_k|^2 < 9R^2/16$. Near the isolated pole a_k,

$$h(z) = \alpha_k \log |z - a_k|^2 + H_k(z),$$

where H_k is smooth and harmonic. Consequently b and P_0 are continuous near Z_k. There is a product neighborhood $V_k \Subset B_R$ of Z_k, with $|w|$ bounded below by a positive number, on which $1/4 \le \lambda \le 3/4$.

At smooth points of V_k, positivity and the two-dimensional determinant expansion give

$$\begin{aligned} \det H_v &\ge \det\bigl(\lambda H_P + (1-\lambda) CI\bigr) \\ &\ge \lambda(1-\lambda) C \operatorname{tr} H_P \ge c_k b_{z\bar z}, \end{aligned}$$

where $c_k > 0$ may depend on k and C. Here $P_{z\bar z} = b^{-1} + |w|^2 b_{z\bar z}$. With $\zeta = z - a_k$, shrink the first factor of V_k so that

$$b_{z\bar z} = |\zeta|^{2\alpha_k} \mathrm{e}^{H_k} \left| \frac{\alpha_k}{\zeta} + \partial_z H_k \right|^2 \ge c_k' |\zeta|^{2\alpha_k - 2}$$

for some $c_k' > 0$. Since $F = C^{-2} \det H_v$, this lower bound implies $F \notin L^p$ whenever $p(1 - \alpha_k) \ge 1$: the w-disk has positive area and the radial integral in z contains

$$\int_0^{\delta_k} r^{1 - 2p(1-\alpha_k)} \, \mathrm{d}r = +\infty.$$

For each $p > 1$ such a k exists because $\alpha_k \downarrow 0$. □

The bounded-product capacity estimate in Section 1.6 also holds for the discontinuous potential P. Thus a first-order capacity bound, even together with a constant positive density, cannot supply the missing boundary control.

Example 14.20.2 On the bidisk in $\mathbb{C}^2$ with coordinates (z, w), the function

$$H(z, w) = 2|z|(1 + |w|^2)$$

is locally Lipschitz, plurisubharmonic and not C^1 along $\{z = 0\}$. Plurisubharmonicity follows by writing its two summands as convex exponential compositions of $\log|z|$ and $\log|z| + \log|w|^2$. At $z \neq 0$,

$$H_{z\bar{z}} = \frac{1 + |w|^2}{2|z|}, \qquad H_{w\bar{w}} = 2|z|, \qquad |H_{z\bar{w}}|^2 = |w|^2.$$

Hence $\det(H_{j\bar{k}}) = 1$, and pluripolar nullity gives $(\mathrm{dd^c} H)^2 = 2\pi^{-2}\,\mathrm{d}\Lambda$ on the entire bidisk.

The last example rules out a purely local implication from Hölder continuity and a smooth positive density to smoothness; being local, it says nothing about the global hypotheses of Theorem 14.17.1. Nor does Theorem 14.20.2 contradict that theorem: there the solution is not locally Hölder continuous on the ball Ω, and its density is not smooth on the rest of X, which is the regular locus of the barrier $\rho = 0$. The trace criterion of Theorem 14.20.1 avoids both global hypotheses by identifying the bounded solution with a smooth Dirichlet solution on each ball.

14.21 Equations with resolved logarithmic poles

We now prescribe a singularity type with logarithmic poles. If the poles become a divisor on a modification, the singular part can be removed there, and what remains is a smooth residual form. When this residual form is strictly positive, the bounded Hermitian theory on the modification provides the remaining bounded potential, and pushing forward solves the equation in the prescribed type.

In this section $n \geq 2$, and the background is a Hermitian form h on X. Let $\psi \leq 0$ be a quasi-plurisubharmonic function that is smooth outside a nonempty analytic set A, its pole set. Assume that there is a modification $\pi : Y \to X$, biholomorphic over $X \setminus A$, such that $\pi^{-1}(A)$ is the support $|D|$ of a simple normal crossing divisor $D = \sum_j D_j$ and

$$\psi \circ \pi = \sum_j c_j \log|s_j|^2 + b, \qquad \beta = \pi^* h + \mathrm{dd^c} b - \sum_j c_j \Theta_j > 0, \tag{14.61}$$

where $c_j > 0$, b is smooth on Y, s_j is a holomorphic section of $\mathcal{O}(D_j)$ defining D_j, and Θ_j is the curvature form of a smooth Hermitian metric on $\mathcal{O}(D_j)$, so that

$\mathrm{dd^c}\log|s_j|^2 = [D_j] - \Theta_j$. Thus β is the smooth part of the current $\pi^*h + \mathrm{dd^c}(\psi\circ\pi)$, which we call the *residual form*.

Theorem 14.21.1 *For every nonzero nonnegative $f \in L^p(X, h^n)$, $p > 1$, there are $\kappa > 0$ and a normalized $u \in \mathrm{PSH}(X, h)$ such that*

$$\mathrm{MA}_h^{\mathrm{ext}}(u) = \kappa f h^n, \qquad u = \psi + O(1). \tag{14.62}$$

The lifted remainder $v = (u - \psi)\circ\pi$ extends Hölder continuously over Y, so u is locally Hölder on $X \setminus A$. Its current is

$$\pi^*h + \mathrm{dd^c}(u\circ\pi) = \sum_j c_j[D_j] + \beta + \mathrm{dd^c}v. \tag{14.63}$$

The positive residual current $\beta + \mathrm{dd^c}v$ has zero Lelong numbers. If h is Kähler, then $\kappa = \int_Y \beta^n / \int_X f h^n$, and the normalized solution is unique among all normalized solutions u' of (14.62) with $u' = \psi + O(1)$, continuous or not. If the density $g = (f\circ\pi)\,\pi^*h^n/\beta^n$ is smooth and strictly positive on Y, the residual current $\beta + \mathrm{dd^c}v$ may be chosen smooth and strictly positive.

Proof Define $J = \pi^*h^n/\beta^n$ and $g = (f\circ\pi)J$ off the exceptional set, assigning any value to g on that volume-zero set. The smooth nonnegative J is bounded. Change of variables on the biholomorphic locus gives

$$\int_Y g\beta^n = \int_X f h^n, \qquad \int_Y g^p\beta^n \le \|J\|_\infty^{p-1}\int_X f^p h^n. \tag{14.64}$$

Thus g is a nonzero L^p density. Theorems 10.1.1 and 14.4.1 give a bounded Hölder β-plurisubharmonic v and $\kappa > 0$ with $(\beta + \mathrm{dd^c}v)^n = \kappa g\beta^n$. If h is Kähler, then β is Kähler and the mass identity fixes the stated scalar. For smooth positive g, Theorem 9.1.1 gives a smooth solution instead.

Set $u = \psi + v\circ\pi^{-1}$ on $X \setminus A$ and $u = -\infty$ on A. Push forward the positive current $\sum c_j[D_j] + \beta + \mathrm{dd^c}v$. Pushforward commutes with $\mathrm{dd^c}$, $\pi_*\pi^*h = h$, and the pushed locally integrable potential is u almost everywhere. Its quasi-plurisubharmonic representative equals $\psi + v\circ\pi^{-1}$ off A and tends to $-\infty$ at A because v is bounded. Hence $h + \mathrm{dd^c}u \ge 0$ and $u = \psi + O(1)$ in the two-sided ordinary sense. The pulled-back identity is (14.63); bounded residuals have zero Lelong number. The equation holds off A by (14.64), and Theorem 6.1.1 extends it as (14.62). Subtracting $\sup_X u$ changes neither the equation nor the ordinary type.

For uniqueness when h is Kähler, let u' be a normalized solution with $u' = \psi + O(1)$. On $Y \setminus D$, $w = (u' - \psi)\circ\pi$ is bounded and β-plurisubharmonic. Since w is bounded, Lemma 1.3.7 extends it across D to a bounded β-plurisubharmonic function on Y. On each relatively compact subset of $Y \setminus D$, sufficiently deep truncations of u' equal u'. Thus locality in Theorem 6.1.1 gives the bounded equation $\kappa g\beta^n$ there; both sides give D zero mass. The global equation follows, its mass fixes κ, and closed full-mass uniqueness gives $w = v$+constant as recalled in Section 34.19. Normalization fixes that constant. □

The Hölder constants depend on the fixed geometry and divisor metrics, the c_j, a lower bound for the positivity of β, p, and the L^p norm of the density κg itself. In particular, the argument gives no estimate that is uniform as β degenerates or as κ becomes unbounded. In simple normal crossing coordinates a density comparable to $\prod_j |z_j|^{-2a_j}$ belongs locally to L^p exactly when

$$pa_j < 1 \quad \text{for every } j, \tag{14.65}$$

by the factors $\int_0^\epsilon r_j^{1-2pa_j}\,\mathrm{d}r_j$. A smooth positive density f on X need not give a strictly positive g on Y, since the Jacobian factor $J = \pi^* h^n/\beta^n$ of the proof can vanish on the exceptional set.

Example 14.21.1 Take $X = \mathbb{P}^n$, $h = \lambda\omega_{\mathrm{FS}}$, $\int_X \omega_{\mathrm{FS}}^n = 1$, and $0 < c < \lambda$. Put

$$\psi_c = c \log \frac{\sum_{j=1}^n |Z_j|^2}{\sum_{j=0}^n |Z_j|^2}.$$

Its pole is $P = [1 : 0 : \cdots : 0]$. On the point blowup $\pi : Y \to X$, let $q : Y \to \mathbb{P}^{n-1}$ be the direction map. In affine blowup coordinates $x = (z, zw)$, Poincaré–Lelong gives

$$\pi^* h + \mathrm{dd^c}(\psi_c \circ \pi) = c[E] + (\lambda - c)\pi^*\omega_{\mathrm{FS}} + cq^*\omega_{\mathrm{FS}}.$$

The residual form $\beta = (\lambda - c)\pi^*\omega_{\mathrm{FS}} + cq^*\omega_{\mathrm{FS}}$ is positive: $\pi^*\omega_{\mathrm{FS}}$ is positive in the directions normal to E, and $q^*\omega_{\mathrm{FS}}$ in the directions tangent to E. Write $H = \pi^*[\omega_{\mathrm{FS}}]$. Since $H|_E = 0$ and $E^n = (-1)^{n-1}$, its mass is

$$\int_Y \bigl((\lambda - c)\pi^*\omega_{\mathrm{FS}} + cq^*\omega_{\mathrm{FS}}\bigr)^n = \lambda^n - c^n. \tag{14.66}$$

Hence, for every nonzero nonnegative $f \in L^p$ with $\int_X f h^n = \lambda^n - c^n$, Theorem 14.21.1 gives $\kappa = 1$ and a solution of $\mathrm{MA}_h^{\mathrm{ext}}(u) = f h^n$ with the nonminimal type $u = \psi_c + O(1)$.

For an explicit solution, choose a smooth function v on Y with $v|_E$ nonconstant, small enough that $S = \beta + \mathrm{dd^c} v$ is still positive, and put $u = \psi_c + v \circ \pi^{-1}$ off P. The density f of its measure, given by $f \circ \pi = S^n/\pi^* h^n$ off E, lies in every L^p with $1 < p < n/(n-1)$: $\pi^* h^n$ vanishes to order $|z|^{2(n-1)}$ along E, so the local integral of f^p is finite precisely when $(n-1)(p-1) < 1$. Different directions of approach to P give different limits of $u - \psi_c$. The divisor $c[E]$ of the current upstairs leaves no divisor downstairs, since E is contracted to a point. On $X \setminus \{P\}$, where u is smooth and strictly h-plurisubharmonic, the Hermitian metric $h + \mathrm{dd^c} u$ is isometric to $(Y \setminus E, S)$. Its metric completion is Y with the metric S, so the whole divisor E is restored: removing the smooth real codimension-two submanifold E does not change the infimum of path lengths in Y. Finally, if h is replaced by a sufficiently small nonclosed perturbation, both h and the residual form remain positive, so the existence part of Theorem 14.21.1 still applies.

14.21.1 Residual mass

When h is not Kähler, the scalar in Theorem 14.21.1 is still determined by masses if h satisfies the power condition $\mathrm{dd^c}(h^k) = 0$, $1 \le k \le n-1$, of Theorem 2.2.2, which fixes the mass of every bounded solution. The condition persists under pullback and under addition of a smooth closed form: expand each power and apply the original identities to its terms. For $n = 2$ the condition is simply $\mathrm{dd^c} h = 0$, so it includes the nonclosed Hopf metric of Proposition 20.6.1. The residual form then has strictly smaller mass than h, the difference being carried by the divisor.

Proposition 14.21.1 *Under* (14.61)*, assume* $\mathrm{dd^c}(h^k) = 0$ *for* $1 \le k \le n-1$*, and put* $H = \pi^* h$*. Then*

$$\int_X h^n - \int_Y \beta^n = \sum_j c_j \sum_{i=0}^{n-1} \int_{D_j} H^i \wedge \beta^{n-1-i} > 0. \tag{14.67}$$

Thus the constructed solution of Theorem 14.21.1 has $\kappa = \int_Y \beta^n / \int_X f h^n$*. If* $\int_X f h^n = \int_X h^n$*, its scalar is strictly less than one.*

Proof Let $C = \sum_j c_j \Theta_j - \mathrm{dd^c} b$, so $\beta = H - C$ with C closed. The mixed forms $Q_i = H^i \wedge \beta^{n-1-i}$ satisfy $\mathrm{dd^c} Q_i = 0$: expand $\beta = H - C$ and apply the power condition to each H^k. With $\Psi = \psi \circ \pi$, $\mathrm{dd^c}\Psi = \sum_j c_j [D_j] - C$. Distributional integration by parts against the smooth $\mathrm{dd^c}$-closed Q_i gives

$$\int_Y (H^n - \beta^n) = \sum_i \int_Y C \wedge Q_i = \sum_j c_j \sum_i \int_{D_j} Q_i .$$

Change of variables gives $\int_Y H^n = \int_X h^n$. Every integrand on the right is nonnegative, since H is semipositive and β positive; the $i = 0$ term on each nonempty D_j is strictly positive. This includes exceptional divisors. By Theorem 2.2.2, the residual solution has mass $\int_Y \beta^n$, giving the scalar. □

14.22 Minimal singularities on blowups

On a blowup, the background itself can force an exceptional divisor into every positive current. The coefficient of this divisor is then part of the minimal ordinary type, while the rest of the potential descends to the target of the blowup, so the equation reduces to one on the target. The density changes by the Jacobian of the blowup, which determines the loss of integrability.

In this section the roles of the letters differ from those in Section 14.21: X is a blowup and Y its target. Let (Y, h) be a connected compact Hermitian n-fold, $n \ge 2$, let $Z \subset Y$ be a connected smooth center of codimension $r \ge 2$, and write $\pi : X = \mathrm{Bl}_Z Y \to Y$ for the blowup, with exceptional divisor E. Let s_E be

the canonical section of $\mathcal{O}(E)$, choose a smooth Hermitian metric on $\mathcal{O}(E)$ with curvature form Θ_E, so that $\mathrm{dd^c}\log|s_E|^2 = [E] - \Theta_E$, put $L = \log|s_E|^2$, and fix $c > 0$. The smooth background

$$\theta = \pi^* h + c\Theta_E \tag{14.68}$$

can be indefinite, and it is nonclosed when h is nonclosed. Positivity is imposed on $\theta + \mathrm{dd^c}u$, not on θ.

Proposition 14.22.1 *Every $u \in \mathrm{PSH}(X, \theta)$ has, up to an additive constant, a unique h-plurisubharmonic target potential q such that*

$$u = cL + q \circ \pi + C, \qquad \theta + \mathrm{dd^c}u = \pi^*(h + \mathrm{dd^c}q) + c[E]. \tag{14.69}$$

The potentials with minimal ordinary singularities are exactly those of the form $cL + O(1)$, and u is one of them if and only if q is bounded. There is a strict θ-plurisubharmonic barrier with logarithmic coefficient $c + \delta$ for some $\delta > 0$.

Proof Put $T = \theta + \mathrm{dd^c}u$ and $q = \pi_*(u - cL)$ as a scalar distribution. The latter is locally integrable: off Z it is the inverse-coordinate function, and a smooth target volume pulls back with bounded Jacobian, so its absolute integral is controlled by that of $u - cL$ on X. Since $\pi_*[E] = 0$,

$$S = \pi_* T = h + \mathrm{dd^c}q \geq 0.$$

A smooth local strictly plurisubharmonic shift gives a quasi-plurisubharmonic representative of q. Its pullback $q \circ \pi$ is not identically $-\infty$ and satisfies $\pi^*(h + \mathrm{dd^c}q) \geq 0$, by Lemma 1.22.1: since π is dominant, the composition of a local plurisubharmonic function with π is again plurisubharmonic and not identically $-\infty$.

Off E, $T = \pi^* S$. The difference is an order-zero current supported on E, and it is closed: both derivatives equal $\pi^* \mathrm{d}h$. To identify it, write $R = T - \pi^* S$. In a chart where $E = \{z = 0\}$, order zero gives $zR = \bar{z}R = 0$. Closedness then gives $\mathrm{d}z \wedge R = \mathrm{d}\bar{z} \wedge R = 0$. Thus only its normal $(1,1)$ coefficient remains, a measure on E; the tangential equations in $\mathrm{d}R = 0$ make that measure a constant multiple of integration on E. Connectedness of E identifies one constant a globally, so $R = a[E]$. Its cohomology class is $c[E]$. On a line in an exceptional fiber, $\mathcal{O}(E)$ has degree -1, so $[E]$ is nonzero and $a = c$. The difference between the two scalar potentials in (14.69) has $\mathrm{dd^c}$ zero. Local elliptic regularity makes it pluriharmonic; compactness and connectedness make it constant.

Since $h > 0$, $q = 0$ is admissible, and every h-plurisubharmonic q is bounded above on compact Y. Hence cL is minimal and two-sided bounded comparison with it is exactly boundedness of q. For the barrier choose another divisor metric, with logarithmic norm $L' = L + \sigma$ and curvature $\Theta'_E = \Theta_E - \mathrm{dd^c}\sigma$ for a smooth real function σ, so that $-\Theta'_E$ is positive on the vertical tangent bundle of $E \to Z$, using the tautological $\mathcal{O}(-1)$. In adapted coordinates

$$\pi(y, z, w) = (y, z, zw), \tag{14.70}$$

π^*h controls the nonvertical directions and $|z|^2|\mathrm{d}w|^2$. For small $\delta > 0$, the vertical positivity of $-\delta\Theta'_E$ dominates its mixed errors by completing the square; away from E, compactness allows the same δ. Thus $\pi^*h - \delta\Theta'_E > 0$. For the fixed background θ in (14.68), take

$$w = (c+\delta)L' - c\sigma = (c+\delta)L + \delta\sigma.$$

Then $\theta + \mathrm{dd^c}w = (c+\delta)[E] + \pi^*h - \delta\Theta'_E$ dominates a positive Hermitian form. The smooth correction $\delta\sigma$ preserves the stated logarithmic coefficient. □

Theorem 14.22.1 *Fix a smooth positive volume form μ on X and a nonzero nonnegative $f \in L^p(X,\mu)$, $p > 1$. There exist $\kappa > 0$ and a normalized minimal-type solution of*

$$\mathrm{MA}^{\mathrm{ext}}_\theta(u) = \kappa f\mu, \qquad u = cL + q\circ\pi + C, \tag{14.71}$$

where q is Hölder on Y. The divisor coefficient is exactly c. In (14.70), $u - cL = q(y,0) + C + O(|z|^\alpha)$ on smaller charts for some $\alpha > 0$, so its limit is constant along each exceptional fiber.

If $\pi_*(f\mu) = Fh^n$, then $F \in L^s(Y,h^n)$ for every

$$1 < s < \frac{rp}{(r-1)p+1}. \tag{14.72}$$

For a point center, data bounded above and below by positive constants near E attain the strict threshold $s < n/(n-1)$, and for finite p no strictly larger universal exponent than $np/((n-1)p+1)$ can be guaranteed. If h is Kähler, the class $[\theta]$ is big and non-nef, has volume $\int_Y h^n$, and $\kappa = \int_Y h^n / \int_X f\mu$; the normalized solution is unique among all normalized solutions of (14.71) with minimal ordinary singularities. Under $\mathrm{dd^c}(h^j) = 0$, $1 \le j \le n-1$, the scalar of the constructed solution has the same integral formula.

Proof *Integrability and existence.* In (14.70) the complex Jacobian is z^{r-1}. Put $J = \pi^*h^n/\mu$, so $J \asymp |z|^{2(r-1)}$ on nested charts and $F\circ\pi = f/J$ off E. For $1 < s < p$, change of variables and Hölder's inequality give

$$\int_Y F^s h^n = \int_X f^s J^{1-s}\mu \tag{14.73}$$

$$\le \|f\|^s_{L^p(\mu)} \left(\int_X J^{-(s-1)p/(p-s)}\mu\right)^{(p-s)/p}. \tag{14.74}$$

The normal complex integral is finite precisely if $(r-1)(s-1)p/(p-s) < 1$, which is (14.72). Theorems 10.1.1 and 14.4.1 on (Y,h) supply q and κ with $(h + \mathrm{dd^c}q)^n = \kappa F h^n$. Use (14.69) off E and Theorem 6.1.1 across it. Hölder continuity gives $q(\pi(y,z,w)) = q(y,0) + O(|z|^\alpha)$ uniformly on smaller charts.

Sharpness of the exponent. For f bounded above and below by positive constants near the exceptional divisor of a point center, F is comparable to $\mathrm{dist}_h(\cdot,Z)^{-2(n-1)}$ near Z, giving the strict threshold. More generally, $f \asymp |s_E|^{-2a}$ with $0 \le a < 1/p$

belongs to L^p upstairs, while its pushforward has threshold $s < n/(n-1+a)$. Letting $a \uparrow 1/p$ proves the stated limitation; it makes no finite-p endpoint assertion.

The Kähler case. When h is Kähler, the strict barrier current $(c+\delta)[E]+\pi^*h-\delta\Theta'_E$ constructed in Proposition 14.22.1 makes $[\theta]$ big. Its degree on an exceptional-fiber line is $-c$, so it is not nef. The minimal current $c[E]+\pi^*h$ has non-pluripolar top mass $\int_Y h^n$, and the minimal mass theorem identifies this with $\mathrm{vol}([\theta])$ as recalled in Section 34.16. Full-mass uniqueness and mass integration fix the scalar and normalized current as recalled in Section 34.19. A normalized solution of minimal ordinary type, possibly discontinuous, still has bounded q by Proposition 14.22.1; on every relatively compact set off E, deep truncations equal that competitor, so locality in Theorem 6.1.1 gives the bounded target equation off Z. Both target measures give Z zero mass, so closed uniqueness applies globally. If only the power conditions hold, Theorem 2.2.2 fixes the scalar of the constructed solution. Quantitative Hölder bounds depend on κF, not on an unnormalized F alone. □

For the prescribed pullback measure $\pi^*(h^n)$, choose $q = 0$ and $\kappa = 1$. The current is $c[E]+\pi^*h$. Its smooth part π^*h is degenerate on E exactly in the directions tangent to the exceptional fibers, and its density relative to a smooth volume form is $|z|^{2(r-1)}$ times a smooth positive factor. On $X \setminus E$, where the solution $u = cL$ is smooth and strictly θ-plurisubharmonic, the metric $\theta + \mathrm{dd^c}u = \pi^*h$ is isometric to $(Y \setminus Z, h)$; its metric completion is Y, so each exceptional fiber collapses to a point of Z. The distance to E is comparable to $|z|$ on bounded adapted charts. Neither the density order nor this distance exponent depends on c.

Example 14.22.1 If $n = 2$ and Z is a point on a compact Kähler surface, $[\theta] = \pi^*[h] + c[E]$ has Zariski positive part $\pi^*[h]$ and negative part cE: $E^2 = -1$ and $\pi^*[h] \cdot E = 0$. Its volume is $\int_Y h^2$, although it is non-nef. The solution with $\kappa = 1$ for the measure $\pi^*(h^2)$ has logarithmic coefficient exactly c, its density vanishes to order $|z|^2$ along E, and the completion of its metric on $X \setminus E$ collapses E to the point Z. The stronger barrier from Proposition 14.22.1 has coefficient $c + \delta$.

Theorem 14.22.2 *Let $\pi : Y_m \to Y_0$ be a finite nonempty sequence of blowups of connected smooth centers of codimensions $r_j \geq 2$ over a compact Hermitian (Y_0, h_0). Let E_j be the exceptional divisor at stage j, let $\pi_{>j}$ denote the subsequent map, choose $a_j > 0$, and set*

$$\Delta = \sum_j a_j \pi_{>j}^* E_j, \qquad \mathrm{dd^c} L_\Delta = [\Delta] - \Theta_\Delta, \qquad \theta = \pi^* h_0 + \Theta_\Delta,$$

where $L_\Delta = \sum_j a_j \log |s_j|^2$, with s_j the canonical section of $\pi_{>j}^* O(E_j)$ for a smooth Hermitian metric, and Θ_Δ is the corresponding combination of curvature forms. Every θ-positive current is $\pi^*(h_0 + \mathrm{dd^c} q) + [\Delta]$ and every potential is $L_\Delta + q \circ \pi + C$, with $q \in \mathrm{PSH}(Y_0, h_0)$. Minimal ordinary type is exactly $L_\Delta + O(1)$, equivalent to bounded q. For potentials of this type, every prime exceptional coefficient is the one prescribed by the effective total transform Δ. There is a strict barrier with divisor $\Delta + B$ for an effective exceptional B positive on every exceptional component. For nonzero nonnegative upstairs L^p data, $p > 1$, a minimal solution has Hölder q, with pushed density in every L^s satisfying

$$1 < s < \frac{Rp}{(R-1)p + 1}, \qquad R = \prod_j r_j. \tag{14.75}$$

For Kähler h_0 the mass, scalar, and closed full-mass uniqueness are those of the target; the power conditions on h_0 fix the scalar for the constructed nonclosed solution. For the pullback measure $\pi^*(h_0^n)$, the metric $\pi^* h_0$ on the complement of the exceptional set has metric completion Y_0, each fiber collapsing to a point, and the zero divisor of the density is that of the squared modulus of the holomorphic Jacobian, independently of the a_j.

Proof Apply Proposition 14.22.1 successively, allowing an intermediate smooth background to be indefinite. The difference between each current and the pullback of its pushforward is closed of order zero, and exceptional-fiber degree fixes its coefficient. Pullback of earlier divisor currents produces the total transforms, proving the representation without an SNC requirement. The initial $q = 0$ is admissible; upper bounds on compact targets prove minimality and the bounded-q criterion. At SNC charts this is the usual sum of logarithms.

At each stage choose an auxiliary divisor metric as in Proposition 14.22.1, with curvature Θ'_{E_j}, so that $h_j = \pi_j^* h_{j-1} - \delta_j \Theta'_{E_j} > 0$ for a sufficiently small $\delta_j > 0$. Expanding yields $h_m = \pi^* h_0 - \Theta_B$ for $B = \sum_j \delta_j \pi_{>j}^* E_j$, effective with a positive coefficient on every exceptional component. If $\mathrm{dd^c} L_B = [B] - \Theta_B$ uses these auxiliary metrics, then the fixed background satisfies $\theta + \mathrm{dd^c}(L_\Delta + L_B) = h_m + [\Delta + B]$, which is the strict barrier current. The Jacobian calculation and Hölder estimate apply stagewise. If $s = rp/((r-1)p+1)$, then $1 - 1/s = (1 - 1/p)/r$; iteration over the stages gives (14.75), with strict inequality. The target Hölder equation, mass and uniqueness are obtained as in Theorem 14.22.1. For the pullback measure take $q = 0$ and use the target path comparison away from the exceptional set. The Jacobian fixes

the density, while $[\Delta]$ fixes the divisor current; these are independent pieces of the equation. □

14.23 Representing measures in an ordinary type

We return to the general setting of the chapter, with the Hermitian form ω fixed at its beginning. Locally, every finite non-pluripolar measure is absolutely continuous with respect to the Monge–Ampère measure of a bounded plurisubharmonic function (Lemma 1.6.2). We globalize this statement in a prescribed ordinary type. The local potentials are glued to a strictly θ-plurisubharmonic potential lying below the reference and are then truncated relative to the reference. A decreasing convex sum of the resulting countable family has a Monge–Ampère measure that dominates every local piece in the sense of absolute continuity. Its potential has the prescribed ordinary type, and the given measure has an integrable density with respect to its Monge–Ampère measure.

Proposition 14.23.1 *Let $\theta \geq 0$ be a smooth big real $(1,1)$-form, and let $\varphi \in \mathrm{PSH}(X,\theta)$ be such that the envelope $P_{\epsilon\theta}(\varphi)$ of Section 1.19 is not identically $-\infty$ for some $0 < \epsilon < 1$. For every finite non-pluripolar measure μ there are*

$$\psi \in \mathrm{PSH}(X,\theta), \qquad \psi \sim \varphi, \qquad 0 \leq f \in L^1\big(\mathrm{MA}_\theta^{\mathrm{ext}}(\psi)\big)$$

such that

$$\mu = f\,\mathrm{MA}_\theta^{\mathrm{ext}}(\psi).$$

The measure $\mathrm{MA}_\theta^{\mathrm{ext}}(\psi)$ may have infinite mass, but the density f is integrable with respect to it.

Proof Translate φ below zero. Put $q = P_{\epsilon\theta}(\varphi) \leq \varphi$, and choose a strict big potential $\rho \leq 0$ with $\theta + \mathrm{dd^c}\rho \geq a\omega$, where $a > 0$. Then

$$s = q + (1-\epsilon)\rho \leq \varphi, \qquad \theta + \mathrm{dd^c} s \geq (1-\epsilon)a\omega.$$

In particular s is θ-plurisubharmonic and not identically $-\infty$. Its pole set is pluripolar, as is that of φ, so both are negligible for μ.

Cover X by finitely many closed coordinate balls K_i, each contained in a larger coordinate ball B_i. Apply Lemma 1.6.2 to $\mu_i = \mathbf{1}_{K_i}\mu$. This gives bounded local plurisubharmonic v_i, normalized by $1 \leq v_i \leq 2$, with

$$\mu_i \ll \nu_i := (\mathrm{dd^c} v_i)^n.$$

Take a smooth cutoff χ_i which is zero near K_i and -3 on a boundary collar of B_i. Choose $\delta_i > 0$ so small that

$$\theta + \mathrm{dd^c}\big(s + \delta_i(v_i + \chi_i)\big) \geq \tfrac{1}{2}(1-\epsilon)a\omega + \delta_i \mathrm{dd^c} v_i.$$

Let S_i equal $\max(s, s + \delta_i(v_i + \chi_i))$ on B_i and s elsewhere. The boundary collar makes this a global θ-plurisubharmonic function. Since $\chi_i \le 0$ may be arranged,

$$s \le S_i \le s + 2\delta_i \le \varphi + 2\delta_i.$$

For every positive integer m, set

$$q_{i,m} = \max(\varphi - m, S_i) - 2\delta_i.$$

These potentials have the same ordinary type as φ, and

$$\varphi - m - 2\delta_i \le q_{i,m} \le \varphi. \tag{14.76}$$

On a neighborhood of K_i, $S_i = s + \delta_i v_i$ away from the pole set of s. Let

$$D_{i,m} = \{s + \delta_i v_i > \varphi - m\}$$

in that neighborhood, restricting to points where the potentials are finite. This is a plurifinely open set there. Locality and positive mixed products give

$$\mathbf{1}_{D_{i,m}} \mathrm{MA}_\theta^{\mathrm{ext}}(q_{i,m}) \ge \delta_i^n \mathbf{1}_{D_{i,m}} \nu_i. \tag{14.77}$$

Here s need not be bounded. After a local smooth correction, the positive product inequality holds at every common finite truncation level of s and the bounded potential v_i. Exhaust the complement of the pole set of s. The measure ν_i is non-pluripolar, so it loses no mass in that exhaustion. Then restrict the resulting inequality by plurifine locality. This proves (14.77) for the extended measures.

For μ_i-almost every point of K_i, both s and φ are finite, and hence that point belongs to $D_{i,m}$ for some m. Consequently, a Borel set which is null for every $\mathrm{MA}_\theta^{\mathrm{ext}}(q_{i,m})$ is null for every μ_i, and therefore for μ.

Enumerate the countable family $q_{i,m}$ as q_k, and write its bounds as $\varphi - C_k \le q_k \le \varphi$ with $C_k < \infty$. Choose positive t_k such that

$$\sum_k t_k < 1, \qquad B := \sum_k t_k C_k < \infty.$$

The finite convex combinations

$$\psi_N = \sum_{k=1}^{N} t_k q_k + \left(1 - \sum_{k=1}^{N} t_k\right) \varphi$$

decrease and lie between $\varphi - B$ and φ. Their limit ψ is θ-plurisubharmonic, satisfies $\psi \ge \varphi - B$, and hence $\psi \sim \varphi$. For any fixed k, separate its summand to write

$$\psi = t_k q_k + (1 - t_k) w_k, \qquad w_k \in \mathrm{PSH}(X, \theta), \qquad w_k \sim \varphi.$$

The remainder is obtained by the same decreasing convex-sum construction. Positive non-pluripolar mixed products give

$$\mathrm{MA}_\theta^{\mathrm{ext}}(\psi) \geq t_k^n \mathrm{MA}_\theta^{\mathrm{ext}}(q_k).$$

This is valid also for infinite measures: first restrict away from the common pole set, which is the pole set of φ by the ordinary-type bounds, and then exhaust by finite truncations. All measures ignore that pole set. The preceding null-set conclusion now gives $\mu \ll \mathrm{MA}_\theta^{\mathrm{ext}}(\psi)$.

By Theorem 6.1.1, the measure $\mathrm{MA}_\theta^{\mathrm{ext}}(\psi)$ is σ-finite. The Radon–Nikodym theorem applies to this σ-finite measure and the finite μ. It gives a nonnegative density f with

$$\int_X f \, \mathrm{MA}_\theta^{\mathrm{ext}}(\psi) = \mu(X) < \infty,$$

as claimed. If $\mu = 0$, one may simply take $\psi = \varphi$ and $f = 0$. □

Lemma 14.23.1 *Let $\theta \geq 0$ be a smooth big real $(1,1)$-form, and let μ be a finite non-pluripolar measure on X. There are a bounded $\psi \in \mathrm{PSH}(X,\theta)$ and a nonnegative $f \in L^1(\mathrm{MA}_\theta(\psi))$ such that*

$$\mu = f \, \mathrm{MA}_\theta(\psi).$$

Proof Apply Proposition 14.23.1 with $\varphi = 0$. Semipositivity of θ gives $P_{\epsilon\theta}(0) = 0$ for every $0 < \epsilon < 1$, and $\psi \sim 0$ means that ψ is bounded. □

These representations give only an L^1 density, whereas Theorem 14.9.1 requires a bounded density with respect to the measure of a bounded potential; for an unbounded prescribed type, moreover, the representing potential is itself unbounded. The existence argument for general measures in Section 31.6 therefore uses a bounded Hermitian reference and relative compactness instead.

14.24 The homogeneous equation with a Hölder reference

A bounded density against a Hölder reference measure gives an exact homogeneous equation. The coefficient is obtained with the solution. Continuous approximation of the density is needed before passing to smooth reference measures, since weak convergence does not preserve integrals of a fixed Borel function.

Theorem 14.24.1 *Let h be a Hermitian form on a connected compact complex manifold X. Suppose $u \in \mathrm{PSH}(X,h) \cap C^{0,\alpha}(X)$ for some $0 < \alpha \le 1$, and let ν be a finite nonzero positive measure with*

$$\nu \le A\mathrm{MA}_h(u), \qquad A > 0.$$

There are a constant $c > 0$ and a Hölder continuous $w \in \mathrm{PSH}(X,h)$ such that

$$\sup_X w = 0, \qquad \mathrm{MA}_h(w) = c\nu.$$

In particular, its mass is finite and positive. No mass bound over all bounded h-plurisubharmonic functions is assumed.

Proof *Step 1: approximate the density and reference.* Write $\sigma = \mathrm{MA}_h(u)$ and $\nu = Ag\sigma$, with $0 \le g \le 1$. Choose continuous $g_l \in [0,1]$ tending to g in $L^1(\sigma)$. Regularity of the finite measure supplies this approximation. The inequality $|s^{1/n} - t^{1/n}|^n \le |s-t|$ on $[0,1]$, followed by Hölder's inequality, gives $g_l^{1/n} \to g^{1/n}$ in $L^1(\sigma)$.

By Lemma 1.21.5, there are smooth $v_j \in \mathrm{PSH}(X,h)$ tending uniformly to u with a common Hölder norm. Their bounded products $\sigma_j = h_{v_j}^n$ tend weakly to σ. Choose a dense countable family of continuous tests, including the constant one. For each l, choose $j(l) \ge l$ so that integration of $g_l^{1/n}$, and of g_l multiplied by the first l tests, against $\sigma_{j(l)} - \sigma$ has absolute value at most $1/l$. Write $\widehat{v}_l = v_{j(l)}$ and

$$\nu_l = Ag_l h_{\widehat{v}_l}^n.$$

The common bounded-reference mass and $0 \le g_l \le 1$ give uniformly bounded masses. The diagonal and density approximation imply

$$\nu_l \rightharpoonup \nu, \qquad \lim_l \int_X g_l^{1/n} h_{\widehat{v}_l}^n = \int_X g^{1/n}\,\mathrm{d}\sigma > 0.$$

Discard finitely many terms if needed. Each ν_l has a continuous density with respect to smooth volume and positive mass. Thus Theorem 10.1.1 gives continuous normalized h-plurisubharmonic φ_l and $c_l > 0$ with $h_{\varphi_l}^n = c_l\nu_l$.

Step 2: control the coefficients and potentials. Since both right-hand sides have smooth-volume densities, Lemma 1.7.3 gives

$$h_{\varphi_l} \wedge h_{\widehat{v}_l}^{n-1} \ge (c_l A)^{1/n} g_l^{1/n} h_{\widehat{v}_l}^n.$$

The trace bound in Lemma 1.8.10 is uniform for references with a fixed supremum norm, as its proof shows. Integrating therefore bounds c_l above. By Proposition 1.8.1, the solution measures $\mu_l = h_{\varphi_l}^n \le C h_{\widehat{v}_l}^n$ have a common square-capacity bound.

Fix $\varepsilon = 1/2$, the zero competitor, and $D > 0$ with $2D < \delta_{1/2}$. The backwards estimate of Lemma 10.3.2 gives

$$\mathrm{Cap}_h\{\varphi_l < \inf_X \varphi_l + D\} \ge a_0 > 0.$$

The normalized tail estimate (1.15) then bounds $-\inf_X \varphi_l$ uniformly. Applying Lemma 10.3.1 at $s = t = D$ also gives

$$D^n a_0 \le C\mu_l(X) = Cc_l\nu_l(X).$$

Since the masses of ν_l are uniformly bounded above, c_l is bounded away from zero.

Step 3: take a uniform limit. Extract a subsequence with $c_l \to c > 0$ and φ_l converging in $L^1(dV)$, using Theorem 1.4.1. All potentials now have common upper and lower bounds. The common Hölder norms of $\widehat{v}_l$ and Corollary 1.8.2 give, uniformly in j, k,

$$\int_X |\varphi_j - \varphi_k|\, d\mu_j \le C\|\varphi_j - \varphi_k\|_{L^1(dV)}^{\alpha/(\alpha+2n)} \longrightarrow 0.$$

Use Proposition 10.3.1 in both orders to see that this subsequence is uniformly Cauchy. Its continuous limit w is h-plurisubharmonic and has supremum zero. Uniform bounded-product continuity and $\nu_l \rightharpoonup \nu$ yield $\mathrm{MA}_h(w) = c\nu$. Finally Theorem 14.4.2, with reference u and domination constant cA, gives the Hölder assertion. Its mass is $c\nu(X)$. □

14.25 Singular measures on shrinking spheres

A bounded density with respect to the measure of a bounded potential gives an exponential equation by Theorem 14.9.1. The following construction turns this analytic hypothesis into a test against a probability measure fixed by a coordinate ball. It applies to singular data on every Hermitian background, including backgrounds with zero lower mass.

Fix a Hermitian form h on X, with $n \ge 2$, a holomorphic coordinate ball centered at a point p, and a smooth cutoff $0 \le \chi \le 1$ supported in that ball and equal to one near a smaller closed ball. Choose $r_0 > 0$ so small that all spheres of radii $r_j = r_0 2^{-j}$, $j \ge 1$, lie in the smaller ball. Let σ_j denote their normalized Euclidean surface probabilities, extended by zero to X, and put

$$S_n = \sum_{j\ge1} r_j^{n/2}, \qquad \rho = \frac{1}{S_n}\sum_{j\ge1} r_j^{n/2}\sigma_j. \tag{14.78}$$

For a finite positive measure ν, define

$$M_\rho(\nu) = \left\| \frac{d\nu}{d\rho} \right\|_{L^\infty(\rho)},$$

with value $+\infty$ when $\nu \not\ll \rho$. The measure ρ is chosen before ν or the exponent in the equation. Transporting the same measure under a change of coordinates leaves the

test unchanged. Allowing the existence of some coordinate ball with this construction gives a sufficient condition independent of a specified chart.

Proposition 14.25.1 *The measure ρ is a singular non-pluripolar probability. There are $k > 0$ and $u_\rho \in \mathrm{PSH}(X,h) \cap C^{0,1/2}(X)$ with $\sup_X u_\rho = 0$ such that*

$$h + \mathrm{dd^c} u_\rho \geq h/2, \qquad \mathrm{MA}_h(u_\rho) \geq k\rho, \qquad 0 < \mathrm{MA}_h(u_\rho)(X) < \infty.$$

Proof In the coordinate ball write $R = |z|$ and set

$$\psi_j = \chi \log \max\{R^2, r_j^2\} + (1 - \chi),$$

extending ψ_j by one outside it. On the transition region of χ, R is bounded away from zero and exceeds all r_j. Hence all ψ_j agree there with the same smooth function. Where $\chi = 1$ they are plurisubharmonic, and outside its support they are constant. One fixed $K \geq 1$ therefore satisfies $\mathrm{dd^c}\psi_j \geq -Kh$ for every j. Put

$$Z = 2K \sum_{j\geq 1} \sqrt{r_j}, \qquad d_j = \frac{\sqrt{r_j}}{Z}, \qquad u_0 = \sum_{j\geq 1} d_j \psi_j.$$

The estimate $\|\psi_j\|_\infty \leq C(1+|\log r_j|)$ gives uniform convergence, and $\sum d_j = 1/(2K)$ yields $h + \mathrm{dd^c} u_0 \geq h/2$.

For two points of the inner ball at Euclidean distance t, the reverse triangle inequality gives

$$|\log \max\{|z|^2, r_j^2\} - \log \max\{|z'|^2, r_j^2\}| \leq 2\log(1 + t/r_j).$$

The contribution of $r_j \geq t$ is at most $Ct \sum_{r_j \geq t} r_j^{-1/2} \leq C\sqrt{t}$. For $r_j < t$, summing the geometric tail gives at most $C\sqrt{t} \sum_{\ell\geq 0} 2^{-\ell/2}(1 + \ell)$. On the cutoff transition and outside, the series is a fixed smooth function. These estimates give a local $1/2$-Hölder bound near every point. A finite cover and the bound on the oscillation give the global bound.

On the smaller ball, the currents $\mathrm{dd^c}\psi_j$ are closed and positive. Expand the product of $h + \sum_{j\leq N} d_j \mathrm{dd^c}\psi_j$ there and retain its positive diagonal terms. By Lemma 1.6.7, these are $d_j^n \sigma_j$. Uniform convergence of the corrected bounded potentials gives weak convergence of their products. Testing against nonnegative functions and first retaining any fixed finite number of diagonal terms therefore gives

$$\mathrm{MA}_h(u_0) \geq \sum_{j\geq 1} d_j^n \sigma_j = \frac{S_n}{Z^n}\rho.$$

Here the right-hand side is supported strictly inside the smaller ball, so the inequality extends to X. Each σ_j is non-pluripolar by the same lemma; countable additivity gives that property for ρ. The countable union of the spheres has zero smooth volume, which proves singularity. Local bounded-product estimates on a finite cover make the

mass of u_0 finite, and the retained inequality makes it positive. Set $k = S_n/Z^n$ and subtract $\sup_X u_0$ to obtain u_ρ. □

Corollary 14.25.1 *Let ν be a finite nonzero positive measure with $M_\rho(\nu) < \infty$. There are $c > 0$ and a Hölder continuous $w \in \mathrm{PSH}(X, h)$ satisfying*

$$\sup_X w = 0, \qquad \mathrm{MA}_h(w) = c\nu, \qquad 0 < \mathrm{MA}_h(w)(X) < \infty.$$

Proof By Proposition 14.25.1, $\nu \le (M_\rho(\nu)/k)\mathrm{MA}_h(u_\rho)$, where u_ρ is Hölder continuous with exponent $1/2$. Apply Theorem 14.24.1. The equation and $0 < c < \infty$ give its positive finite mass. □

Theorem 14.25.1 *Let ν be a finite nonzero positive measure with $M_\rho(\nu) < \infty$. Then ν is non-pluripolar and*

$$\mathrm{MA}_h(u_\rho) \ge \frac{k}{M_\rho(\nu)}\nu.$$

For every $\lambda > 0$ there is a unique bounded $U_\lambda \in \mathrm{PSH}(X, h)$ satisfying

$$\mathrm{MA}_h(U_\lambda) = \mathrm{e}^{\lambda U_\lambda}\nu, \qquad 0 < \mathrm{MA}_h(U_\lambda)(X) < \infty.$$

Proof Since $\nu \le M_\rho(\nu)\rho$, the reference inequality proves the first assertion. Write $\alpha = \mathrm{MA}_h(u_\rho)$. Then $\nu = f\alpha$ with $0 \le f \le M_\rho(\nu)/k$. The form $h > 0$ is semipositive and big, so Theorem 14.9.1 gives the unique bounded solution. Its boundedness and the equation give positive finite mass. □

The scalar in the exponential equation is fixed: adding a constant to U_λ changes its right-hand side. The theorem imposes no supremum normalization and does not assert uniqueness among unbounded potentials. For example, it applies to every bounded nonzero nonnegative density on any one of the chosen spheres. Failure of the test gives no obstruction to solvability. The homogeneous equation is supplied separately by Corollary 14.25.1, with a positive coefficient obtained as part of the solution. The construction does not identify a largest admissible coefficient or establish uniqueness for that equation.

14.26 Lower mass and solvability for all measures

Throughout the rest of the chapter, h denotes a Hermitian form on X, used as the background, and densities are taken with respect to the fixed smooth positive probability volume form $\mathrm{d}V$; the sections that use another background say so explicitly. No singularity type is prescribed: the unknown potentials range over all of $\mathrm{PSH}(X, h)$. Constants belong to $\mathrm{PSH}(X, h)$, and every $u \in \mathrm{PSH}(X, h)$ is bounded above, so $u \preceq v$ for every bounded $v \in \mathrm{PSH}(X, h)$.

The masses of bounded potentials are measured by the lower and upper masses of Definition 6.5.1,

$$v_-(h) = \inf_v \int_X (h + \mathrm{dd^c} v)^n, \qquad v_+(h) = \sup_v \int_X (h + \mathrm{dd^c} v)^n,$$

where v ranges over the bounded functions in $\mathrm{PSH}(X, h)$. The form h has *positive lower mass* if $v_-(h) > 0$. If h is Kähler, Stokes' theorem gives $v_-(h) = v_+(h) = \int_X h^n$; on a non-Kähler manifold the lower mass can vanish (Theorem 26.18.1).

For a nonzero nonnegative $q \in L^p(\mathrm{d}V)$ with $p > 1$, Theorem 10.1.1 gives a constant $c > 0$ and a continuous $u \in \mathrm{PSH}(X, h)$ with $\mathrm{MA}_h(u) = cq\,\mathrm{d}V$, and Proposition 10.6.1 shows that c is determined by q. We call $c_h(q) = c$ the *normalization scalar* of q, and for the measure $\nu = q\,\mathrm{d}V$ we also write $c_h(\nu) = c_h(q)$. We say that a finite measure ν admits a *positive scaled subsolution* if there are $u \in \mathrm{PSH}(X, h)$ and a constant $a > 0$ such that $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a\nu$.

If ν admits a solution of $\mathrm{MA}_h^{\mathrm{ext}}(u) = c\nu$ with $c > 0$, then it admits in particular a positive scaled subsolution. We show that every nonzero finite non-pluripolar measure admits such a solution if and only if h has positive lower mass. The key estimate is a consequence of strict domination: if $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq aq\,\mathrm{d}V$, then $a \leq c_h(q)$. When $v_-(h) = 0$, there are smooth probability densities with arbitrarily small normalization scalars, and a weighted sum of such densities, with scalars decreasing fast enough, is a single probability density admitting no positive scaled subsolution.

Lemma 14.26.1 *Let $0 \leq q \in L^p(\mathrm{d}V)$, $p > 1$, be nonzero. If $u \in \mathrm{PSH}(X, h)$ and $a > 0$ satisfy*

$$\mathrm{MA}_h^{\mathrm{ext}}(u) \geq aq\,\mathrm{d}V,$$

then $a \leq c_h(q)$. Consequently, for nonzero nonnegative bounded densities q, r,

$$q \leq r \implies c_h(q) \geq c_h(r), \qquad c_h(tq) = t^{-1} c_h(q) \quad (t > 0).$$

Proof Let v be a continuous solution of $\mathrm{MA}_h(v) = c_h(q) q\,\mathrm{d}V$, and suppose, to reach a contradiction, that $a > c_h(q)$. Then $\tau = c_h(q)/a < 1$ and, for every real A,

$$\mathrm{MA}_h(v + A) = c_h(q) q\,\mathrm{d}V \leq \tau\,\mathrm{MA}_h^{\mathrm{ext}}(u).$$

The translate $v + A$ is bounded, so $P_{h/2}(v + A) \geq \inf_X v + A$ is not identically $-\infty$, and $u \preceq v + A$. Theorem 14.1.1, with $\delta = 1/2$ and $c = \tau$, therefore gives $v + A \geq u$ for every real A. Letting $A \to -\infty$ at a point where u is finite gives a contradiction. Hence $a \leq c_h(q)$.

If $q \leq r$, a continuous solution of $\mathrm{MA}_h(w) = c_h(r) r\,\mathrm{d}V$ satisfies $\mathrm{MA}_h(w) \geq c_h(r) q\,\mathrm{d}V$, so the first assertion gives $c_h(r) \leq c_h(q)$. Finally, the equation $\mathrm{MA}_h(v) = c_h(q) q\,\mathrm{d}V$ can be written as $\mathrm{MA}_h(v) = t^{-1} c_h(q)\,(tq)\,\mathrm{d}V$, and uniqueness of the scalar gives $c_h(tq) = t^{-1} c_h(q)$. □

The proof uses only that v is bounded. Hence, more generally, if a nonnegative density g satisfies $\mathrm{MA}_h(v) = c\,g\,\mathrm{d}V$ for some bounded $v \in \mathrm{PSH}(X, h)$ and some $c > 0$, then every $u \in \mathrm{PSH}(X, h)$ and $a > 0$ with $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq ag\,\mathrm{d}V$ satisfy $a \leq c$.

Lemma 14.26.2 *Fix $p > 1$. If nonzero nonnegative densities $q_j, q \in L^p(\mathrm{d}V)$ satisfy $q_j \to q$ in L^p, then $c_h(q_j) \to c_h(q)$.*

Proof We first show that the scalars $c_h(q_j)$ lie in a compact subset of $(0, +\infty)$. Fix a Gauduchon metric γ on X (Definition 4.1.1; in dimension one, any Hermitian metric). Pairing the equation for q_j with γ^{n-1}, as in Proposition 14.13.1 with $\theta = h$ and barrier $\rho = 0$, gives

$$c_h(q_j)^{1/n} \int_X \left(\frac{q_j \, \mathrm{d}V}{\gamma^n} \right)^{1/n} \gamma^n \leq \int_X h \wedge \gamma^{n-1}.$$

Since $q_j^{1/n} \to q^{1/n}$ in L^n, the integrals on the left converge to the corresponding integral for q, which is positive. Hence the scalars are bounded above. The lower-density estimate of Theorem 10.3.1 gives $c_h(q_j)\|q_j\|_{L^p} \geq c_p > 0$, so they are also bounded away from zero.

Consequently, the normalized continuous solutions u_j of $\mathrm{MA}_h(u_j) = c_h(q_j) q_j \, \mathrm{d}V$ have uniformly bounded L^p densities. By Theorem 10.3.2, every subsequence has a further subsequence along which u_j converges uniformly to some u and $c_h(q_j)$ converges to some $c > 0$. Continuity of bounded Monge–Ampère products under uniform convergence gives $\mathrm{MA}_h(u) = cq \, \mathrm{d}V$, and uniqueness of the scalar gives $c = c_h(q)$. Since every subsequence of $(c_h(q_j))$ has a further subsequence converging to $c_h(q)$, the whole sequence converges to $c_h(q)$. □

Theorem 14.26.1 *Suppose $v_-(h) = 0$. There is a probability measure $\mu = f \, \mathrm{d}V$, with $f \in L^1(\mathrm{d}V)$ and $f \geq m$ almost everywhere for a constant $m > 0$, such that no $u \in \mathrm{PSH}(X, h)$ and $a > 0$ satisfy*

$$\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a\mu. \tag{14.79}$$

In particular, the equation $\mathrm{MA}_h^{\mathrm{ext}}(u) = c\mu$ has no solution $u \in \mathrm{PSH}(X, h)$ for any $c > 0$; neither a singularity type nor finiteness of the mass of u is imposed.

Proof By Theorems 26.1.1 and 26.14.1, $v_-(h)$ is the infimum of the normalization scalars $c_h(\nu)$ over smooth strictly positive probability measures ν. Since $v_-(h) = 0$, we can choose such measures $\nu_j = f_j \, \mathrm{d}V$ with

$$c_h(\nu_j) \leq 2^{-2j} \qquad (j \geq 1).$$

Set

$$\mu = \sum_{j=1}^{\infty} 2^{-j} \nu_j, \qquad f = \sum_{j=1}^{\infty} 2^{-j} f_j.$$

By monotone convergence, $\int_X f \, \mathrm{d}V = 1$, so $f \in L^1$. Moreover $f \geq \frac{1}{2} \min_X f_1 =: m > 0$, and μ is non-pluripolar, being absolutely continuous with respect to $\mathrm{d}V$.

Suppose that (14.79) held for some u and $a > 0$. Since $\mu \geq 2^{-j} \nu_j$, we would have

$$\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a 2^{-j} \nu_j$$

for every j, and Lemma 14.26.1 would give $a 2^{-j} \leq c_h(\nu_j) \leq 2^{-2j}$. Thus $a \leq 2^{-j}$ for every j, contradicting $a > 0$. □

For the reference 0, Definition 13.4.1 says that $u \in \mathrm{PSH}(X,h)$ belongs to the relative envelope class $\mathcal{E}_{\mathrm{env}}(X,h,0)$ if, for every $b \geq 1$, some $g \in \mathrm{PSH}(X,h)$ satisfies $g \leq bu$.

Corollary 14.26.1 *The following conditions are equivalent:*

(1) $v_-(h) > 0$.
(2) *For every nonzero finite non-pluripolar measure* μ *there are* $c > 0$ *and* $u \in \mathcal{E}_{\mathrm{env}}(X,h,0)$ *such that* $\mathrm{MA}_h^{\mathrm{ext}}(u) = c\mu$.
(3) *For every probability density* $f \in L^1(\mathrm{d}V)$ *bounded below by a positive constant, there are* $u \in \mathrm{PSH}(X,h)$ *and* $a > 0$ *such that* $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a f \,\mathrm{d}V$.

Proof The Hermitian form h is semipositive and big, and the reference 0 satisfies (13.20), since $P_h[0] = 0$ and $P_{\varepsilon h}(0) = 0$ for every $0 < \varepsilon < 1$. Hence, if $v_-(h) > 0$, Theorem 31.1.1, applied with $\theta = h$ and $\varphi = 0$, gives (2). Condition (2) implies (3), because a finite measure that is absolutely continuous with respect to $\mathrm{d}V$ is non-pluripolar. Finally, if $v_-(h) = 0$, the density of Theorem 14.26.1 violates (3); thus (3) implies (1). □

Corollary 14.26.2 *Assume* $v_-(h) = 0$, *and let* $\mu = f\,\mathrm{d}V$ *be the measure of Theorem 14.26.1. Then* $f \notin L^p(\mathrm{d}V)$ *for every* $p > 1$. *Moreover, for every probability density* $g \in L^1(\mathrm{d}V)$ *and every* $0 < t < 1$, *the probability density*

$$g_t = (1-t)g + tf$$

admits no positive scaled subsolution, although $\|g_t - g\|_{L^1} \leq 2t$. *In particular, the probability densities admitting no positive scaled subsolution are dense among all probability densities in* $L^1(\mathrm{d}V)$.

Proof If $f \in L^p$ for some $p > 1$, Theorem 10.1.1 would give a continuous solution of $\mathrm{MA}_h(u) = c f \,\mathrm{d}V$ with $c > 0$, contradicting the theorem. Since $g_t \,\mathrm{d}V \geq t\mu$, a positive scaled subsolution for $g_t \,\mathrm{d}V$ would also give one for μ. Finally, $\|g_t - g\|_{L^1} = t\|f - g\|_{L^1} \leq 2t$. □

Smooth strictly positive probability densities are also dense in $L^1(\mathrm{d}V)$, and each of them admits a smooth solution of the normalized equation. Thus, when the lower mass vanishes, solvability is not preserved under L^1 approximation. The obstruction comes from the way the density concentrates, not from its size: the density in Theorem 14.26.1 is bounded below by a positive constant. It occurs, for instance, on the compact threefold of Theorem 26.18.1, where every Hermitian form has zero lower mass.

Theorem 14.26.1 does not exclude unbounded solutions of the exponential equation $\mathrm{MA}_h^{\mathrm{ext}}(u) = \mathrm{e}^{\lambda u}\mu$ with $\lambda > 0$, because the factor $\mathrm{e}^{\lambda u}$ need not have a positive lower bound. It does exclude bounded solutions, since a bounded solution would satisfy $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq \mathrm{e}^{\lambda \inf_X u}\mu$. On suitable products, Theorem 14.34.3 chooses the concentrating components of such a density so that its exponential equation has a solution for every positive exponent. We do not know whether this holds for every density admitting no positive scaled subsolution, nor which individual measures admit a solution of the normalized equation when $v_-(h) = 0$.

14.27 Subsolutions for an individual density

When $v_-(h) = 0$, some densities admit no positive scaled subsolution. For one fixed density f, we now determine the largest coefficient a for which $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a f \, \mathrm{d}V$ has a solution. The bounded truncations of f have normalization scalars, and their limit is the answer. Moreover, the largest coefficient is attained: the normalized continuous solutions for the truncations have an L^1 cluster limit, and a lower bound for Monge–Ampère densities passes to L^1 limits of potentials by means of monotone upper envelopes.

Let $0 \leq f \in L^1(\mathrm{d}V)$ have positive integral. Its truncations are bounded and nonzero, and we put

$$f_k = \min(f, k), \qquad b_h(f) = \lim_{k \to \infty} c_h(f_k). \tag{14.80}$$

By Lemma 14.26.1, the scalars $c_h(f_k)$ decrease as k increases, so the limit exists in $[0, c_h(f_1)]$. We call $b_h(f)$ the *subsolution threshold* of f; Theorem 14.27.1 below justifies the name. The same lemma gives

$$b_h(f) = \inf\{c_h(q) : 0 \leq q \leq f, \ q \in L^\infty, \ \textstyle\int_X q \, \mathrm{d}V > 0\}. \tag{14.81}$$

Indeed, every such q satisfies $q \leq f_k$ for $k \geq \|q\|_{L^\infty}$, hence $c_h(q) \geq c_h(f_k) \geq b_h(f)$, while the truncations f_k are themselves admissible.

The Monge–Ampère operator is not continuous under L^1 convergence of potentials, but a lower bound for a Monge–Ampère density survives such convergence. The proof replaces the sequence by monotone upper envelopes, which converge in capacity, and uses the continuity of damped measures, Theorem 7.3.1, applied with the Hermitian form h and the weight $t \mapsto \mathrm{e}^{-t}$. For nonpositive $v \in \mathrm{PSH}(X, h)$, the corresponding damped measure is $\mathrm{e}^v \mathrm{MA}_h^{\mathrm{ext}}(v)$, with weight zero on the pole set; it has finite mass and depends weakly continuously on v under convergence in capacity.

Lemma 14.27.1 *Let $s_j, s \in \mathrm{PSH}(X, h)$ be bounded above by a common constant and satisfy $s_j \to s$ in $L^1(X)$. Suppose $g_j, g \geq 0$, $g_j \to g$ in $L^1(\mathrm{d}V)$, and*

$$\mathrm{MA}_h^{\mathrm{ext}}(s_j) \geq g_j \, \mathrm{d}V \quad \textit{for every } j.$$

Then $\mathrm{MA}_h^{\mathrm{ext}}(s) \geq g \, \mathrm{d}V$.

Proof Subtracting a common constant, which does not change the extended measures, we may assume that all potentials are nonpositive. Pass to a subsequence along which $s_j \to s$ and $g_j \to g$ almost everywhere, and set

$$a_j = \inf_{\ell \geq j} g_\ell, \qquad w_j = \left(\sup_{\ell \geq j} s_\ell \right)^*.$$

Then $0 \leq a_j \uparrow g$ almost everywhere, and $w_j \in \mathrm{PSH}(X, h)$ decreases to s.

Step 1: $\mathrm{MA}_h^{\mathrm{ext}}(w_j) \geq a_j\,\mathrm{d}V$. Fix j. For $N \geq j$, the finite maximum $m_N = \max_{j\leq \ell\leq N} s_\ell$ satisfies $\mathrm{MA}_h^{\mathrm{ext}}(m_N) \geq a_j\,\mathrm{d}V$: on the set $\{m_N = s_\ell\}$, Proposition 6.2.1 gives $\mathrm{MA}_h^{\mathrm{ext}}(m_N) \geq \mathrm{MA}_h^{\mathrm{ext}}(s_\ell) \geq g_\ell\,\mathrm{d}V \geq a_j\,\mathrm{d}V$, and these sets cover X. As $N \to \infty$, the functions m_N increase, are bounded above by zero, and have regularized limit w_j. By Lemma 1.8.9, $m_N \to w_j$ in capacity, so the damped measures $\mathrm{e}^{m_N}\mathrm{MA}_h^{\mathrm{ext}}(m_N)$ converge weakly to $\mathrm{e}^{w_j}\mathrm{MA}_h^{\mathrm{ext}}(w_j)$. Since $m_N \to w_j$ almost everywhere and $a_j \leq g$, dominated convergence gives $\mathrm{e}^{m_N}a_j \to \mathrm{e}^{w_j}a_j$ in $L^1(\mathrm{d}V)$. Passing to the limit in $\mathrm{e}^{m_N}\mathrm{MA}_h^{\mathrm{ext}}(m_N) \geq \mathrm{e}^{m_N}a_j\,\mathrm{d}V$ gives

$$\mathrm{e}^{w_j}\mathrm{MA}_h^{\mathrm{ext}}(w_j) \geq \mathrm{e}^{w_j}a_j\,\mathrm{d}V.$$

The pole set of w_j has zero volume and is not charged by $\mathrm{MA}_h^{\mathrm{ext}}(w_j)$. Dividing by the positive weight off this set gives $\mathrm{MA}_h^{\mathrm{ext}}(w_j) \geq a_j\,\mathrm{d}V$.

Step 2: passage to s. Since w_j decreases to $s \in \mathrm{PSH}(X,h)$, Lemma 1.8.9 gives $w_j \to s$ in capacity, and the damped measures of w_j converge weakly to $\mathrm{e}^s\mathrm{MA}_h^{\mathrm{ext}}(s)$. Moreover $0 \leq \mathrm{e}^{w_j}a_j \leq g$ and $\mathrm{e}^{w_j}a_j \to \mathrm{e}^s g$ almost everywhere, so dominated convergence and Step 1 give

$$\mathrm{e}^s\mathrm{MA}_h^{\mathrm{ext}}(s) \geq \mathrm{e}^s g\,\mathrm{d}V.$$

Dividing by e^s on $\{s > -N\}$ and letting $N \to \infty$ gives $\mathrm{MA}_h^{\mathrm{ext}}(s) \geq g\,\mathrm{d}V$ off the pole set of s. Both measures give zero mass to the pole set, which proves the lemma. □

Theorem 14.27.1 *For every nonnegative $f \in L^1(\mathrm{d}V)$ with positive integral,*

$$b_h(f) = \max\{a \geq 0 : \textit{there exists } u \in \mathrm{PSH}(X,h) \textit{ with } \mathrm{MA}_h^{\mathrm{ext}}(u) \geq a f\,\mathrm{d}V\}.$$

In particular, $f\,\mathrm{d}V$ admits a positive scaled subsolution if and only if $b_h(f) > 0$.

Proof If $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a f\,\mathrm{d}V$ with $a > 0$, then also $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq a f_k\,\mathrm{d}V$ for every k, and Lemma 14.26.1 gives $a \leq c_h(f_k)$. Letting $k \to \infty$ gives $a \leq b_h(f)$. If $b_h(f) = 0$, the coefficient zero is attained by the zero potential.

Suppose now that $b = b_h(f) > 0$, and let u_k be continuous solutions of

$$\mathrm{MA}_h(u_k) = c_h(f_k)f_k\,\mathrm{d}V, \qquad \sup_X u_k = 0.$$

By Theorem 1.4.1, a subsequence u_{k_j} converges in L^1 to some $u \in \mathrm{PSH}(X,h)$ with $\sup_X u = 0$. The densities $c_h(f_{k_j})f_{k_j}$ are dominated by $c_h(f_1)f$ and converge to bf almost everywhere, hence in L^1. Lemma 14.27.1 now gives $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq bf\,\mathrm{d}V$, so the maximum is attained at $a = b$. □

When $b_h(f) > 0$, a function $u \in \mathrm{PSH}(X,h)$ with $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq b_h(f)f\,\mathrm{d}V$ is called a *threshold subsolution* for f, and a threshold subsolution with $\mathrm{MA}_h^{\mathrm{ext}}(u) = b_h(f)f\,\mathrm{d}V$ is called a *threshold solution*; the theorem shows that threshold subsolutions exist. Its proof preserves only a lower bound for the density. It shows neither that the normalized solutions u_k converge in capacity, nor that their limit has

finite mass, nor that equality holds in the limit; these are the additional difficulties of the exact equation for an individual density. The threshold does not depend on the choice of truncations. If (q_k) is any increasing sequence of nonzero bounded densities converging to f almost everywhere, then $c_h(q_k) \geq b_h(f)$ by (14.81); conversely, the second half of the proof, applied to normalized solutions for q_k, gives a subsolution with coefficient $\lim_k c_h(q_k)$, which is therefore at most $b_h(f)$. Hence $\lim_k c_h(q_k) = b_h(f)$.

14.27.1 The greatest normalized threshold subsolution

Suppose $b_h(f) > 0$. The threshold subsolutions with supremum zero form a family that is stable under finite maxima and under L^1 limits. Its upper envelope is therefore again a normalized threshold subsolution, and it dominates all the others.

Proposition 14.27.1 *Suppose $b = b_h(f) > 0$. The family*

$$\mathcal{S}_f = \{s \in \mathrm{PSH}(X,h) : \sup_X s = 0,\ \mathrm{MA}_h^{\mathrm{ext}}(s) \geq b f\, \mathrm{d}V\}$$

is nonempty and compact in $L^1(X)$. Its upper envelope

$$\Phi_f = \left(\sup_{s\in\mathcal{S}_f} s\right)^*$$

belongs to $\mathcal{S}_f$ and is therefore its greatest member. Moreover, let u_λ be the greatest exponential solutions of Corollary 14.34.1 and $v_\lambda = u_\lambda - \sup_X u_\lambda$. Every L^1 limit of a sequence v_{λ_j} with $\lambda_j \downarrow 0$ belongs to $\mathcal{S}_f$, and hence lies below Φ_f.

Proof The family is nonempty by Theorem 14.27.1. By Theorem 1.4.1, an L^1 limit of members of $\mathcal{S}_f$ is h-plurisubharmonic with supremum zero, and Lemma 14.27.1, with $g_j = g = bf$, shows that it satisfies the measure inequality. Thus $\mathcal{S}_f$ is a closed subset of the compact set of normalized h-plurisubharmonic functions, hence compact. It is also stable under finite maxima: if $s_1, s_2 \in \mathcal{S}_f$, then $\max(s_1, s_2)$ has supremum zero, and Proposition 6.2.1, applied on the sets where the maximum equals s_1 or s_2, gives $\mathrm{MA}_h^{\mathrm{ext}}(\max(s_1,s_2)) \geq bf\,\mathrm{d}V$.

By Choquet's lemma there is a sequence $(s_i)_{i\geq 1}$ in $\mathcal{S}_f$ with $(\sup_i s_i)^* = \Phi_f$. Fix $s_0 \in \mathcal{S}_f$. The finite maxima $t_N = \max(s_0, s_1, \ldots, s_N)$ belong to $\mathcal{S}_f$, increase with N, and satisfy $s_0 \leq t_N \leq 0$; their regularized limit is Φ_f. Hence $t_N \to \Phi_f$ almost everywhere and, by dominated convergence, in L^1. Lemma 14.27.1 gives $\mathrm{MA}_h^{\mathrm{ext}}(\Phi_f) \geq bf\,\mathrm{d}V$, and $s_0 \leq \Phi_f \leq 0$ forces $\sup_X \Phi_f = 0$. Thus $\Phi_f \in \mathcal{S}_f$, and by construction it dominates every member of $\mathcal{S}_f$.

Finally, suppose $v_{\lambda_j} \to v$ in L^1 with $\lambda_j \downarrow 0$. The measures $\mathrm{MA}_h^{\mathrm{ext}}(v_{\lambda_j}) = \mathrm{e}^{\lambda_j u_{\lambda_j}} f\,\mathrm{d}V$ have densities converging in L^1 to bf, by Corollary 14.34.1. Applying Lemma 14.27.1 to these densities and potentials shows that $v \in \mathcal{S}_f$. □

The proposition gives a greatest normalized threshold subsolution, but not the equation $\mathrm{MA}_h^{\mathrm{ext}}(\Phi_f) = b f \, \mathrm{d}V$; in particular, it does not show that Φ_f has finite mass.

Proposition 14.27.2 *Let $0 \le f \in L^1(\mathrm{d}V)$ have positive integral. If $f \in L^p(\mathrm{d}V)$ for some $p > 1$, then $b_h(f) = c_h(f)$. In general,*

$$b_h(f) \ge \frac{v_-(h)}{\int_X f \, \mathrm{d}V}.$$

If h is Kähler, then $b_h(f) = \int_X h^n / \int_X f \, \mathrm{d}V$.

Proof Suppose that $f \in L^p$ with $p > 1$, and let v be a continuous solution of $\mathrm{MA}_h(v) = c_h(f) f \, \mathrm{d}V$. It is a subsolution with coefficient $c_h(f)$, so Theorem 14.27.1 gives $c_h(f) \le b_h(f)$. Conversely, Lemma 14.26.1, applied to a threshold subsolution, gives $b_h(f) \le c_h(f)$.

For general f, the continuous solution for f_k has total mass $c_h(f_k) \int_X f_k \, \mathrm{d}V$, which is at least $v_-(h)$ by the definition of the lower mass. Letting $k \to \infty$ and using monotone convergence gives the lower bound for $b_h(f)$. If h is Kähler, Stokes' theorem for bounded potentials gives instead the identity $c_h(f_k) \int_X f_k \, \mathrm{d}V = \int_X h^n$, and the same limit proves the last assertion. □

14.27.2 Smooth comparison tests

The infimum (14.81) runs over bounded measurable densities below f. One may ask whether smooth densities suffice to compute the threshold. A smooth test g is in general not below f, so we compare it with f through the ratio $\|g/f\|_{L^\infty}$. Thus let f be a probability density bounded below by a positive constant, and define

$$C_h^{\mathrm{sm}}(f) = \inf_g c_h(g) \|g/f\|_{L^\infty},$$

where g ranges over smooth strictly positive probability densities. For each such g, with $R = \|g/f\|_{L^\infty}$, a subsolution with coefficient a for $f \, \mathrm{d}V$ is a subsolution with coefficient a/R for $g \, \mathrm{d}V$, so $a \le R c_h(g)$ by Lemma 14.26.1. Hence $b_h(f) \le C_h^{\mathrm{sm}}(f)$, with equality if f is smooth (take $g = f$). When the lower mass vanishes, the two quantities can differ even in their positivity.

Theorem 14.27.2 *If $v_-(h) = 0$, there is a probability density $f \in L^1(\mathrm{d}V)$ bounded below by a positive constant such that*

$$b_h(f) = 0 < C_h^{\mathrm{sm}}(f).$$

Thus $f\,\mathrm{d}V$ admits no positive scaled subsolution, although $c_h(g)\|g/f\|_{L^\infty}$ is bounded below by a positive constant for all smooth strictly positive probability densities g.

Proof We construct $f = (1+Q)/M$, where $Q \geq 0$ concentrates on closed nowhere dense sets in such a way that it has essential infimum zero on every nonempty open set.

Step 1: the pieces. Let $(U_i)_{i\geq 1}$ be a countable basis of nonempty open subsets of X. We construct inductively numbers $\alpha_j > 0$, nonzero bounded densities q_j, and closed nowhere dense sets $K_j \subset X$ such that

$$\int_X q_j\,\mathrm{d}V \leq 1, \qquad q_j = 0 \text{ outside } K_j, \qquad c_h(q_j) \leq \alpha_j 2^{-j}.$$

Start with $\alpha_1 = 1/4$. Once α_j has been chosen, Theorems 26.1.1 and 26.14.1 and $v_-(h) = 0$ give a smooth strictly positive probability density g_j with $c_h(g_j) < \alpha_j 2^{-j}$. Removing from X an open dense set of small volume, we obtain a closed nowhere dense set K_j for which $q_j = g_j \mathbf{1}_{K_j}$ is nonzero and, since g_j is bounded, arbitrarily close to g_j in L^2. By Lemma 14.26.2 with $p = 2$, we can therefore choose K_j so that $c_h(q_j) \leq \alpha_j 2^{-j}$.

After $K_1, \dots, K_N$ have been chosen, put

$$m_N = \min_{1\leq i\leq N} \mathrm{d}V\left(U_i \setminus \bigcup_{j=1}^{N} K_j\right) > 0;$$

each set inside the minimum is open and nonempty, since a finite union of closed nowhere dense sets is closed and nowhere dense. Choose

$$0 < \alpha_{N+1} \leq \min\{\alpha_N/2,\ 2^{-N-2} m_N\},$$

and continue. In particular,

$$\sum_{j>N} \alpha_j \leq 2\alpha_{N+1} \leq 2^{-N-1} m_N.$$

Step 2: the concentrating part. The function $Q = \sum_j \alpha_j q_j$ is nonnegative and integrable. We claim that its essential infimum on every nonempty open set is zero. Since every nonempty open set contains some U_i, it suffices to consider U_i. Take $N \geq i$ and remove $K_1, \dots, K_N$ from U_i. On the remaining set, whose volume is at least m_N, the first N summands of Q vanish. By Markov's inequality, the set where the tail $\sum_{j>N} \alpha_j q_j$ exceeds 2^{-N} has volume at most

$$2^N \sum_{j>N} \alpha_j \int_X q_j \, \mathrm{d}V \le m_N/2.$$

Hence $Q \le 2^{-N}$ on a subset of U_i of positive volume. Letting $N \to \infty$ proves the claim.

Step 3: $b_h(f) = 0$. Set $M = \int_X (1+Q)\, \mathrm{d}V$ and $f = (1+Q)/M$, a probability density with $f \ge 1/M$. If $\mathrm{MA}_h^{\mathrm{ext}}(u) \ge a f \, \mathrm{d}V$ with $a > 0$, then $\mathrm{MA}_h^{\mathrm{ext}}(u) \ge (a\alpha_j/M) q_j \, \mathrm{d}V$, and Lemma 14.26.1 gives

$$\frac{a\alpha_j}{M} \le c_h(q_j) \le \alpha_j 2^{-j} \quad \text{for every } j.$$

This is impossible. Hence $b_h(f) = 0$ by Theorem 14.27.1.

Step 4: $C_h^{\mathrm{sm}}(f) > 0$. Let g be a smooth strictly positive probability density and put $R = \|g/f\|_{L^\infty}$. Then $g \le R(1+Q)/M$ almost everywhere, and this forces $g \le R/M$ everywhere. Otherwise, by continuity, $g > R(1+\varepsilon)/M$ on a nonempty open set for some $\varepsilon > 0$, while $Q < \varepsilon$ on a subset of positive volume of this set by Step 2, a contradiction. The order and homogeneity of the scalar in Lemma 14.26.1 now give $c_h(g) \ge c_h(R/M) = (M/R) c_h(1)$, that is,

$$R c_h(g) \ge M c_h(1).$$

The constant density $g = 1$ attains this value, since $\operatorname{ess\,inf}_X Q = 0$ gives $\|1/f\|_{L^\infty} = M$. Thus $C_h^{\mathrm{sm}}(f) = M c_h(1) > 0$, as required. □

The point is that a smooth test g with $\|g/f\|_{L^\infty} \le R$ is controlled by the essential infimum of f on open sets. It therefore cannot detect an increase of f that leaves this essential infimum unchanged on every open set, whereas bounded measurable tests below f do detect it. The theorem concerns only the existence of subsolutions. Exact solutions of $\mathrm{MA}_h^{\mathrm{ext}}(u) = b_h(f) f \, \mathrm{d}V$, the singularity class in which they should be sought, and compactness of their normalized solutions are further problems; see Problem 33.1.1.

14.28 Gauduchon tests for integrable densities

For a smooth strictly positive probability density, the normalization scalar is an infimum of Gauduchon quotients by Theorem 26.1.1. We extend this dual formula to the threshold of an arbitrary integrable density. A uniform bound for all Gauduchon tests in a single L^r norm allows the passage from smooth to bounded densities, and monotone truncation then reaches all integrable densities, including those with zero threshold. The formula is most naturally written for the nth root of the density.

Recall that a Hermitian form γ is *Gauduchon* if $\mathrm{dd}^{\mathrm{c}}(\gamma^{n-1}) = 0$ (Definition 4.1.1); in dimension one every Hermitian form is Gauduchon. For a Gauduchon form γ and a nonnegative measurable function p, put

$$L_{h,\gamma}(p) = \frac{\displaystyle\int_X p(\mathrm{d}V/\gamma^n)^{1/n}\gamma^n}{\displaystyle\int_X h \wedge \gamma^{n-1}} = \int_X p\, a_\gamma \,\mathrm{d}V, \qquad a_\gamma = \frac{(\gamma^n/\mathrm{d}V)^{(n-1)/n}}{\int_X h \wedge \gamma^{n-1}}.$$

Since the coefficient a_γ is smooth and strictly positive, each individual test $L_{h,\gamma}$ is finite on L^n; the supremum over γ may be infinite. In dimension one the test is $\int_X p\,\mathrm{d}V / \int_X h$. For real or complex $p \in L^n(\mathrm{d}V)$, define the *root functional*

$$\rho_h(p) = b_h(|p|^n)^{-1/n} \quad (p \neq 0), \qquad \rho_h(0) = 0,$$

with the convention $0^{-1/n} = +\infty$.

Theorem 14.28.1 *For every real or complex $p \in L^n(\mathrm{d}V)$,*

$$\rho_h(p) = \sup_{\gamma \text{ Gauduchon}} L_{h,\gamma}(|p|). \tag{14.82}$$

Equivalently, for every nonzero nonnegative $f \in L^1(\mathrm{d}V)$,

$$b_h(f)^{1/n} = \inf_{\gamma \text{ Gauduchon}} \frac{\displaystyle\int_X h \wedge \gamma^{n-1}}{\displaystyle\int_X (f\,\mathrm{d}V/\gamma^n)^{1/n}\gamma^n}. \tag{14.83}$$

Both sides of (14.82) *may be $+\infty$, and both sides of* (14.83) *may vanish.*

Proof It suffices to prove (14.82) for $p \geq 0$, since both sides depend only on $|p|$; the case $p = 0$ is immediate.

Step 1: smooth strictly positive p. Apply Theorem 26.1.1, with background h, to the probability measure $\mu = p^n \mathrm{d}V/Z$, where $Z = \int_X p^n\,\mathrm{d}V$. By homogeneity (Lemma 14.26.1) its scalar is $c_h(\mu) = Z c_h(p^n)$, while the denominator of each Gauduchon quotient is $Z^{-1/n}\int_X p(\mathrm{d}V/\gamma^n)^{1/n}\gamma^n$. The factors of Z cancel, and the dual formula becomes

$$c_h(p^n)^{-1/n} = \sup_\gamma L_{h,\gamma}(p).$$

Since $b_h(p^n) = c_h(p^n)$ by Proposition 14.27.2, this proves (14.82) for such p.

Step 2: a uniform bound for the tests. The lower-density estimate of Theorem 10.3.1, with exponent two, gives a constant $m_h > 0$ such that

$$c_h(p^n)\|p^n\|_{L^2} \geq m_h$$

for smooth strictly positive p. By Step 1, therefore,

$$L_{h,\gamma}(p) \leq m_h^{-1/n}\|p\|_{L^{2n}} \quad \text{for every } \gamma. \tag{14.84}$$

Approximating nonnegative functions in L^{2n} by smooth strictly positive ones extends this bound to all nonnegative $p \in L^{2n}$. Since $a_\gamma > 0$, duality gives $\|a_\gamma\|_{L^{2n/(2n-1)}} \leq$

$m_h^{-1/n}$ for every γ. In particular, $p \mapsto \sup_\gamma L_{h,\gamma}(p)$ is Lipschitz on the cone of nonnegative functions in L^{2n}, with the same constant.

Step 3: bounded p. Let $p \geq 0$ be bounded and nonzero, and approximate it in L^{2n} by smooth strictly positive functions p_j. By Hölder's inequality, $p_j^n \to p^n$ in L^2, so Lemma 14.26.2 gives

$$c_h(p_j^n) \longrightarrow c_h(p^n) > 0.$$

By the Lipschitz bound derived from (14.84),

$$\sup_\gamma L_{h,\gamma}(p_j) \longrightarrow \sup_\gamma L_{h,\gamma}(p).$$

Passing to the limit in the identity of Step 1 for p_j, and using $b_h(p^n) = c_h(p^n)$ (Proposition 14.27.2), we obtain (14.82) for bounded p.

Step 4: general p. For nonnegative $p \in L^n$, put $p_k = \min(p, k)$. Then $p_k^n = \min(p^n, k^n)$ are truncations of p^n, so the definition of b_h and Step 3 give

$$\rho_h(p) = \lim_{k\to\infty} c_h(p_k^n)^{-1/n} = \sup_k \sup_\gamma L_{h,\gamma}(p_k).$$

For each fixed γ, monotone convergence gives $\sup_k L_{h,\gamma}(p_k) = L_{h,\gamma}(p)$. Interchanging the two suprema proves (14.82). Finally, every denominator in (14.83) is positive; taking reciprocals in (14.82) with $p = f^{1/n}$ proves (14.83), including the case $b_h(f) = 0$. □

For a nonsmooth density we do not claim that the infimum in (14.83) is attained by a Gauduchon form; attainment by Gauduchon currents is studied in Section 26.9.

For $n \geq 2$, the coefficient of the test has norm

$$\|a_\gamma\|_{L^{n/(n-1)}} = \frac{(\int_X \gamma^n)^{(n-1)/n}}{\int_X h \wedge \gamma^{n-1}}$$

in the exponent dual to n. By (26.64) in Theorem 26.14.1, positive lower mass is therefore equivalent to a uniform bound for these norms, that is, for all tests on L^n simultaneously. Without positive lower mass, Step 2 of the proof still bounds the coefficients uniformly in the weaker norm of $L^{2n/(2n-1)}$, on every compact Hermitian manifold. This suffices to pass from smooth to bounded densities, and monotone truncation then treats all integrable densities.

Proposition 14.28.1 *Let f be a nonzero nonnegative function in $L^1(\mathrm{d}V)$ and let $p \in L^n(\mathrm{d}V)$ be real or complex. If h_1, h_2 are Hermitian forms on X and $mh_1 \le h_2 \le Mh_1$ for positive constants m, M, then*

$$m^n b_{h_1}(f) \le b_{h_2}(f) \le M^n b_{h_1}(f), \qquad M^{-1}\rho_{h_1}(p) \le \rho_{h_2}(p) \le m^{-1}\rho_{h_1}(p).$$

If $h_2 - h_1 = \mathrm{dd^c} a$ for a smooth real function a, then $b_{h_1}(f) = b_{h_2}(f)$ and $\rho_{h_1}(p) = \rho_{h_2}(p)$.

Proof For every Gauduchon form γ, the numerators in (14.83) satisfy

$$m\int_X h_1 \wedge \gamma^{n-1} \le \int_X h_2 \wedge \gamma^{n-1} \le M\int_X h_1 \wedge \gamma^{n-1},$$

while the denominators do not depend on the background. Taking the infimum over γ and then nth powers proves the bounds for the thresholds; taking reciprocal nth roots gives the bounds for ρ, with the stated conventions at zero and infinity. If $h_2 - h_1 = \mathrm{dd^c} a$, the numerators agree by Stokes' theorem, since $\mathrm{dd^c}(\gamma^{n-1}) = 0$. □

Any two Hermitian metrics on the compact manifold X are comparable. Hence the positivity of $b_h(f)$, and the set of real or complex $p \in L^n$ with $\rho_h(p) < +\infty$, do not depend on the choice of h. The dependence on the reference volume is equally simple. If $\mathrm{d}V$ is replaced by $\mathrm{d}V' = \sigma\,\mathrm{d}V$ with a smooth function $\sigma > 0$, the measure $f\,\mathrm{d}V$ has density $f' = f/\sigma$ with respect to $\mathrm{d}V'$, and Theorem 14.27.1 shows that the threshold of f' relative to $\mathrm{d}V'$ equals $b_h(f)$. Correspondingly, the map $p \mapsto \sigma^{-1/n} p$ from $L^n(\mathrm{d}V)$ to $L^n(\mathrm{d}V')$ preserves both the L^n norm and the root functional.

14.29 Exact equations on products with zero lower mass

Positive lower mass guarantees solvability for all measures, but an individual density can have a positive threshold and an exact equation even when the lower mass vanishes. We construct explicit examples on products. Let (X_0, h_0) be a connected compact Hermitian manifold of dimension $m \ge 1$ with $\nu_-(h_0) = 0$. On its product with a projective space, a singular potential pulled back from the projective factor solves an explicit equation whose density has a sublogarithmic singularity. The coefficient is computed from the normalization scalars of bounded truncations, the equation itself follows from the product structure of the Monge–Ampère measure, and the product background again has zero lower mass.

Throughout this section, $Y = \mathbb{P}^k$ with $k \ge 1$, κ is the Fubini–Study form normalized by $\int_Y \kappa^k = 1$, and $X = X_0 \times Y$, a compact complex manifold of dimension $N = m + k$ with the Hermitian background $H = h_0 + \kappa$. Forms and functions on the factors are identified with their pullbacks to X. Put

$$V_0 = \int_{X_0} h_0^m, \qquad C = \binom{N}{m}, \qquad \mu = V_0^{-1} h_0^m \wedge \kappa^k, \qquad R = \frac{\mu}{\mathrm{d}V},$$

where $\mathrm{d}V$ is any smooth positive probability volume form on X. Then μ is a smooth positive probability volume form, and R is smooth and bounded above and below by positive constants. The normalization scalar c_H and the threshold b_H are those of Sections 14.26 and 14.27, now on the N-dimensional manifold X with background H.

For $0 < \alpha < 1$ define, on Y,

$$\psi([z_0 : \cdots : z_k]) = \log \frac{\sum_{i=1}^k |z_i|^2}{\sum_{i=0}^k |z_i|^2}, \qquad u_\alpha = 1 - (1-\psi)^\alpha.$$

The function ψ is smooth on $Y \setminus \{o\}$, where $o = [1 : 0 : \cdots : 0]$, and tends to $-\infty$ at o; moreover $\psi \le 0$, with equality exactly on the hyperplane $\{z_0 = 0\}$. Thus $u_\alpha \le 0$, and u_α has a single pole at o, where $u_\alpha(o) = -\infty$.

Lemma 14.29.1 *The function u_α is κ-plurisubharmonic with supremum zero, and*

$$\mathrm{MA}^{\mathrm{ext}}_\kappa(u_\alpha) = q_\alpha \kappa^k, \qquad \int_Y q_\alpha \kappa^k = 1.$$

The density q_α is smooth and strictly positive on $Y \setminus \{o\}$, belongs to $L^1(\kappa^k)$, and belongs to no $L^p(\kappa^k)$ with $p > 1$. If we set $q_\alpha(o) = +\infty$, then every truncation $\min(q_\alpha, s)$, $s > 0$, is strictly positive and continuous on Y.

Proof In homogeneous coordinates, $\kappa + \mathrm{dd^c}\psi = \mathrm{dd^c} \log \sum_{i=1}^k |z_i|^2 \ge 0$ on $Y \setminus \{o\}$. The function $\chi(t) = 1 - (1-t)^\alpha$, $t \le 0$, is increasing and convex, with $0 < \chi' \le \alpha$. Hence, off o,

$$\kappa + \mathrm{dd^c} u_\alpha \ge (1 - \chi'(\psi))\kappa + \chi'(\psi)(\kappa + \mathrm{dd^c}\psi) \ge (1-\alpha)\kappa.$$

Since u_α is bounded above, it extends across o as a κ-plurisubharmonic function, with value $-\infty$ at o. On the hyperplane $\{z_0 = 0\}$ we have $\psi = 0$, hence $u_\alpha = 0$, so $\sup_Y u_\alpha = 0$.

To compute the measure, work in the affine chart $z_0 = 1$ and put $r = \sum_{i=1}^k |z_i|^2$. On this chart $\kappa = \mathrm{dd^c} \log(1+r)$ and $\kappa + \mathrm{dd^c} u_\alpha = \mathrm{dd^c} F$, where $s(r) = 1 - \log(r/(1+r))$ and

$$F(r) = \log(1+r) + 1 - s(r)^\alpha, \qquad Q(r) = rF'(r) = \frac{r + \alpha s(r)^{\alpha-1}}{1+r}.$$

For a radial function, the Levi form has the tangential eigenvalue $F'(r) = Q(r)/r$, with multiplicity $k-1$, and the radial eigenvalue

$$Q'(r) = \frac{1 - \alpha s(r)^{\alpha-1} + \alpha(1-\alpha) r^{-1} s(r)^{\alpha-2}}{(1+r)^2} > 0.$$

Integrating in the radial variable gives $\int_{\{a<r<b\}} (\mathrm{dd^c}F)^k = Q(b)^k - Q(a)^k$; the constant of proportionality is fixed by the case $F = \log(1+r)$, for which $(\mathrm{dd^c}F)^k = \kappa^k$

has mass one on the chart and $Q(r) = r/(1+r)$. Since again $Q(0) = 0$ and $Q(\infty) = 1$, the punctured chart has mass one. The complement of the chart is a hyperplane, which has zero volume, and the non-pluripolar measure does not charge o. Hence $\int_Y q_\alpha \kappa^k = 1$.

Relative to κ^k, whose tangential and radial eigenvalues are $1/(1+r)$ and $1/(1+r)^2$, the density on this chart is

$$q_\alpha(r) = (1+r)^{k+1}(Q(r)/r)^{k-1}Q'(r) \asymp r^{-k}(1-\log r)^{-1-k(1-\alpha)} \quad (r \downarrow 0).$$

Near $r = 0$ the smooth volume is comparable to $r^{k-1}\mathrm{d}r$ in the radial variable, so q_α is integrable. For $p > 1$, the substitution $L = 1 - \log r$ turns the integral of q_α^p into the integral of $\mathrm{e}^{k(p-1)L}$ times a power of L, which diverges. The same asymptotics show that $q_\alpha(r) \to +\infty$ uniformly as $r \downarrow 0$, so every truncation $\min(q_\alpha, s)$ is continuous at o. Finally, $q_\alpha \geq (1-\alpha)^k > 0$ by the lower bound $\kappa + \mathrm{dd^c} u_\alpha \geq (1-\alpha)\kappa$. □

Lemma 14.29.2 *Let g be a strictly positive continuous function on Y, and put $M_g = \int_Y g\kappa^k$. Then*

$$c_H(Rg) = \frac{CV_0}{M_g}.$$

Proof Suppose first that g is smooth. Since κ is Kähler, Theorem 9.1.1 on Y gives a smooth ϕ_g with $A_g = \kappa + \mathrm{dd^c}\phi_g > 0$ and $A_g^k = (g/M_g)\kappa^k$; the scalar is determined by integration, since both sides have mass one. On X, since $h_0^{m+1} = 0$ and $A_g^{k+1} = 0$ for dimensional reasons,

$$(H + \mathrm{dd^c}\phi_g)^N = Ch_0^m \wedge A_g^k = (CV_0/M_g)Rg\,\mathrm{d}V.$$

Uniqueness of the scalar gives $c_H(Rg) = CV_0/M_g$. For continuous $g > 0$, choose smooth $g_l > 0$ converging uniformly to g. Since g has a positive minimum, $(1-\varepsilon_l)g \leq g_l \leq (1+\varepsilon_l)g$ for some $\varepsilon_l \in (0,1)$ tending to zero. The order and homogeneity of the scalar in Lemma 14.26.1 give

$$(1-\varepsilon_l)c_H(Rg_l) \leq c_H(Rg) \leq (1+\varepsilon_l)c_H(Rg_l).$$

Since $M_{g_l} \to M_g$, the smooth case proves the formula. □

Theorem 14.29.1 *The Hermitian form H is not closed and satisfies $v_-(H) = 0$. For every $0 < \alpha < 1$, the function $f = Rq_\alpha$ is a probability density in $L^1(\mathrm{d}V)$, belonging to no $L^p(\mathrm{d}V)$ with $p > 1$, and*

$$b_H(f) = CV_0 > 0, \qquad \mathrm{MA}_H^{\mathrm{ext}}(u_\alpha) = b_H(f)f\,\mathrm{d}V.$$

The potential u_α, pulled back to X, has supremum zero and finite mass CV_0. It belongs to $\mathcal{E}_{\mathrm{env}}(X, H, 0)$, and $P_{\delta H}(u_\alpha) \not\equiv -\infty$ for every $0 < \delta < 1$.

Proof *Step 1: the threshold.* Write $a = \min_X R > 0$, $A = \max_X R$, and $M_s = \int_Y \min(q_\alpha, s)\kappa^k$ for $s > 0$. By Lemma 14.29.1, the truncations $\min(q_\alpha, s)$ are continuous and strictly positive, and $M_s \uparrow 1$ as $s \to \infty$. The truncations of f satisfy

$$R\min(q_\alpha, j/A) \le \min(Rq_\alpha, j) \le R\min(q_\alpha, j/a).$$

Hence Lemma 14.29.2 and the monotonicity of the scalar give

$$\frac{CV_0}{M_{j/a}} \le c_H(\min(f, j)) \le \frac{CV_0}{M_{j/A}}.$$

Both bounds tend to CV_0 as $j \to \infty$, so $b_H(f) = CV_0$, whatever the reference volume $\mathrm{d}V$.

Step 2: the equation. For $u_{\alpha,j} = \max(u_\alpha, -j)$, the binomial expansion of bounded local products, with factor forms of degrees m and k, gives

$$\mathrm{MA}_H(u_{\alpha,j}) = Ch_0^m \wedge \mathrm{MA}_\kappa(u_{\alpha,j}).$$

Multiplying by $\mathbf{1}_{\{u_\alpha > -j\}}$ and letting $j \to \infty$, as in the definition (6.1) of the extended measure, we obtain

$$\mathrm{MA}_H^{\mathrm{ext}}(u_\alpha) = Ch_0^m \wedge q_\alpha\kappa^k = CV_0\, q_\alpha\mu = CV_0 f\,\mathrm{d}V,$$

a measure of mass CV_0. The bounds $a \le R \le A$ transfer the integrability properties of q_α to f.

Step 3: lower mass and nonclosedness. Pull back bounded h_0-plurisubharmonic functions whose masses on X_0 tend to zero. The same expansion shows that their H-masses are C times their masses on X_0, so $v_-(H) = 0$. If h_0 were closed, Stokes' theorem would give every bounded h_0-plurisubharmonic function the mass $V_0 > 0$, contradicting $v_-(h_0) = 0$. Hence h_0, and therefore H, is not closed.

Step 4: the envelopes. Choose $\alpha < \beta < 1$. For $b \ge 1$ and $\varepsilon > 0$ with $\varepsilon\beta \le 1$, the number

$$K_b = \sup_{s \ge 1}\{bs^\alpha - \varepsilon s^\beta\} - b$$

is finite, since $\beta > \alpha$. The function $g_b = -\varepsilon(1-\psi)^\beta - K_b$ on Y satisfies $\kappa + \mathrm{dd}^{\mathrm{c}} g_b \ge (1 - \varepsilon\beta)\kappa \ge 0$, by the chain-rule computation in the proof of Lemma 14.29.1, applied to the increasing convex function $t \mapsto -\varepsilon(1-t)^\beta$, whose derivative is at most $\varepsilon\beta$ for $t \le 0$. With $L = 1 - \psi \ge 1$, the inequality $g_b \le bu_\alpha$ reads $bL^\alpha - \varepsilon L^\beta - b \le K_b$, so it holds on $Y \setminus \{o\}$, and also at o, where both sides are $-\infty$. Thus the pullback of g_b belongs to $\mathrm{PSH}(X, H)$ and lies below bu_α. Since $b \ge 1$ is arbitrary, $u_\alpha \in \mathcal{E}_{\mathrm{env}}(X, H, 0)$ by Definition 13.4.1. For $0 < \delta < 1$, take $b = 1$ and $\varepsilon\beta \le \delta$. Then g_1 is δH-plurisubharmonic and lies below u_α, so $P_{\delta H}(u_\alpha) \ge g_1$ is not identically $-\infty$. □

Corollary 14.29.1 *Let X_0 be the elliptic threefold of Theorem 26.18.1, with the balanced metric ω of Proposition 26.18.1. On $X_0 \times \mathbb{P}^2$, with background $H = \omega + \kappa$, the densities $f = Rq_\alpha$ of the preceding theorem satisfy*

$$v_-(H) = 0, \qquad b_H(f) = 240\pi, \qquad \mathrm{MA}_H^{\mathrm{ext}}(u_\alpha) = 240\pi f \, \mathrm{d}V.$$

Proof Theorem 26.18.1 gives $v_-(\omega) = 0$, and Proposition 26.18.1 gives $V_0 = 24\pi$. The product theorem applies with $m = 3$, $k = 2$ and $C = \binom{5}{3} = 10$. □

These examples show that an individual density can have a positive threshold and an exact equation even though the background has zero lower mass. The exactness comes from the product structure. For $k \geq 2$, the radial flux also identifies the normalized exponential limit in Theorem 14.35.1; the first moment determines whether scalar centering has a finite limit. Problem 33.1.1 asks for an exact equation for every integrable density with positive threshold.

14.29.1 Closed factors and arbitrary integrable densities

The preceding examples use an explicit potential on projective space. On a closed factor, the mass bound from Stokes' theorem instead makes every threshold subsolution exact. This gives equations for arbitrary integrable densities on that factor, with no assumption that they are bounded below.

For this subsection let (X_0, h_0) be any connected compact Hermitian manifold of dimension $m \geq 1$, and let (Y, κ) be connected compact Kähler of dimension $k \geq 2$, normalized by $\int_Y \kappa^k = 1$. On $X = X_0 \times Y$ put

$$N = m + k, \qquad H = h_0 + \kappa, \qquad C = \binom{N}{m}, \qquad V_0 = \int_{X_0} h_0^m, \qquad c_0 = CV_0.$$

Forms and functions on the factors are pulled back when used on X. For any smooth positive probability volume form $\mathrm{d}V$ on X, put

$$\mu = V_0^{-1} h_0^m \wedge \kappa^k, \qquad R = \frac{\mu}{\mathrm{d}V}, \qquad a = \min_X R > 0, \qquad A = \max_X R.$$

Theorem 14.29.2 *For every nonzero nonnegative $g \in L^1(Y,\kappa^k)$, with $M_g = \int_Y g\kappa^k$, one has*

$$b_H(Rg) = \frac{c_0}{M_g}.$$

There is $v \in \mathrm{PSH}(Y,\kappa)$ with $\sup_Y v = 0$ and $\int_Y \mathrm{MA}_\kappa^{\mathrm{ext}}(v) = 1$ whose pullback u satisfies

$$\mathrm{MA}_H^{\mathrm{ext}}(u) = \frac{c_0}{M_g} Rg\,\mathrm{d}V, \qquad \int_X \mathrm{MA}_H^{\mathrm{ext}}(u) = c_0.$$

If $v_-(h_0) = 0$, then $v_-(H) = 0$ and H is not closed.

Proof We first compute the scalars of bounded densities, then use the closed factor's mass bound to identify the equation for an unbounded density.

Step 1: bounded densities. If g is bounded and nonzero, Theorem 10.1.1 on Y gives a bounded continuous v with $\mathrm{MA}_\kappa(v) = c_\kappa(g) g\kappa^k$. Closed Stokes gives $c_\kappa(g) = 1/M_g$. The bounded product expansion gives

$$\mathrm{MA}_H(v) = Ch_0^m \wedge \mathrm{MA}_\kappa(v) = \frac{c_0}{M_g} Rg\,\mathrm{d}V.$$

Uniqueness of the bounded normalization scalar therefore gives $c_H(Rg) = c_0/M_g$, including densities with zeros.

Step 2: the threshold. For general $g \in L^1$, the original truncations on X satisfy

$$R\min(g, j/A) \le \min(Rg, j) \le R\min(g, j/a).$$

By Step 1 and Lemma 14.26.1,

$$\frac{c_0}{\int_Y \min(g, j/a)\kappa^k} \le c_H(\min(Rg, j)) \le \frac{c_0}{\int_Y \min(g, j/A)\kappa^k}.$$

Both bounds tend to c_0/M_g.

Step 3: the exact equation. By Proposition 14.27.2, $b_\kappa(g) = 1/M_g$. Thus Theorem 14.27.1 on Y gives $v \in \mathrm{PSH}(Y,\kappa)$ with supremum zero and

$$\mathrm{MA}_\kappa^{\mathrm{ext}}(v) \ge (g/M_g)\kappa^k.$$

For $v_j = \max(v, -j)$, closed Stokes gives $\int_Y \mathrm{MA}_\kappa(v_j) = 1$. The defining non-pluripolar truncations consequently give $\int_Y \mathrm{MA}_\kappa^{\mathrm{ext}}(v) \le 1$. The prescribed lower measure has mass one, so equality holds both in mass and in the measure inequality.

The pullback u is H-plurisubharmonic, and $\max(u, -j)$ is the pullback of v_j. Multiplying the bounded product expansion by the pullback of $\mathbf{1}_{\{v>-j\}}$ and passing to the defining non-pluripolar limit gives

$$\mathrm{MA}_H^{\mathrm{ext}}(u) = Ch_0^m \wedge \mathrm{MA}_\kappa^{\mathrm{ext}}(v) = \frac{c_0}{M_g} Rg\,\mathrm{d}V.$$

Its mass is c_0. Finally, when $v_-(h_0) = 0$, pulling back bounded potentials from X_0 whose masses tend to zero proves $v_-(H) = 0$ by the same expansion. Closedness of h_0 would contradict that vanishing by Stokes' theorem, so H is not closed. □

On the elliptic threefold of Theorem 26.18.1, with the balanced metric of Proposition 26.18.1, the product with $\mathbb{P}^2$ has $c_0 = 240\pi$. Thus every probability density from the projective factor has this threshold and a finite-mass threshold solution. The theorem concerns factor densities; it does not give an exact equation for an arbitrary density on X or identify limits of normalized exponential solutions.

14.30 Singular measures on products with a curve

The closed-factor equations above concern integrable densities. A curve factor also allows a direct test on a measure: its logarithmic potential determines an exact equation, and continuity of that potential supplies the energy control needed for every positive exponent. The resulting product measure may be singular with respect to smooth volume, even when the solution is continuous.

Let $Y = \mathbb{P}^1$ and let κ be the Fubini–Study form of mass one. For the chordal distance d_{ch}, put

$$G(x,y) = \log d_{\mathrm{ch}}(x,y)^2 + 1, \qquad K(x,y) = 1 - G(x,y) \geq 0.$$

For a Borel probability μ on Y, define

$$Q_\mu(x) = \int_Y G(x,y)\,\mathrm{d}\mu(y). \tag{14.85}$$

We say that μ is non-polar if it gives every polar Borel set mass zero.

14.30.1 The logarithmic potential and its measure trace

Lemma 14.30.1 *For every probability μ, the function Q_μ is κ-plurisubharmonic, has κ-mean zero, and satisfies*

$$\kappa + \mathrm{dd}^{\mathrm{c}} Q_\mu = \mu, \qquad Q_\mu \leq 1.$$

If μ is non-polar, then $\mathrm{MA}^{\mathrm{ext}}_\kappa(Q_\mu) = \mu$. Every $p \in \mathrm{PSH}(Y,\kappa)$ with $\mathrm{MA}^{\mathrm{ext}}_\kappa(p) \geq \mu$ is of the form $Q_\mu + C$.

Proof The Poincaré–Lelong formula gives $\mathrm{dd}^{\mathrm{c}}_x G(x,y) = \delta_y - \kappa$. After a rotation sending y to $[1:0]$, the variable $t = d_{\mathrm{ch}}(x,y)^2$ is uniformly distributed on $[0,1]$ for the measure κ. Thus

$$\int_Y G(x,y)\kappa(x) = \int_0^1 (\log t + 1)\,\mathrm{d}t = 0, \qquad \sup_y \int_Y |G(x,y)|\kappa(x) < \infty.$$

The continuous potentials $\int \max(G(x,y), -L)\,\mathrm{d}\mu(y)$ are κ-plurisubharmonic by Lemma 1.3.1 and averaging, and decrease to Q_μ. Tonelli's theorem gives its integrability and mean zero; the decreasing-limit property gives its canonical values. Distributional Fubini proves the curvature identity.

In degree one the extended measure of p is

$$\mathrm{MA}^{\mathrm{ext}}_\kappa(p) = \mathbf{1}_{\{p > -\infty\}}(\kappa + \mathrm{dd}^{\mathrm{c}} p).$$

The pole set of Q_μ is polar, so non-polarity gives its asserted measure. For any p, distributional Stokes gives the full current $\kappa + \mathrm{dd}^{\mathrm{c}} p$ mass one, and its extended measure has mass at most one. Domination of the probability μ therefore forces both measures to equal μ. The distribution $p - Q_\mu$ is harmonic on the compact connected curve, hence constant, and canonical equality gives the assertion everywhere. □

For real Sobolev functions on Y use the Dirichlet form

$$E(p,q) = \int_Y \mathrm{d}p \wedge \mathrm{d}^{\mathrm{c}} q.$$

It is symmetric and nonnegative on the diagonal. The space $H^1(Y)$ and its norm are taken for the Fubini–Study Riemannian metric.

Lemma 14.30.2 *Suppose $Q = Q_\mu$ is finite and continuous. Then μ is non-polar, $Q \in H^1(Y)$, and smooth restriction extends to a continuous linear map*

$$\mathrm{Tr}_\mu : H^1(Y) \longrightarrow L^1(\mu).$$

For every $h \in H^1(Y)$,

$$\int_Y \mathrm{Tr}_\mu\, h\,\mathrm{d}\mu = \int_Y h\kappa - E(h,Q). \tag{14.86}$$

For $h \in \mathrm{PSH}(Y,\kappa) \cap H^1(Y)$ this trace agrees μ-almost everywhere with its canonical values. The trace commutes with Lipschitz real compositions.

Proof Continuity gives the uniform kernel bound

$$A_\mu := \sup_x \int_Y K(x,y)\,\mathrm{d}\mu(y) = 1 - \inf_Y Q < \infty. \tag{14.87}$$

To prove non-polarity, take a nontrivial subharmonic function on a coordinate disk. Cut off its positive Hessian measure on a slightly larger disk. The logarithmic potential

of this finite measure has the same Hessian on the smaller disk, so their difference is harmonic there. This is the local Riesz decomposition: it also follows directly from the distributional fundamental solution and harmonic regularity. On compact subdisks the kernel $-\log|z-a|^2$ differs from $K(z,a)$ by a bounded smooth term. Symmetry of K, Tonelli's theorem and (14.87) make the logarithmic potential integrable against μ; its harmonic remainder is bounded. The pole set consequently has μ-mass zero. A countable disk cover proves the claim for polar Borel sets.

The group $\mathrm{SU}(2)$ acts on Y by Fubini–Study isometries. Average with smooth nonnegative conjugation-invariant kernels of mass one supported near the identity. This gives smooth Q_ϵ, probability measures μ_ϵ, and

$$Q_\epsilon \longrightarrow Q \text{ uniformly}, \qquad \mathrm{dd^c} Q_\epsilon = \mu_\epsilon - \kappa, \qquad \int_Y Q_\epsilon \kappa = 0.$$

Smooth Stokes gives $E(Q_\epsilon, Q_\epsilon) = -\int Q_\epsilon \, \mathrm{d}\mu_\epsilon \le \|Q\|_\infty$. Poincaré's inequality and weak Hilbert compactness show that $Q \in H^1$. Its distributional curvature identity gives (14.86) first for smooth h. Apply this identity to $\sqrt{h^2+\epsilon^2}$, whose gradient has magnitude at most $|\mathrm{d}h|$. Letting $\epsilon \downarrow 0$ yields

$$\int_Y |h| \, \mathrm{d}\mu \le \|h\|_{L^1(\kappa)} + E(h,h)^{1/2} E(Q,Q)^{1/2} \le C_\mu \|h\|_{H^1}.$$

Completion defines the trace and extends the identity.

These group averages converge strongly in H^1: rotations act continuously and isometrically on that space, and the averaging kernels approach the identity. They also converge pointwise to every canonical quasi-subharmonic function. Indeed their induced averages about a point are radial by conjugation invariance. In a coordinate centered at that point they are positive averages of circular means; after a smooth quadratic correction, the submean inequality and upper semicontinuity give the required limit. The correction error tends to zero, and upper semicontinuity gives the limit also at a pole. For a κ-plurisubharmonic H^1 function, strong convergence and the trace bound give $L^1(\mu)$ convergence, while a subsequence converges μ-almost everywhere to the trace. Non-polarity makes the canonical value finite there and identifies the two. Finally, the Sobolev chain rule and smooth approximation show that Lipschitz compositions are continuous in H^1; the corresponding $L^1(\mu)$ limits prove the composition assertion. □

14.30.2 Exponential equations and uniform selection on the curve

Theorem 14.30.1 *Suppose $Q = Q_\mu$ is finite and continuous. For every $\lambda > 0$ there is a unique bounded $w_\lambda \in \mathrm{PSH}(Y, \kappa)$ satisfying*

$$\kappa + \mathrm{dd}^{\mathrm{c}} w_\lambda = \mathrm{e}^{\lambda w_\lambda} \mu, \qquad \int_Y \mathrm{e}^{\lambda w_\lambda} \, \mathrm{d}\mu = 1. \tag{14.88}$$

It is continuous and obeys

$$Q - \sup_Y Q \le w_\lambda \le Q - \inf_Y Q. \tag{14.89}$$

The entire family satisfies, as $\lambda \downarrow 0$,

$$\left\| w_\lambda - Q + \int_Y Q \, \mathrm{d}\mu \right\|_\infty = O(\lambda).$$

The limit is the greatest $p \in \mathrm{PSH}(Y, \kappa)$ with $\mathrm{MA}_\kappa^{\mathrm{ext}}(p) \ge \mu$ and $\int_Y p \, \mathrm{d}\mu \le 0$.

Proof *Variational existence.* On the real Hilbert space

$$\mathcal{H} = \{ q \in H^1(Y) : \int_Y q \kappa = 0 \}$$

consider the extended functional

$$J_\lambda(q) = \tfrac{1}{2} E(q, q) + \lambda^{-1} \log \int_Y \mathrm{e}^{\lambda \, \mathrm{Tr}_\mu \, q} \, \mathrm{d}\mu.$$

It is finite at zero. Jensen's inequality and (14.86) give

$$J_\lambda(q) \ge \tfrac{1}{2} E(q, q) - E(q, Q),$$

so it is coercive and bounded below. Strong H^1 convergence gives $L^1(\mu)$ convergence of traces. A subsequence realizing the lower limit converges almost everywhere for μ, and Fatou's lemma proves strong lower semicontinuity of the exponential term. Jensen excludes a zero integral or a logarithm tending to $-\infty$. Hölder's inequality makes the logarithmic term convex, while the Dirichlet term is strictly convex on $\mathcal{H}$. Separation of a closed convex epigraph makes J_λ weakly lower semicontinuous. Weak compactness therefore gives a unique minimizer q_λ, with

$$0 < Z_\lambda := \int_Y \mathrm{e}^{\lambda \, \mathrm{Tr}_\mu \, q_\lambda} \, \mathrm{d}\mu < \infty.$$

Variation in a smooth mean-zero direction h is justified by its boundedness, which dominates the differentiated integrand by a constant times the integrable exponential. Put $\rho_\lambda = \mathrm{e}^{\lambda \operatorname{Tr}_\mu q_\lambda}/Z_\lambda$. The Euler equation is

$$E(q_\lambda, h) + \int_Y h\rho_\lambda \,\mathrm{d}\mu = 0, \qquad \mathrm{dd}^{\mathrm{c}} q_\lambda = \rho_\lambda \mu - \kappa.$$

The second identity follows for arbitrary smooth tests by subtracting their κ-mean; $\int \rho_\lambda \,\mathrm{d}\mu = 1$ fixes the constant term. The minimizer has a canonical κ-plurisubharmonic representative. Its mean-zero Green representation and Lemma 14.30.2 give

$$q_\lambda(x) = \int_Y G(x,y)\rho_\lambda(y)\,\mathrm{d}\mu(y) \le 1, \qquad \rho_\lambda \le \mathrm{e}^{\lambda}/Z_\lambda \quad \mu\text{-a.e.}$$

The kernel bound then gives $q_\lambda \ge 1 - (\mathrm{e}^{\lambda}/Z_\lambda)A_\mu$.

To obtain continuity, the continuous functions $\int \min(K(x,y), L)\,\mathrm{d}\mu(y)$ increase to the continuous function $1 - Q(x)$. Dini's theorem gives

$$\sup_x \int_Y (K(x,y) - L)_+ \,\mathrm{d}\mu(y) \longrightarrow 0. \tag{14.90}$$

Multiplication by the bounded density ρ_λ preserves this estimate. Its truncated Green potentials converge uniformly, so q_λ is continuous. Now

$$w_\lambda = q_\lambda - \lambda^{-1} \log Z_\lambda$$

solves (14.88) with precisely the displayed constant.

Uniqueness and the barriers. Every bounded κ-plurisubharmonic function is in H^1, by the same smoothing and energy bound used above after subtracting its κ-mean. For two bounded solutions w_1, w_2, their right-hand sides have bounded densities relative to μ. The trace inequality extends distributional Stokes to their difference, giving

$$E(w_1 - w_2, w_1 - w_2) = -\int_Y (w_1 - w_2)(\mathrm{e}^{\lambda w_1} - \mathrm{e}^{\lambda w_2})\,\mathrm{d}\mu \le 0.$$

The difference is constant; the unit exponential integrals force that constant to be zero.

Set $L_0 = Q - \sup Q \le 0$, $R_0 = Q - \inf Q \ge 0$, and $z = (L_0 - w_\lambda)_+$. The H^1 chain rule, canonical trace and extended Stokes give

$$E(z,z) = -\int_Y z(1 - \mathrm{e}^{\lambda w_\lambda})\,\mathrm{d}\mu \le 0.$$

Indeed $z > 0$ implies $w_\lambda < L_0 \le 0$. Thus z is constant. If it were a positive constant, continuity would give $w_\lambda = L_0 - z \le -z$ everywhere, contradicting its unit exponential integral. This proves the lower barrier. Testing $(w_\lambda - R_0)_+$ gives the

upper barrier with the same argument and the reversed exponential difference. In particular $\|w_\lambda\|_\infty \le \operatorname{osc} Q$.

Selection. Write $q_\lambda = w_\lambda - \int_Y w_\lambda \kappa$, consistent with the variational normalization. The barriers give $e^{\lambda w_\lambda} = 1 + O(\lambda)$ uniformly, and the Green identity gives

$$\|q_\lambda - Q\|_\infty \le \|e^{\lambda w_\lambda} - 1\|_\infty \sup_x \int_Y |G(x,y)|\, d\mu(y) = O(\lambda).$$

The last kernel integral is bounded by $1 + A_\mu$. The q_λ are uniformly bounded, so Taylor's formula gives

$$\lambda^{-1} \log Z_\lambda = \int_Y q_\lambda \, d\mu + O(\lambda) = \int_Y Q \, d\mu + O(\lambda).$$

This proves the whole-family estimate. Finally, Lemma 14.30.1 identifies every critical subsolution as $Q + C$. Its μ-mean is at most zero exactly when $C \le -\int Q \, d\mu$, proving the order characterization. □

14.30.3 The product equation and its maximal coefficient

Let (X_0, h_0) be a connected compact Hermitian manifold of dimension $m \ge 1$. Set

$$X = X_0 \times Y, \qquad N = m + 1, \qquad H = h_0 + \kappa,$$
$$V_0 = \int_{X_0} h_0^m, \qquad \nu = M \frac{h_0^m}{V_0} \otimes \mu, \qquad c = \frac{N V_0}{M},$$

where $M > 0$ and factor forms and potentials are pulled back to X when used there. Thus $\nu(X) = M$.

Proposition 14.30.1 *If μ is non-polar, then ν is non-pluripolar and*

$$u = (Q_\mu - \sup_Y Q_\mu) \circ \pi_Y, \qquad \mathrm{MA}_H^{\mathrm{ext}}(u) = c\nu, \qquad \int_X \mathrm{MA}_H^{\mathrm{ext}}(u) = N V_0.$$

This is the unique supremum-zero solution among pullbacks of κ-plurisubharmonic functions. It is bounded exactly when Q_μ is bounded, and continuous exactly when Q_μ is continuous. If $v_-(h_0) = 0$, then $v_-(H) = 0$ and H is not closed.

Proof A nontrivial local plurisubharmonic function on a product chart has a nontrivial subharmonic restriction to the curve for smooth-volume-almost every point of X_0, by local integrability and Fubini's theorem. Non-polarity of μ and a second application of Fubini give its pole set product measure zero. A countable cover proves that ν is non-pluripolar.

For bounded $p \in \mathrm{PSH}(Y, \kappa)$, bounded multilinearity and Lemma 1.7.2 give

$$\mathrm{MA}_H(p \circ \pi_Y) = N h_0^m \otimes (\kappa + dd^c p). \tag{14.91}$$

Only one curve factor survives in the expansion. For arbitrary p, apply this to $p_j = \max(p, -j)$, restrict to the pullback of $\{p > -j\}$ and increase j. The defining extended limit gives the same formula with $\mathrm{MA}_\kappa^{\mathrm{ext}}(p)$ on the right. Lemma 14.30.1 now proves the equation, finite mass and separated uniqueness. Boundedness and continuity follow from the same constant-difference identity.

If $v_-(h_0) = 0$, pull back bounded potentials whose h_0-masses tend to zero. Their H-masses are N times those masses, because $\int_Y \kappa = 1$, so $v_-(H) = 0$. A closed h_0 would give every bounded potential mass $V_0 > 0$ by Stokes. Hence h_0 is not closed; restricting H to a factor slice shows that H is not closed either. □

For this fixed product measure define its subsolution threshold by

$$b_H(\nu) = \sup\{a \ge 0 : \exists p \in \mathrm{PSH}(X, H), \mathrm{MA}_H^{\mathrm{ext}}(p) \ge a\nu\}.$$

For $\nu = f\,\mathrm{d}V$ this agrees with the individual-density threshold of Theorem 14.27.1.

Theorem 14.30.2 *Suppose $Q = Q_\mu$ is finite and continuous. Then $b_H(\nu) = c$, attained by the bounded continuous u of Proposition 14.30.1. For every $\lambda > 0$, the continuous potential*

$$U_\lambda = \lambda^{-1} \log c + w_\lambda \circ \pi_Y$$

satisfies

$$\mathrm{MA}_H(U_\lambda) = \mathrm{e}^{\lambda U_\lambda}\nu, \qquad \int_X \mathrm{MA}_H(U_\lambda) = NV_0.$$

It dominates every $p \in \mathrm{PSH}(X, H)$ with $\mathrm{MA}_H^{\mathrm{ext}}(p) \ge \mathrm{e}^{\lambda p}\nu$, and it is the unique bounded solution. For $v_\lambda = U_\lambda - \sup_X U_\lambda$ and $c_\lambda = \mathrm{e}^{\lambda \sup_X U_\lambda}$,

$$\mathrm{MA}_H(v_\lambda) = c_\lambda \mathrm{e}^{\lambda v_\lambda}\nu, \qquad c_\lambda = c\,\mathrm{e}^{\lambda \sup_Y w_\lambda},$$
$$\|v_\lambda - u\|_\infty = O(\lambda), \qquad \lambda^{-1}\log(c_\lambda/c) \longrightarrow \sup_Y Q - \int_Y Q\,\mathrm{d}\mu.$$

All the constructed potentials belong to $\mathcal{E}_{\mathrm{env}}(X, H, 0)$. The same coefficient c is attained if the defining supremum for $b_H(\nu)$ is restricted to bounded potentials or to this envelope class.

Proof Lemma 14.30.2 gives non-polarity, and Theorem 14.30.1 constructs w_λ. Substituting it in (14.91) proves the exponential equation and its finite mass. Supremum normalization gives the displayed c_λ, and the uniform curve estimate gives both limits. For any bounded H-plurisubharmonic p and $t \ge 1$, the constant $a_t = t \inf_X p$ is an H-plurisubharmonic competitor below tp. Hence $P_H(tp)$ is genuine for every t, which proves the envelope-class assertion.

Greatestness. Write $s = U_\lambda$. If b is a bounded exponential subsolution, then on $\{s < b - \epsilon\}$,

$$\mathrm{MA}_H(s) \le \mathrm{e}^{-\lambda\epsilon}\mathrm{MA}_H(b - \epsilon).$$

The bounded strict domination theorem, Theorem 10.2.2, gives $s \ge b - \epsilon$. Letting $\epsilon \downarrow 0$ proves $s \ge b$, and applying the argument in both directions proves bounded uniqueness.

For an arbitrary exponential subsolution r, fix $A > 0$ and put $p = s - A$, $W = \max(r, p)$. These maxima are H-plurisubharmonic by Lemma 1.3.1, and W is bounded. Choose j with $-j < \inf_X p$ and set $r_j = \max(r, -j)$; then $W = \max(r_j, p)$. Plurifine locality on $\{r_j > p\}$ and Lemma 1.7.1, applied to $p \le W$ on their contact set, give

$$\mathrm{MA}_H(W) \ge \mathbf{1}_{\{r_j > p\}} \mathrm{MA}_H(r_j) + \mathbf{1}_{\{r_j \le p\}} \mathrm{MA}_H(p).$$

On the first set $r_j = r > -j$, so strict-superlevel locality identifies the measure with $\mathrm{MA}_H^{\mathrm{ext}}(r)$. On the second, $W = p$ and $\mathrm{MA}_H(p) = \mathrm{e}^{\lambda s}\nu \ge \mathrm{e}^{\lambda p}\nu$. Thus W is a bounded exponential subsolution, and $r \le W \le s$. This uses bounded products before every restriction and applies also when the measure of r has infinite mass.

The maximal coefficient. Suppose $\mathrm{MA}_H^{\mathrm{ext}}(r) \ge a\nu$ with $a > 0$, and put $B = \sup_X r$. For every $\lambda > 0$ the potential $r + \lambda^{-1} \log a - B$ is an exponential subsolution, since its exponential is at most a. Greatestness gives

$$r + \lambda^{-1} \log a - B \le \lambda^{-1} \log c + w_\lambda \circ \pi_Y.$$

Evaluate at a fixed finite point of r, multiply by λ, and let $\lambda \downarrow 0$. The uniform barriers for w_λ give $a \le c$. The equation for u attains c in each stated class. □

The order characterization of the zero-exponent limit is confined to the separated sector. Bounded uniqueness at a positive exponent and maximality of the coefficient do not determine all normalized critical potentials on the nonclosed product.

Proposition 14.30.2 *Suppose, for some $C > 0$ and $\delta > 0$,*

$$\mu(B_{\mathrm{ch}}(x, r)) \le C r^{\delta} \qquad (x \in Y,\ 0 < r \le 1).$$

Then Q_μ is finite and continuous, so Theorem 14.30.2 applies. In particular it applies to

$$\mathrm{d}\mu(\vartheta) = (1 + \epsilon \cos\vartheta)\frac{\mathrm{d}\vartheta}{2\pi}, \qquad 0 < \epsilon < 1,$$

on the circle $[1 : \mathrm{e}^{\mathrm{i}\vartheta}]$. This measure and its product ν are singular with respect to smooth volume, and Q_μ is nonconstant on its support.

Proof Since $K = -\log d_{\mathrm{ch}}^2$, layer-cake integration gives

$$\sup_x \int_{\{K(x,y) > L\}} K(x, y)\, \mathrm{d}\mu(y) \le C\left(L + \frac{2}{\delta}\right)\mathrm{e}^{-\delta L/2}.$$

Consequently the continuous truncated-kernel potentials converge uniformly to Q_μ. Weighted arclength on the circle has the ball bound with $\delta = 1$. On that circle the kernel is $1 + \log \sin^2((\vartheta - \varphi)/2)$, whose first cosine coefficient is -2. Integrating its L^1 Fourier series against $1 + \epsilon \cos\varphi$ gives

$$Q_\mu([1 : \mathrm{e}^{\mathrm{i}\vartheta}]) = 1 - 2\log 2 - \epsilon \cos\vartheta.$$

This proves nonconstancy, and the support has smooth curve volume zero. Its product with X_0 also has smooth volume zero. □

14.31 Stability of the subsolution threshold

We now study how the threshold $b_h(f)$ depends on f. By (14.83), $b_h^{1/n}$ is an infimum of functions that are continuous on L^1, and is therefore upper semicontinuous. It is not continuous in general: when $v_-(h) = 0$, every density with positive threshold is an L^1 limit of densities with zero threshold. For density roots, (14.82) expresses ρ_h as a supremum of positive linear functionals. Hence ρ_h is a norm on the space where it is finite, this space is complete for a suitable norm, and the threshold depends continuously on the root in that norm.

Theorem 14.31.1 *Suppose f_j, f are nonzero nonnegative L^1 densities and $f_j \to f$ in $L^1(\mathrm{d}V)$. Then*

$$\limsup_{j\to\infty} b_h(f_j) \le b_h(f).$$

Moreover,

$$b_h(f) = \lim_{\delta\downarrow 0} \sup\{c_h(q) : q \in L^\infty,\ q \ge 0,\ q \not\equiv 0,\ \|q - f\|_{L^1} < \delta\}, \tag{14.92}$$

and the suprema are finite for sufficiently small δ.

Proof For a Gauduchon form γ on X, write $A_\gamma(f) = \int_X (f\,\mathrm{d}V/\gamma^n)^{1/n}\gamma^n$. Since $|s^{1/n} - t^{1/n}| \le |s-t|^{1/n}$ for $s, t \ge 0$, Hölder's inequality shows that A_γ is continuous on L^1; it is positive at every nonzero nonnegative density. By Theorem 14.28.1, $b_h^{1/n}$ is the infimum over γ of the continuous positive functions $f \mapsto \int_X h \wedge \gamma^{n-1}/A_\gamma(f)$. It is therefore upper semicontinuous, and testing a single γ bounds it above on an L^1 neighborhood of f.

For the second assertion, recall that $b_h(q) = c_h(q)$ for bounded q (Proposition 14.27.2). By the first assertion, $\limsup_j c_h(q_j) \le b_h(f)$ for every sequence of nonzero nonnegative bounded densities $q_j \to f$ in L^1. Hence the limit in (14.92) is at most $b_h(f)$, and the local upper bound makes the suprema finite for small δ. Conversely, the truncations f_k converge to f in L^1 and satisfy $c_h(f_k) \ge b_h(f)$, so every supremum in (14.92) is at least $b_h(f)$. □

Since $b_h \ge 0$, upper semicontinuity makes b_h continuous at every density where it vanishes. If $v_-(h) = 0$, these are its only points of continuity. Indeed, let $b_h(f) > 0$ and $g = f/\int_X f\,\mathrm{d}V$. By Corollary 14.26.2 and Theorem 14.27.1, the densities $(1-t)g + tf_0$, where f_0 is the density of Theorem 14.26.1, have zero threshold and converge to g in L^1 as $t \downarrow 0$; multiplying them by $\int_X f\,\mathrm{d}V$ gives densities with zero threshold converging to f. These statements concern only the scalar b_h; they say nothing about capacity convergence of the corresponding potentials or about the limits of their Monge–Ampère measures.

14.31.1 Finite sums of densities

Since (14.82) expresses $\rho_h(p)$ as a supremum of positive linear functionals evaluated at $|p|$, the root functional is homogeneous, monotone and subadditive. Subadditivity shows that the sum of two densities with positive threshold again has positive threshold. In the statements below, f and g are nonzero nonnegative L^1 densities, and p and q are real or complex functions in L^n.

Proposition 14.31.1 *The functional ρ_h satisfies $\rho_h(tp) = |t|\rho_h(p)$ for scalars $t \neq 0$, $\rho_h(p) \le \rho_h(q)$ whenever $|p| \le |q|$, and*

$$\rho_h(p+q) \le \rho_h(p) + \rho_h(q).$$

In particular, if $b_h(f), b_h(g) > 0$, then

$$b_h(f+g) \ge \left(b_h(f)^{-1/n} + b_h(g)^{-1/n}\right)^{-n} > 0.$$

Proof By (14.82), $\rho_h(p) = \sup_\gamma L_{h,\gamma}(|p|)$ is a supremum of positive linear functionals evaluated at $|p|$. This gives homogeneity and monotonicity, and, together with $|p+q| \le |p| + |q|$, the triangle inequality. Finally, $(f+g)^{1/n} \le f^{1/n} + g^{1/n}$ gives

$$b_h(f+g)^{-1/n} = \rho_h\big((f+g)^{1/n}\big) \le \rho_h(f^{1/n}) + \rho_h(g^{1/n}) = b_h(f)^{-1/n} + b_h(g)^{-1/n},$$

which is equivalent to the asserted lower bound for $b_h(f+g)$. □

Proposition 14.31.2 *The real or complex vector space*

$$\mathcal{D}_h = \{p \in L^n(\mathrm{d}V) : \rho_h(p) < +\infty\}$$

is complete for the norm $\|p\|_{\mathcal{D}_h} = \|p\|_{L^n} + \rho_h(p)$. It is an order ideal in L^n: if $q \in \mathcal{D}_h$ and $|p| \le |q|$, then $p \in \mathcal{D}_h$. It contains L^∞ and is therefore dense in L^n for the L^n norm.

Moreover, $\mathcal{D}_h = L^n$ if and only if $v_-(h) > 0$, and in that case the norm $\|\cdot\|_{\mathcal{D}_h}$ is equivalent to the L^n norm. If h is Kähler, then

$$\rho_h(p) = \left(\int_X h^n\right)^{-1/n} \|p\|_{L^n}.$$

Proof By Proposition 14.31.1, $\mathcal{D}_h$ is a vector space and an order ideal, and $\|\cdot\|_{\mathcal{D}_h}$ is a norm on it. Bounded functions belong to $\mathcal{D}_h$, because $b_h(|p|^n) = c_h(|p|^n) > 0$ for bounded nonzero p.

We next show that ρ_h is lower semicontinuous on L^n. If $p_j \to p$ in L^n, then $|p_j|^n \to |p|^n$ in L^1, and the upper semicontinuity of b_h in Theorem 14.31.1 gives

$$\rho_h(p) \le \liminf_j \rho_h(p_j).$$

This includes the case $b_h(|p|^n) = 0$, in which the right side must be infinite; for $p = 0$ the inequality is trivial. Now let (p_j) be a Cauchy sequence in $\mathcal{D}_h$. It converges in L^n to some p, and lower semicontinuity gives $\rho_h(p) \le \liminf_j \rho_h(p_j) < +\infty$, so $p \in \mathcal{D}_h$. Applied to $p_j - p_k$ as $k \to \infty$, lower semicontinuity also gives

$$\rho_h(p_j - p) \le \liminf_{k\to\infty} \rho_h(p_j - p_k),$$

which tends to zero as $j \to \infty$. Together with L^n convergence, this proves completeness.

If $v_-(h) > 0$, Proposition 14.27.2 gives $\rho_h(p) \le v_-(h)^{-1/n}\|p\|_{L^n}$, so $\mathcal{D}_h = L^n$ with an equivalent norm. If $v_-(h) = 0$, the density f of Theorem 14.26.1 has $b_h(f) = 0$ by Theorem 14.27.1; thus $f^{1/n}$ belongs to L^n but not to $\mathcal{D}_h$. The Kähler formula follows from the same proposition. □

Thus, when the lower mass vanishes, $\mathcal{D}_h$ is a proper dense subspace of L^n, complete for the stronger norm $\|\cdot\|_{\mathcal{D}_h}$; its nonnegative elements are the nth roots of the densities admitting a positive scaled subsolution. A finite sum of such densities again admits a positive scaled subsolution, but a convergent infinite sum need not: the smooth summands in Theorem 14.26.1 give an example. By Proposition 14.28.1, the space $\mathcal{D}_h$ does not depend on the Hermitian form h, and the norms $\|\cdot\|_{\mathcal{D}_h}$ for different Hermitian forms are equivalent. The closure of the bounded functions for this norm is studied in Section 14.31.2.

The restriction of ρ_h to $\mathcal{D}_h$ is itself a norm: if $p \ne 0$, then $\rho_h(p) \ge L_{h,\gamma}(|p|) > 0$ for any Gauduchon form γ. Whether this weaker norm is complete depends on the upper mass.

Proposition 14.31.3 *The norm ρ_h is complete on $\mathcal{D}_h$ if and only if $v_+(h) < +\infty$. When the upper mass is finite,*

$$\|p\|_{L^n} \le v_+(h)^{1/n}\rho_h(p) \qquad (p \in \mathcal{D}_h),$$

so ρ_h and $\|\cdot\|_{\mathcal{D}_h}$ are equivalent norms.

Proof Suppose $v_+(h) < +\infty$. A continuous solution for a bounded density q has mass $c_h(q)\int_X q\,\mathrm{d}V \le v_+(h)$. Applying this to the truncations of $|p|^n$ and letting the truncation level increase gives $b_h(|p|^n)\|p\|_{L^n}^n \le v_+(h)$, which is the asserted inequality. Hence ρ_h and $\|\cdot\|_{\mathcal{D}_h}$ are equivalent, and completeness follows from Proposition 14.31.2.

Suppose instead that $v_+(h) = +\infty$. By Theorems 26.1.1 and 26.14.1, the normalization scalars of smooth strictly positive probability densities are unbounded above. For each j, choose such a density f_j with

$$c_h(f_j) \ge (j2^j)^n, \qquad \text{and put} \qquad p_j = j f_j^{1/n}.$$

Then $\|p_j\|_{L^n} = j$ and $\rho_h(p_j) = j c_h(f_j)^{-1/n} \le 2^{-j}$, so the partial sums $P_N = \sum_{j\le N} p_j$ form a Cauchy sequence for ρ_h.

Fix a Gauduchon form γ. Its coefficient a_γ is bounded below by a positive constant, so (14.82) gives $\rho_h(p) \geq c\|p\|_{L^1}$ with a constant $c > 0$. Hence $\sum_j p_j$ converges in L^1 to a nonnegative function P. If P_N converged for ρ_h to an element of $\mathcal{D}_h$, that element would also be the L^1 limit, hence equal to P almost everywhere. But $P \geq p_j$ gives $\|P\|_{L^n} \geq j$ for every j, so $P \notin L^n$. Therefore ρ_h is not complete. □

The two mass properties play separate roles: positive lower mass makes every L^n function admissible, whereas finite upper mass makes the root norm control the L^n norm. The norm $\|\cdot\|_{\mathcal{D}_h}$ is complete without either assumption.

All four combinations occur. On a compact Kähler manifold both mass properties hold. The Hopf threefold has positive lower mass and infinite upper mass (Corollary 8.7.1). The elliptic threefold of Theorem 26.18.1 has zero lower mass, and finite upper mass for its balanced metric (Proposition 26.18.1). The product manifolds of Corollary 26.18.2 have zero lower mass and infinite upper mass. Since neither $\mathcal{D}_h$ nor the completeness of ρ_h depends on the choice of h (Propositions 6.5.1 and 14.28.1), we obtain the following table.

Manifold	Domain $\mathcal{D}_h$	Is ρ_h complete?
Kähler manifold	L^n	Yes
Hopf threefold	L^n	No
Elliptic threefold	$\mathcal{D}_h \subsetneq L^n$	Yes
Product example	$\mathcal{D}_h \subsetneq L^n$	No

14.31.2 Approximation by bounded density roots

Bounded functions are dense in $\mathcal{D}_h$ for the L^n norm, but not obviously for the norm $\|\cdot\|_{\mathcal{D}_h}$. Let $\mathcal{D}_h^0$ denote the closure of L^∞ in $\mathcal{D}_h$ for this norm. We show that a function belongs to $\mathcal{D}_h^0$ exactly when its tails are small uniformly over all Gauduchon tests. The basic tool is a subcritical estimate. For every $r > n$,

$$\rho_h(p) \leq C_r\|p\|_{L^r} \qquad (p \in L^r), \tag{14.93}$$

where the constant C_r depends on h, the reference volume and r, but not on p. Indeed, for nonzero $p \in L^r$ the density $|p|^n$ belongs to $L^{r/n}$, so $b_h(|p|^n) = c_h(|p|^n)$ by Proposition 14.27.2, and the lower-density estimate of Theorem 10.3.1, with exponent r/n, gives $c_h(|p|^n)\||p|^n\|_{L^{r/n}} \geq c_{r/n} > 0$.

Proposition 14.31.4 *For $p \in \mathcal{D}_h$, the following conditions are equivalent:*

(1) $p \in \mathcal{D}_h^0$;
(2) $\rho_h(|p|\mathbf{1}_{\{|p|>K\}}) \to 0$ *as* $K \to \infty$;
(3) *whenever* $|q_j| \leq |p|$ *and* $q_j \to 0$ *in measure, one has* $\|q_j\|_{\mathcal{D}_h} \to 0$.

By (14.82)*, the second condition can be written as*

$$\sup_{\gamma \text{ Gauduchon}} L_{h,\gamma}(|p|\mathbf{1}_{\{|p|>K\}}) \longrightarrow 0 \qquad (K \to \infty).$$

The space $\mathcal{D}_h^0$ is a closed order ideal in $\mathcal{D}_h$. It contains L^r for every $r > n$, and smooth functions are dense in it. If $v_-(h) > 0$, then $\mathcal{D}_h^0 = \mathcal{D}_h = L^n$.

Proof For $K > 0$, set $p_K = p \min(1, K/|p|)$ where $p \neq 0$, and $p_K = 0$ where $p = 0$. Then $|p - p_K| = (|p| - K)_+$ and

$$(|p| - K)_+ \leq |p|\mathbf{1}_{\{|p|>K\}}, \qquad |p|\mathbf{1}_{\{|p|>2K\}} \leq 2(|p| - K)_+.$$

Since the L^n norms of the tails tend to zero, these inequalities and the monotonicity of ρ_h show that the second condition is equivalent to $p_K \to p$ in $\mathcal{D}_h$; in particular, it implies the first. Conversely, if a is bounded and $K \geq \|a\|_{L^\infty}$, then $(|p|-K)_+ \leq |p-a|$, so $\|p - p_K\|_{\mathcal{D}_h} \leq \|p - a\|_{\mathcal{D}_h}$. Approximating p by bounded functions a shows that the first condition implies $p_K \to p$, hence the second.

Assume the second condition, and let q_j be as in the third. Fix K. On $\{|p| \leq K\}$, the functions q_j are bounded by K and tend to zero in measure, hence in L^{2n}; by (14.93) with $r = 2n$, the root functional of $q_j\mathbf{1}_{\{|p|\leq K\}}$ tends to zero. On the complementary set, $\rho_h(q_j\mathbf{1}_{\{|p|>K\}}) \leq \rho_h(|p|\mathbf{1}_{\{|p|>K\}})$. Letting first j and then K tend to infinity gives $\rho_h(q_j) \to 0$, and dominated convergence gives $\|q_j\|_{L^n} \to 0$. Conversely, the third condition applied to $q_j = |p|\mathbf{1}_{\{|p|>j\}}$ gives the second.

Since the second condition passes from p to every function dominated by $|p|$, the space $\mathcal{D}_h^0$ is an order ideal; it is closed by definition. For $p \in L^r$ with $r > n$, the truncations p_K converge to p in L^r, hence in $\mathcal{D}_h$ by (14.93). Bounded functions can be approximated in L^{2n} by smooth functions, which then converge in $\mathcal{D}_h$ by the same estimate; hence smooth functions are dense in $\mathcal{D}_h^0$. Under positive lower mass, Proposition 14.31.2 shows that $\mathcal{D}_h = L^n$ with an equivalent norm, and bounded functions are dense in L^n; hence $\mathcal{D}_h^0 = \mathcal{D}_h = L^n$. □

By Proposition 14.28.1, the space $\mathcal{D}_h^0$ does not depend on the choice of the Hermitian form h. Convergence in $\mathcal{D}_h$ controls the threshold: if $p_j \to p \neq 0$ in $\mathcal{D}_h$, then

$$|\rho_h(p_j) - \rho_h(p)| \leq \rho_h(p_j - p) \longrightarrow 0, \qquad b_h(|p_j|^n) \longrightarrow b_h(|p|^n) > 0.$$

For $p \in \mathcal{D}_h^0$, the uniform tail condition also gives a uniform modulus for exponential damping and error bounds for the scalars of the exponential equations; see Proposition 14.34.1. It does not by itself give capacity convergence of the solutions. We do not know whether $\mathcal{D}_h^0 = \mathcal{D}_h$ when $v_-(h) = 0$.

14.31.3 Density roots from a closed factor

The product formula of Theorem 14.29.2 identifies a complete subspace of density roots with uniformly vanishing tails even when the ambient lower mass is zero. Use the product data $X_0, Y, N, H, c_0, \mu, R$ of Section 14.29.1. The spaces $\mathcal{D}_H$ and $\mathcal{D}_H^0$ are now taken on the N-dimensional product with reference volume $\mathrm{d}V$.

Proposition 14.31.5 *For real or complex $\xi \in L^N(Y, \kappa^k)$, put $J\xi = R^{1/N}\pi_Y^*\xi$. Then*

$$\|J\xi\|_{L^N(\mathrm{d}V)} = \|\xi\|_{L^N(\kappa^k)}, \qquad \rho_H(J\xi) = c_0^{-1/N}\|\xi\|_{L^N(\kappa^k)}.$$

The image of J is a closed linear subspace of $\mathcal{D}_H^0$. If $g = |\xi|^N$ and $A = \max_X R$, then

$$\rho_H\big(J\xi\mathbf{1}_{\{|J\xi|>K\}}\big) \le \left(\frac{1}{c_0}\int_{\{g>K^N/A\}} g\kappa^k\right)^{1/N} \longrightarrow 0.$$

For $\mathrm{d}V = \mu$, so that $R = 1$, the exact tail formula is

$$\rho_H\big(\pi_Y^*\xi\mathbf{1}_{\{|\xi|>K\}}\big) = \left(\frac{1}{c_0}\int_{\{|\xi|>K\}} |\xi|^N\kappa^k\right)^{1/N}.$$

Proof Since $|J\xi|^N = R|\xi|^N$, integration against $\mathrm{d}V$ gives the first norm identity. For nonzero ξ, Theorem 14.29.2 applied to $g = |\xi|^N$ gives the root-functional identity; for $\xi = 0$ it holds by definition. Applying the two identities to differences yields

$$\|J\xi - J\eta\|_{\mathcal{D}_H} = (1 + c_0^{-1/N})\|\xi - \eta\|_{L^N(\kappa^k)}.$$

Bounded approximations of ξ in L^N have bounded images because R is bounded, so $J\xi \in \mathcal{D}_H^0$. Completeness of $L^N(Y, \kappa^k)$ and the displayed identity make the image closed.

On $\{|J\xi| > K\}$ one has $g > K^N/A$, and hence

$$|J\xi|\mathbf{1}_{\{|J\xi|>K\}} \le \big(Rg\mathbf{1}_{\{g>K^N/A\}}\big)^{1/N}.$$

Monotonicity of the root functional and its identity for factor roots give the estimate, with the value zero when the tail vanishes. Integrability of g makes the bound tend to zero; the L^N tails also vanish. When $R = 1$, the amplitude cutoff itself is pulled back from Y, so the same norm identity gives equality. □

For $Y = \mathbb{P}^k$ and $\mathrm{d}V = \mu$, take $p_\alpha = \pi_Y^*(q_\alpha^{1/N})$ with q_α from Lemma 14.29.1. Then $p_\alpha \in \mathcal{D}_H^0$ but $p_\alpha \notin L^r(\mathrm{d}V)$ for every $r > N$. Moreover,

$$\rho_H\big(p_\alpha\mathbf{1}_{\{p_\alpha>K\}}\big) \asymp (\log K)^{-k(1-\alpha)/N} \qquad (K \to +\infty).$$

Indeed, the radial estimate of that lemma gives $q_\alpha \asymp r^{-k}(1 - \log r)^{-1-k(1-\alpha)}$. With $L = 1 - \log r$, the density level set $\{q_\alpha > K^N\}$ lies between two sets $\{L > c\log K\}$ for

fixed positive constants c, once K is large. Integrating the radial density $L^{-1-k(1-\alpha)}\,\mathrm{d}L$ and taking its Nth root gives the claimed tail. The integrability exclusion follows from $q_\alpha \notin L^s$ for $s > 1$.

These roots enlarge the examples in $\mathcal{D}_H^0$ beyond the subcritical L^r classes. They give neither $\mathcal{D}_H^0 = \mathcal{D}_H$ nor a general criterion for an exact equation at zero lower mass.

14.32 Power capacity bounds and threshold equations

In this section, X is a connected compact complex manifold of dimension $n \geq 3$, with a Hermitian form h and a smooth positive probability volume $\mathrm{d}V$. The root-tail condition of Proposition 14.31.4 controls the scalar threshold. A power bound for one density's measure supplies the missing control of its approximating potentials: the capacity estimates give a common bound, and stability against the solution measure gives uniform convergence.

Theorem 14.32.1 *Let $0 \leq f \in L^1(\mathrm{d}V)$ have positive integral. Suppose that $A, \alpha > 0$ satisfy*

$$\int_E f\,\mathrm{d}V \leq A\,\mathrm{Cap}_h(E)^{1+\alpha} \qquad (E \subset X \text{ Borel}). \tag{14.94}$$

There is $C > 0$, depending only on (X, h), A, α, such that every measurable $0 \leq g \leq f$ with positive integral satisfies

$$b_h(g) \geq C\left(\int_X g\,\mathrm{d}V\right)^{-\alpha/(1+\alpha)}, \qquad \rho_h(g^{1/n}) \leq C^{-1/n}\left(\int_X g\,\mathrm{d}V\right)^{\alpha/(n(1+\alpha))}. \tag{14.95}$$

In particular, $f^{1/n} \in \mathcal{D}_h^0$. There is $\phi \in \mathrm{PSH}(X, h) \cap C(X)$, with $\sup_X \phi = 0$, such that

$$\mathrm{MA}_h(\phi) = b_h(f) f\,\mathrm{d}V. \tag{14.96}$$

The coefficient $b_h(f)$ and the mass of this measure are finite and strictly positive.

Proof *Step 1: the coefficient and root tails.* Put $g_j = \min(g, j)$ and let ϕ_j be normalized continuous solutions of

$$\mathrm{MA}_h(\phi_j) = c_j g_j\,\mathrm{d}V, \qquad c_j = c_h(g_j), \qquad \sup_X \phi_j = 0,$$

given by Theorem 10.1.1. The definition (14.80) gives $c_j \downarrow b_h(g)$. Their measures satisfy a power capacity bound with constant $c_j A$.

Take competitor zero, $H = 1$ and $\varepsilon = 1/2$ in Lemmas 10.3.1 and 10.3.2. Choose $D > 0$ fixed with $2D < \delta_{1/2}$ and put $U_D = \{\phi_j < \inf_X \phi_j + D\}$. These estimates give

$$D \leq C_\alpha (C_1 c_j A)^{1/n}\,\mathrm{Cap}_h(U_D)^{\alpha/n}, \qquad D^n\,\mathrm{Cap}_h(U_D) \leq C_1 c_j \int_X g_j\,\mathrm{d}V.$$

Combining them yields

$$c_j^{1+\alpha}\left(\int_X g_j\,\mathrm{d}V\right)^{\alpha} \geq c > 0.$$

Taking the limit proves the lower bound for $b_h(g)$. The identity (14.82), with its full family of Gauduchon tests, gives the root estimate. Apply it to $g = f\mathbf{1}_{\{f>K^n\}}$ whenever this density is nonzero. Its mass tends to zero; the zero density has root norm zero. Thus the tails of $f^{1/n}$ tend to zero in both L^n and ρ_h, and Proposition 14.31.4 gives $f^{1/n} \in \mathcal{D}_h^0$.

Step 2: uniform convergence of a subsequence. Now use $f_j = \min(f, j)$, $c_j = c_h(f_j)$ and normalized continuous solutions ϕ_j. Step 1 gives $b_h(f) > 0$, while $c_j \leq c_1 < \infty$. Hence

$$\mathrm{MA}_h(\phi_j)(E) \leq Ac_1\,\mathrm{Cap}_h(E)^{1+\alpha}.$$

The first part of the proof of Proposition 10.3.1, using the capacity tail estimate, gives one $M \geq 1$ with $-M \leq \phi_j \leq 0$ for all j.

By Theorem 1.4.1, extract a subsequence converging in $L^1(\mathrm{d}V)$ and almost everywhere. Since $f\,\mathrm{d}V$ is a fixed finite absolutely continuous measure and the potentials have a common bound, dominated convergence gives

$$\int_X |\phi_j - \phi_k|\,\mathrm{MA}_h(\phi_j) \leq c_1 \int_X |\phi_j - \phi_k| f\,\mathrm{d}V \longrightarrow 0$$

along this subsequence as both indices tend to infinity. Apply Proposition 10.3.1 in both orders, with $H = M$. The subsequence is uniformly Cauchy. Its limit ϕ is continuous, h-plurisubharmonic by distributional positivity, and has supremum zero.

Step 3: passage of the products. On a coordinate ball choose a fixed smooth q with $\mathrm{dd^c}q \geq h$, and put $S_j = \mathrm{dd^c}(\phi_j + q)$ and $S = \mathrm{dd^c}(\phi + q)$. For every $\ell \geq 1$, the calculus of bounded products gives

$$S_j^\ell - S^\ell = \mathrm{dd^c}\left[(\phi_j - \phi)\sum_{a=0}^{\ell-1} S_j^a \wedge S^{\ell-1-a}\right].$$

The local Chern–Levine–Nirenberg estimate bounds its pairing with a compactly supported smooth test form by $C\|\phi_j - \phi\|_\infty$. Expand the Hermitian products as in Proposition 1.7.1:

$$\mathrm{MA}_h(\phi_j) = \sum_{\ell=0}^{n} \binom{n}{\ell} S_j^\ell \wedge (h - \mathrm{dd^c}q)^{n-\ell}.$$

Every term converges, with its smooth correction factor, to the corresponding term for ϕ. On the other hand, $c_j f_j \to b_h(f) f$ in $L^1(\mathrm{d}V)$. The two limits prove (14.96); its prescribed mass is $b_h(f)\int_X f\,\mathrm{d}V$. □

The capacity assumption concerns the fixed datum and implies the root-tail condition. Whether root tails alone suffice for the exact equation when $v_-(h) = 0$ remains part of Problem 33.1.1; whether every positive-threshold root has these tails is the question following Proposition 14.31.4.

14.32.1 A logarithmic density with critical coefficient one

The power capacity condition can hold for a density outside every L^p class with $p > 1$. A bounded continuous potential with logarithmic modulus at one point gives such a datum on each fixed Hermitian background.

Theorem 14.32.2 *In the setting of Theorem 14.32.1, fix $\alpha > 0$. There is $u \in \mathrm{PSH}(X,h) \cap C(X)$ with $h + \mathrm{dd^c} u \geq h/2$ whose measure $\mathrm{MA}_h(u) = f\,\mathrm{d}V$ satisfies*

$$f \in L^1(\mathrm{d}V), \qquad f \notin L^p(\mathrm{d}V) \quad \text{for every } p > 1.$$

For some $A > 0$ it satisfies (14.94), and $b_h(f) = 1$. For all sufficiently large K,

$$\rho_h\big(f^{1/n}\mathbf{1}_{\{f>K\}}\big) \leq C(\log K)^{-\alpha}. \tag{14.97}$$

Proof Choose a holomorphic ball with coordinates centred at x_0 and $R = |z| < 1$, and a smooth cutoff $0 \leq \chi \leq 1$ supported in it and equal to one on a smaller ball. Put

$$q(s) = (1-s)^{-\alpha}, \qquad s = \log R^2, \qquad \psi = \chi q(\log R^2) + 1 - \chi.$$

Set $\psi(x_0) = 0$ and extend $\psi = 1$ outside the ball. In the smaller ball, $q' = \alpha(1-s)^{-\alpha-1} > 0$ and $q'' = \alpha(\alpha+1)(1-s)^{-\alpha-2} > 0$, so ψ is plurisubharmonic there, including its continuous extension at x_0. The transition is smooth and $\mathrm{dd^c}\psi \geq -K_0 h$ globally for a fixed K_0. For sufficiently small $\delta > 0$, the normalized potential $u = \delta\psi - \sup_X \delta\psi$ satisfies $h + \mathrm{dd^c} u \geq h/2$.

The bounded product gives zero mass to x_0. Indeed, after a smooth local correction, its expansion is dominated in total variation by a constant times the top product of a bounded plurisubharmonic function plus a strictly plurisubharmonic quadratic function. Rescaling this sum into $[0,1]$ bounds that top product by local capacity, and a pluripolar point has capacity zero. Off x_0 the potential is smooth. Thus the measure is absolutely continuous; write it as $f\,\mathrm{d}V$. The strict lower bound implies $f \geq c > 0$ almost everywhere.

In the smaller ball the tangential and radial eigenvalues of the Hessian of $q(\log R^2)$ are q'/R^2 and q''/R^2. In the operator convention of the book this gives

$$(\mathrm{dd^c} u)^n = \frac{\delta^n n! \alpha^n (\alpha+1)}{\pi^n} R^{-2n} (1 - \log R^2)^{-n(\alpha+1)-1}\,\mathrm{d}\lambda, \tag{14.98}$$

where $\mathrm{d}\lambda$ is Euclidean volume.

Integration over the ball gives

$$\int_{B_r} (\mathrm{dd}^c u)^n = \delta^n \alpha^n (1 - \log r^2)^{-n(\alpha+1)}.$$

For $k < n$, the degree-k mixed terms with the smooth positive form h have density bounded by $CR^{-2k}(1 - \log R^2)^{-k(\alpha+1)}$ and mass $O(r^2)$ on B_r. The expansion has positive terms in this ball. Hence $f \in L^1$. For $p > 1$, the pure top term gives a positive multiple of the divergent integral

$$\int_0^r R^{2n(1-p)-1}(1 - \log R^2)^{-p(n(\alpha+1)+1)}\, \mathrm{d}R$$

as a lower bound for $\int_{B_r} f^p \, \mathrm{d}V$, since smooth volume densities are comparable. Thus $f \notin L^p$. For all sufficiently small r,

$$\int_{B_r} f \, \mathrm{d}V \le C\big[(1 - \log r^2)^{-n(\alpha+1)} + r^2\big], \qquad \operatorname*{ess\,sup}_{X \setminus B_r} f \le Cr^{-2n}. \tag{14.99}$$

By (1.14),

$$\mathrm{d}V(E) \le C \exp\big(-a \operatorname{Cap}_h(E)^{-1/n}\big).$$

Let $s = \operatorname{Cap}_h(E) > 0$ be small and choose $r = \exp[-as^{-1/n}/(4n)]$. Splitting E inside and outside B_r and applying (14.99), we obtain

$$\int_E f \, \mathrm{d}V \le Cs^{1+\alpha} + C \exp[-as^{-1/n}/(2n)] + C \exp[-as^{-1/n}/2] \le C' s^{1+\alpha}.$$

For larger s use the finite total mass; for $s = 0$ the volume estimate gives $\mathrm{d}V(E) = 0$. This proves (14.94) for every Borel set.

By Theorem 14.32.1, there is a normalized continuous ϕ with $\mathrm{MA}_h(\phi) = b_h(f) f \, \mathrm{d}V$. The explicit potential u is a subsolution with coefficient one, so Theorem 14.27.1 gives $b_h(f) \ge 1$. Suppose $b_h(f) > 1$, and choose $0 < \varepsilon < 1$ with $(1 - \varepsilon)^n b_h(f) > 1$. Positive multilinearity gives

$$\mathrm{MA}_h((1 - \varepsilon)\phi) \ge (1 - \varepsilon)^n b_h(f) f \, \mathrm{d}V.$$

Apply Theorem 10.2.1 to u, ϕ on

$$U_s = \{u < (1 - \varepsilon)\phi + \inf_X (u - (1 - \varepsilon)\phi) + s\}.$$

For sufficiently small $s > 0$ its reverse factor $Q_\varepsilon(s)$ is defined, tends to one as $s \downarrow 0$, and satisfies

$$(1 - \varepsilon)^n b_h(f) \int_{U_s} f \, \mathrm{d}V \le Q_\varepsilon(s) \int_{U_s} f \, \mathrm{d}V.$$

Choose s so that $Q_\varepsilon(s) < (1-\varepsilon)^n b_h(f)$. The set U_s is open and nonempty, and $f \ge c > 0$ almost everywhere, so its $f\,\mathrm{d}V$ measure is positive. This contradiction proves $b_h(f) = 1$.

Finally take $r_K = K^{-1/(4n)}$. The outside bound in (14.99) gives $f \le CK^{1/2} < K$ almost everywhere on $X \setminus B_{r_K}$ for large K. Therefore

$$\int_{\{f>K\}} f\,\mathrm{d}V \le C(\log K)^{-n(\alpha+1)} + CK^{-1/(2n)} \le C'(\log K)^{-n(\alpha+1)}.$$

Apply (14.95) to $g = f\mathbf{1}_{\{f>K\}}$ to get (14.97). □

The potential has logarithmic modulus at x_0 and is not Hölder there. Its root-tail estimate follows from the capacity bound despite the failure of higher L^p integrability. The construction applies to each fixed background, including one with $\nu_-(h) = 0$.

14.33 Limits of exponential equations

In this section θ is an arbitrary smooth real $(1,1)$-form and μ a finite non-pluripolar measure. We consider solutions $u_\lambda \in \mathrm{PSH}(X,\theta)$ of

$$\mathrm{MA}_\theta(u_\lambda) = \mathrm{e}^{\lambda u_\lambda}\mu \qquad (\lambda > 0).$$

As $\lambda \downarrow 0$, one expects suitably normalized solutions to converge to a solution of $\mathrm{MA}_\theta(u) = c\mu$ with a scalar $c > 0$. For an L^p density with $p > 1$ and a Hermitian background, the continuous solutions satisfy $\lambda u_\lambda \to \log c$ uniformly (Proposition 10.6.1). For solutions in a fixed unbounded ordinary type, no such uniform convergence is possible: by Proposition 1.23.1, the L^∞ distance from λu_λ to every finite constant is infinite for each $\lambda > 0$. The limit must instead be formulated through normalized potentials and their measures. Write

$$v_\lambda = u_\lambda - \sup_X u_\lambda, \qquad c_\lambda = \mathrm{e}^{\lambda \sup_X u_\lambda},$$

so that $\mathrm{MA}_\theta(v_\lambda) = c_\lambda \mathrm{e}^{\lambda v_\lambda}\mu$. By Lemma 1.23.2, $\mathrm{e}^{\lambda v_\lambda} \to 1$ in $L^1(\mu)$ as $\lambda \downarrow 0$; hence, if $c_\lambda \to c < +\infty$, the right-hand sides converge in total variation to $c\mu$. If $\mu = f\,\mathrm{d}V$ with $f \in L^p$ for some $p > 1$, Lemma 1.23.2 gives an error linear in λ.

To identify the Monge–Ampère measure of an L^1 limit of the v_λ, one needs in addition a continuity theorem for the Monge–Ampère operator. For potentials of a fixed ordinary type, Corollary 14.8.1 identifies the limiting measure under a common barrier and a domination hypothesis. In a relative envelope class, Theorem 31.3.1 instead constructs a common lower envelope under positive lower mass: for a semipositive big θ and a reference satisfying (13.20), an L^1-convergent sequence in the class whose measures are dominated by one finite non-pluripolar measure converges in capacity, and its measures converge weakly. That argument, with its mass hypothesis, is developed in Chapter 31.

14.33.1 A positive limiting exponent

When the exponents converge to a positive limit, the factor $e^{\lambda u}$ makes the Monge–Ampère mass of deep sublevels uniformly small. If the potentials converge in capacity, the tail criterion of Theorem 7.4.1 then identifies the limit of their Monge–Ampère measures, and convergence of the right-hand sides identifies the equation.

Theorem 14.33.1 *Let θ be any smooth real $(1,1)$-form and μ a finite non-pluripolar measure. Suppose $f_j \geq 0$, $f_j \to f$ in $L^1(\mu)$, and $\lambda_j > 0$ with $\lambda_j \to \lambda > 0$. Let $u_j, u \in \mathrm{PSH}(X,\theta)$ be nonpositive, suppose $u_j \to u$ in capacity, and assume*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) = e^{\lambda_j u_j} f_j \, \mu.$$

Then $\mathrm{MA}_\theta^{\mathrm{ext}}(u)$ is finite and

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = e^{\lambda u} f \, \mu.$$

Moreover, $\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \rightharpoonup \mathrm{MA}_\theta^{\mathrm{ext}}(u)$ weakly, and the right-hand sides converge in total variation.

Proof Discarding finitely many indices, we may assume that $\lambda_j \geq \lambda/2$. The measures $\mathrm{MA}_\theta^{\mathrm{ext}}(u_j)$ have masses at most $\|f_j\|_{L^1(\mu)}$, which are uniformly bounded, and since $u_j \leq 0$, their deep sublevels satisfy

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j)(\{u_j < -T\}) \leq e^{-\lambda T/2} \|f_j\|_{L^1(\mu)}.$$

The tail criterion Theorem 7.4.1, which holds for an arbitrary smooth background by Theorem 7.6.1, therefore shows that $\mathrm{MA}_\theta^{\mathrm{ext}}(u)$ is finite and that $\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \rightharpoonup \mathrm{MA}_\theta^{\mathrm{ext}}(u)$.

It remains to identify this limit with $e^{\lambda u} f \, \mu$. By Lemma 1.8.8, $u_j \to u$ in μ-measure. Since $t \mapsto e^{\lambda t}$ is λ-Lipschitz for $t \leq 0$, the functions $e^{\lambda u_j}$, which are bounded by one, converge in μ-measure to $e^{\lambda u}$. The change of exponent is uniform for nonpositive arguments, because the mean value theorem gives

$$\sup_{t \leq 0} |e^{\lambda_j t} - e^{\lambda t}| \leq |\lambda_j - \lambda| \sup_{s \geq 0} s e^{-(\lambda/2)s} \longrightarrow 0.$$

Thus $e^{\lambda_j u_j} \to e^{\lambda u}$ in μ-measure, and hence in $f\mu$-measure, since the finite measure $f\mu$ is absolutely continuous with respect to μ. As these functions are bounded by one, the convergence also holds in $L^1(f\mu)$. Therefore

$$\int_X |e^{\lambda_j u_j} f_j - e^{\lambda u} f| \, d\mu \leq \|f_j - f\|_{L^1(\mu)} + \int_X |e^{\lambda_j u_j} - e^{\lambda u}| f \, d\mu \longrightarrow 0.$$

This proves the total-variation convergence of the right-hand sides, and comparing the two limits gives the equation for u. □

Additive normalizations of the potentials can be absorbed into the densities: translating each u_j by a constant multiplies f_j by an exponential factor, and the theorem applies as long as the modified densities still converge in $L^1(\mu)$. Convergence in capacity is a hypothesis; the theorem says nothing about sequences that converge only in L^1, and it does not keep the limit in a prescribed envelope class.

The proof also shows where the difficulty lies as $\lambda_j \downarrow 0$: the tail bound $e^{-\lambda_j T}\|f_j\|_{L^1(\mu)}$ no longer tends to zero uniformly in j as $T \to \infty$. A zero-exponent limit therefore needs another source of uniform tail control, such as the integrability condition of Corollary 7.4.1; a uniform bound on the total masses does not by itself control these tails.

14.34 Exponential equations for an individual density

We return to the Hermitian background h and a fixed nonzero density $0 \le f \in L^1(dV)$, and consider, for $\lambda > 0$, the exponential equation

$$\mathrm{MA}_h^{\mathrm{ext}}(u) = e^{\lambda u} f\, dV, \qquad u \in \mathrm{PSH}(X,h). \tag{14.100}$$

A *solution* is a function $u \in \mathrm{PSH}(X,h)$ satisfying (14.100), and an *exponential subsolution* at exponent λ is a function $s \in \mathrm{PSH}(X,h)$ with $\mathrm{MA}_h^{\mathrm{ext}}(s) \ge e^{\lambda s} f\, dV$. For the truncations $f_k = \min(f,k)$, Theorem 10.1.2 gives continuous solutions u_k of the truncated equations, and these decrease as k increases. Strict domination shows that every exponential subsolution is a common lower bound for the u_k. Hence, as soon as one subsolution exists, the decreasing limit is not identically $-\infty$, and Theorem 14.33.1 shows that it solves (14.100); it is the greatest subsolution. A positive threshold $b_h(f)$ provides exponential subsolutions for every exponent, and the normalized greatest solutions then recover $b_h(f)$ as $\lambda \downarrow 0$.

Theorem 14.34.1 *Fix $\lambda > 0$, and suppose that (14.100) has an exponential subsolution $s \in \mathrm{PSH}(X,h)$. For $k \ge 1$, let u_k be the continuous solution of*

$$\mathrm{MA}_h(u_k) = e^{\lambda u_k} f_k\, dV, \qquad f_k = \min(f,k),$$

given by Theorem 10.1.2. Then u_k decreases to a solution u_λ of (14.100), and $\mathrm{MA}_h^{\mathrm{ext}}(u_\lambda)$ has finite mass. Moreover, u_λ is the greatest exponential subsolution: every exponential subsolution v at exponent λ satisfies $v \le u_\lambda$. In particular, u_λ is the greatest solution of (14.100).

Proof Since $f_k \le f_{k+1}$, Lemma 10.4.2 gives $u_{k+1} \le u_k$.

We first show that every exponential subsolution v lies below each u_k. Let $t > 0$. On the set $\{u_k < v - t\}$,

$$\mathrm{MA}_h(u_k) = e^{\lambda u_k} f_k\, dV \le e^{-\lambda t} e^{\lambda v} f\, dV \le e^{-\lambda t} \mathrm{MA}_h^{\mathrm{ext}}(v-t).$$

Since u_k is bounded, $P_{h/2}(u_k) \geq \inf_X u_k$ is not identically $-\infty$, and $v - t \preceq u_k$. Strict domination, Theorem 14.1.1, therefore gives $u_k \geq v - t$. Letting $t \downarrow 0$ gives $u_k \geq v$.

In particular $s \leq u_k \leq u_1$ for every k, so the decreasing limit $u_\lambda \geq s$ is not identically $-\infty$ and belongs to $\mathrm{PSH}(X, h)$. By Lemma 1.8.9, $u_k \to u_\lambda$ in capacity. Choose a constant $A \geq \sup_X u_1$. The nonpositive functions $u_k - A$ satisfy

$$\mathrm{MA}_h^{\mathrm{ext}}(u_k - A) = \mathrm{e}^{\lambda(u_k - A)}\, \mathrm{e}^{\lambda A} f_k \, \mathrm{d}V,$$

and $\mathrm{e}^{\lambda A} f_k \to \mathrm{e}^{\lambda A} f$ in $L^1(\mathrm{d}V)$. Theorem 14.33.1, applied with $\mu = \mathrm{d}V$ and constant exponents, shows that $\mathrm{MA}_h^{\mathrm{ext}}(u_\lambda)$ is finite and that u_λ solves (14.100). Finally, every exponential subsolution lies below all u_k, hence below u_λ, which is itself a subsolution. □

Being the greatest subsolution, u_λ does not depend on the approximation used to construct it. The equation may have other, smaller solutions with different singularities. If $f \in L^p$ for some $p > 1$, the continuous solution of Theorem 10.1.2 is a subsolution and therefore lies below u_λ. Thus u_λ is bounded, and bounded exponential comparison (Corollary 10.2.2) shows that it coincides with the continuous solution.

Corollary 14.34.1 *Suppose $b = b_h(f) > 0$. Then (14.100) has a greatest solution u_λ for every $\lambda > 0$. If $v \in \mathrm{PSH}(X, h)$ satisfies $\sup_X v = 0$ and $\mathrm{MA}_h^{\mathrm{ext}}(v) \geq b f \, \mathrm{d}V$, then*

$$u_\lambda \geq v + \lambda^{-1} \log b.$$

Put

$$M_\lambda = \sup_X u_\lambda, \qquad v_\lambda = u_\lambda - M_\lambda, \qquad c_\lambda = \mathrm{e}^{\lambda M_\lambda}.$$

Then, as $\lambda \downarrow 0$,

$$c_\lambda \longrightarrow b_h(f), \qquad \mathrm{e}^{\lambda u_\lambda} f \longrightarrow b_h(f) f \quad \text{in } L^1(\mathrm{d}V).$$

Proof By Theorem 14.27.1, a function v as in the statement exists. Since $v \leq 0$, the function $s = v + \lambda^{-1} \log b$ satisfies

$$\mathrm{MA}_h^{\mathrm{ext}}(s) \geq b f \, \mathrm{d}V \geq \mathrm{e}^{\lambda s} f \, \mathrm{d}V,$$

so it is an exponential subsolution. Theorem 14.34.1 gives the greatest solution u_λ and the bound $u_\lambda \geq s$; in particular, $c_\lambda \geq b$.

Set $g_\lambda = \mathrm{e}^{\lambda v_\lambda} f$. By Lemma 1.23.2, applied to the finite measure $f \, \mathrm{d}V$, we have $g_\lambda \to f$ in L^1 as $\lambda \downarrow 0$. Each g_λ is nonzero, since v_λ is finite almost everywhere. The equation for u_λ reads $\mathrm{MA}_h^{\mathrm{ext}}(v_\lambda) = c_\lambda g_\lambda \, \mathrm{d}V$, so Theorem 14.27.1, applied to the density g_λ, gives

$$c_\lambda \leq b_h(g_\lambda).$$

The upper semicontinuity of the threshold (Theorem 14.31.1) therefore gives

$$b \leq \liminf_{\lambda \downarrow 0} c_\lambda \leq \limsup_{\lambda \downarrow 0} c_\lambda \leq b_h(f) = b.$$

This proves $c_\lambda \to b$. Since $\mathrm{e}^{\lambda u_\lambda} f = c_\lambda g_\lambda$ and $g_\lambda \to f$ in L^1, it also proves $\mathrm{e}^{\lambda u_\lambda} f \to b f$ in L^1. □

Since $\mathrm{MA}_h^{\mathrm{ext}}(v_\lambda) = \mathrm{e}^{\lambda u_\lambda} f \, \mathrm{d}V$, the Monge–Ampère measures of the normalized greatest solutions converge in total variation to $b_h(f) f \, \mathrm{d}V$. This answers the questions about the scalar and the measure raised in Section 14.33; the potentials v_λ themselves are harder to control. Under positive lower mass, Corollary 31.7.1 shows that every L^1-convergent sequence v_{λ_j} with $\lambda_j \downarrow 0$ converges in capacity to a solution of $\mathrm{MA}_h^{\mathrm{ext}}(v) = b_h(f) f \, \mathrm{d}V$. For L^p data with $p > 1$, Proposition 14.19.1 gives uniform precompactness. In both cases, convergence of the whole family (v_λ) requires that all its cluster limits coincide. This holds when the dual problem for $f^{1/n}$ over Gauduchon currents, studied in Section 26.9, has a smooth strictly positive maximizer: the whole family then converges uniformly (Corollary 26.9.2). If the maximizer is smooth and semipositive, and strictly positive outside a proper analytic set, Proposition 26.9.5 gives L^1 convergence of the whole family and a fixed lower barrier, and Corollary 26.9.5 strengthens this to uniform convergence for L^p data with $p > 1$.

For a general positive threshold, the corollary gives the lower bound

$$v_\lambda \geq v - \lambda^{-1} \log(c_\lambda / b_h(f))$$

for every normalized threshold subsolution v. The next subsection estimates the scalar error $\log(c_\lambda / b_h(f))$ when $f^{1/n}$ can be approximated by bounded functions in the norm of $\mathcal{D}_h$. When $b_h(f) = 0$, Theorem 14.34.1 still applies whenever an exponential subsolution exists; examples are constructed in Section 14.34.2.

14.34.1 An error bound for the scalar limit

Suppose that $f^{1/n}$ belongs to the space $\mathcal{D}_h^0$ of Section 14.31.2. The uniform tail condition of Proposition 14.31.4 then gives a rate for the convergence $c_\lambda \to b_h(f)$ in Corollary 14.34.1. Split the root $p = f^{1/n}$ at a height K. On $\{p \leq K\}$, the error $p(1 - \mathrm{e}^{\lambda v/n})$ of the damped root has norm $O(K\lambda)$ in $\mathcal{D}_h$, uniformly over normalized potentials v, while on $\{p > K\}$ it is bounded by the tail of p, which is small in that norm. Optimizing over K gives a modulus valid for every normalized potential.

Proposition 14.34.1 *Let $0 \leq p \in \mathcal{D}_h^0$ be nonzero, and put $f = p^n$, $R = \rho_h(p)$ and $b = R^{-n} = b_h(f)$. There is a constant C_h, depending only on h and $\mathrm{d}V$, such that the function*

$$\eta_p(\lambda) = \inf_{K > 0} \left(\| p \mathbf{1}_{\{p > K\}} \|_{\mathcal{D}_h} + C_h K \lambda \right)$$

tends to zero as $\lambda \downarrow 0$ and satisfies

$$\left\| p(1 - \mathrm{e}^{\lambda v/n}) \right\|_{\mathcal{D}_h} \leq \eta_p(\lambda) \qquad \left(v \in \mathrm{PSH}(X, h), \ \sup_X v = 0 \right). \tag{14.101}$$

Let u_λ, v_λ and c_λ be the greatest exponential solutions and their normalizations from Corollary 14.34.1. If $\eta_p(\lambda) < R$, then

$$b \le c_\lambda \le \bigl(R - \eta_p(\lambda)\bigr)^{-n}$$

and

$$\bigl\|\mathrm{MA}_h^{\mathrm{ext}}(v_\lambda) - b f \,\mathrm{d}V\bigr\|_{\mathrm{TV}} \le (c_\lambda - b)\|p\|_{L^n}^n + nb\|p\|_{L^n}^{n-1}\eta_p(\lambda).$$

If $p \in L^r$ for some finite $r > n$, the same bounds hold with $\eta_p(\lambda)$ replaced by $C_{h,r}\|p\|_{L^r}\lambda$, where $C_{h,r}$ depends only on h, $\mathrm{d}V$ and r. In particular, for each such p the scalar and total-variation errors are $O(\lambda)$.

Proof By Lemma 1.5.1, normalized h-plurisubharmonic functions are uniformly bounded in every L^s with $s < +\infty$. By (14.93) with $r = 2n$, their norms $\|v\|_{\mathcal{D}_h}$ are therefore uniformly bounded; let C_h be $1/n$ times this bound. Let v be normalized and $K > 0$. On $\{p \le K\}$ we have

$$0 \le p(1 - \mathrm{e}^{\lambda v/n}) \le K\lambda(-v)/n,$$

since $1 - \mathrm{e}^{-x} \le x$ for $x \ge 0$, while on $\{p > K\}$ we use the bound $p(1 - \mathrm{e}^{\lambda v/n}) \le p$. The monotonicity of $\|\cdot\|_{\mathcal{D}_h}$ and the triangle inequality give

$$\bigl\|p(1 - \mathrm{e}^{\lambda v/n})\bigr\|_{\mathcal{D}_h} \le \|p\mathbf{1}_{\{p>K\}}\|_{\mathcal{D}_h} + C_h K\lambda,$$

and taking the infimum over K proves (14.101). By Proposition 14.31.4, and since the L^n tails of p tend to zero, $\|p\mathbf{1}_{\{p>K\}}\|_{\mathcal{D}_h} \to 0$ as $K \to \infty$. Choosing K first and then letting $\lambda \downarrow 0$ shows that $\eta_p(\lambda) \to 0$.

Now set $q_\lambda = p\,\mathrm{e}^{\lambda v_\lambda/n}$, so that $q_\lambda^n = g_\lambda = \mathrm{e}^{\lambda v_\lambda} f$, with g_λ as in the proof of Corollary 14.34.1. Since $0 \le q_\lambda \le p$ and $\rho_h(p - q_\lambda) \le \eta_p(\lambda)$ by (14.101), the triangle inequality and monotonicity give

$$R - \eta_p(\lambda) \le \rho_h(q_\lambda) \le R.$$

The same proof gives $b \le c_\lambda \le b_h(g_\lambda) = \rho_h(q_\lambda)^{-n}$, which yields the scalar bound. For the measures, the factorization of $p^n - q_\lambda^n$ gives $0 \le p^n - q_\lambda^n \le np^{n-1}(p - q_\lambda)$, and Hölder's inequality implies

$$\|f - g_\lambda\|_{L^1} \le n\|p\|_{L^n}^{n-1}\|p - q_\lambda\|_{L^n} \le n\|p\|_{L^n}^{n-1}\eta_p(\lambda).$$

Since $\mathrm{MA}_h^{\mathrm{ext}}(v_\lambda) = c_\lambda g_\lambda \,\mathrm{d}V$, the identity $c_\lambda g_\lambda - bf = (c_\lambda - b)g_\lambda - b(f - g_\lambda)$, together with $\|g_\lambda\|_{L^1} \le \|f\|_{L^1} = \|p\|_{L^n}^n$, proves the total-variation bound.

Finally, suppose $p \in L^r$ with $n < r < +\infty$, and choose $n < s < r$. By (14.93) with exponent s, and since $\|\cdot\|_{L^n} \le \|\cdot\|_{L^s}$, we have $\|\cdot\|_{\mathcal{D}_h} \le (1 + C_s)\|\cdot\|_{L^s}$. Hölder's inequality and Lemma 1.5.1 then give, for every normalized v,

$$\|p(-v)\|_{\mathcal{D}_h} \le (1 + C_s)\|p(-v)\|_{L^s} \le (1 + C_s)\|p\|_{L^r}\|v\|_{L^{rs/(r-s)}} \le nC_{h,r}\|p\|_{L^r}.$$

Since $0 \le 1 - \mathrm{e}^{\lambda v/n} \le \lambda(-v)/n$, the left side of (14.101) is therefore at most $C_{h,r}\|p\|_{L^r}\lambda$, and the two estimates above can be repeated with this bound in place of $\eta_p(\lambda)$. For λ so small that $C_{h,r}\|p\|_{L^r}\lambda \le R/2$, the function $t \mapsto (R-t)^{-n}$ has bounded derivative on $[0, R/2]$, so the scalar error $c_\lambda - b$, and hence the total-variation error, is $O(\lambda)$. □

For a general $p \in \mathcal{D}_h^0$ the modulus $\eta_p(\lambda)$ tends to zero, but we do not know whether it is $O(\lambda)$. Combined with the lower bound $v_\lambda \ge v - \lambda^{-1}\log(c_\lambda/b)$ for normalized threshold subsolutions v, the proposition gives

$$0 \le \lambda^{-1}\log(c_\lambda/b) \le -\frac{n}{\lambda}\log\bigl(1 - \eta_p(\lambda)/R\bigr),$$

which stays bounded as $\lambda \downarrow 0$ when $\eta_p(\lambda) = O(\lambda)$, in particular for $p \in L^r$ with $r > n$; root tails alone do not give such a bound. Even when a uniform lower barrier for v_λ is available, passing to the limit in capacity requires the singularity-type or lower-mass hypotheses of a continuity theorem. The proposition estimates only scalars and measures; when the lower mass vanishes, it does not give an exact equation at the threshold.

14.34.2 Exponential equations at zero threshold

When $b_h(f) = 0$, no positive multiple of $f\,\mathrm{d}V$ is dominated by a Monge–Ampère measure. An exponential subsolution s only needs $\mathrm{MA}_h^{\mathrm{ext}}(s) \ge \mathrm{e}^{\lambda s} f\,\mathrm{d}V$, however, and the factor $\mathrm{e}^{\lambda s}$ is small where s is very negative. A density concentrating near the pole of a singular potential can therefore admit exponential subsolutions although its threshold vanishes. We construct such densities on the products of Section 14.29.

We keep the notation of that section: $X = X_0 \times Y$ with $Y = \mathbb{P}^k$, the background $H = h_0 + \kappa$, the constants N, C and V_0, the probability volume form $\mu = V_0^{-1} h_0^m \wedge \kappa^k$ with density $R = \mu/\mathrm{d}V$, and the potential u_α with density q_α from Lemma 14.29.1, for a fixed $0 < \alpha < 1$. On $Y \setminus \{o\}$ put $L = 1 - \psi \ge 1$, so that $u_\alpha = 1 - L^\alpha$, and $t = \mathrm{e}^{1-L}$. As functions of L, define

$$a = \alpha L^{\alpha-1}, \qquad Q = t + (1-t)a, \qquad D = t(1-a) + (1-t)\alpha(1-\alpha)L^{\alpha-2},$$

$$W = kQ^{k-1}D, \qquad B_\tau = q_\alpha \mathrm{e}^{\tau(L^\alpha - 1)} \quad (\tau > 0), \qquad b_0 = (1-\alpha)^k.$$

Here Q is the function $Q(r)$ of Lemma 14.29.1, written in terms of L, and $D = -\mathrm{d}Q/\mathrm{d}L$. The weight B_τ is chosen so that $\mathrm{e}^{\tau u_\alpha} B_\tau = q_\alpha$ off o.

Lemma 14.34.1 *As functions of L,*

$$q_\alpha = Q^{k-1} D\, \mathrm{e}^{k(L-1)}, \qquad q_\alpha \ge b_0,$$

and $W(L) \sim k\alpha^k(1-\alpha)L^{-1-k(1-\alpha)}$ *as* $L \to +\infty$. *For every* $\tau > 0$, $\mathrm{e}^{\tau(L^\alpha-1)}W(L) \to +\infty$ *as* $L \to +\infty$. *In particular,* $B_\tau\kappa^k$ *has infinite mass on every punctured neighborhood of* o.

Proof In the notation of the proof of Lemma 14.29.1, $t = r/(1+r)$ and $s(r) = L$. Since the mass of $q_\alpha\kappa^k$ on $\{r_1 < r < r_2\}$ is $Q(r_2)^k - Q(r_1)^k$, this measure has radial distribution $-\mathrm{d}(Q^k)/\mathrm{d}L = W(L)\,\mathrm{d}L$. The Fubini–Study measure κ^k corresponds to $Q = t$, so its radial distribution is $k\mathrm{e}^{-k(L-1)}\mathrm{d}L$. Both measures are invariant under the unitary group of the chart, so q_α is the ratio of the two distributions, which is the stated formula. The lower bound $q_\alpha \geq b_0$ follows from $\kappa + \mathrm{dd^c}u_\alpha \geq (1-\alpha)\kappa$ off o. As $L \to +\infty$, t tends to zero exponentially, so $Q \sim \alpha L^{\alpha-1}$ and $D \sim \alpha(1-\alpha)L^{\alpha-2}$; this gives the asymptotics of W. Consequently,

$$\log\bigl(\mathrm{e}^{\tau(L^\alpha-1)}W(L)\bigr) = \tau L^\alpha - [1+k(1-\alpha)]\log L + O(1) \longrightarrow +\infty,$$

and the mass of $B_\tau\kappa^k$ on $\{L > T\}$, which equals $\int_T^\infty \mathrm{e}^{\tau(L^\alpha-1)}W(L)\,\mathrm{d}L$, is infinite for every T. □

Theorem 14.34.2 *Let* $f \geq 0$ *be a nonzero integrable function on* X, *and put* $F = f/R$.

(1) *If* $\lambda > 0$ *and* $F \leq AB_\lambda$ *almost everywhere for a constant* $A > 0$, *then*

$$s_\lambda = u_\alpha + \lambda^{-1}\log(CV_0/A)$$

is an exponential subsolution at exponent λ, *of mass* CV_0, *and the equation* $\mathrm{MA}_H^{\mathrm{ext}}(u) = \mathrm{e}^{\lambda u} f\,\mathrm{d}V$ *has a greatest solution, whose mass is finite and positive.*

(2) *Suppose that* F *is locally essentially bounded on* $X \setminus (X_0 \times \{o\})$ *and*

$$\lim_{T\to+\infty} \operatorname*{ess\,sup}_{x\in X_0,\ L(y)>T} \frac{\log^+(F(x,y)/q_\alpha(y))}{L(y)^\alpha} = 0,$$

where $\log^+ r = \log\max(1,r)$ *for* $r \geq 0$. *Then the hypothesis of (1), and hence its conclusion, holds for every* $\lambda > 0$.

Proof (1) By Theorem 14.29.1, $\mathrm{MA}_H^{\mathrm{ext}}(u_\alpha) = CV_0 q_\alpha \mu$. Off the pole fiber $X_0 \times \{o\}$ we have $\mathrm{e}^{\lambda u_\alpha}B_\lambda = q_\alpha$ and $f\,\mathrm{d}V = F\mu \leq AB_\lambda\mu$, hence

$$\mathrm{e}^{\lambda s_\lambda} f\,\mathrm{d}V \leq (CV_0/A)\mathrm{e}^{\lambda u_\alpha}AB_\lambda\mu = CV_0 q_\alpha\mu = \mathrm{MA}_H^{\mathrm{ext}}(s_\lambda),$$

and both measures vanish on the pole fiber. Thus s_λ is an exponential subsolution, and its mass is CV_0, since adding a constant does not change the Monge–Ampère measure. Theorem 14.34.1 now gives the greatest solution u and the finiteness of its mass. The mass $\int_X \mathrm{e}^{\lambda u} f\,\mathrm{d}V$ is positive because u is finite almost everywhere and f has positive integral.

(2) Fix $\lambda > 0$. By hypothesis, there is T such that $F/q_\alpha \leq \mathrm{e}^{(\lambda/2)L^\alpha}$ almost everywhere on $\{L > T\}$. Since $\mathrm{e}^{(\lambda/2)L^\alpha} \leq \mathrm{e}^\lambda \mathrm{e}^{\lambda(L^\alpha-1)}$ for $L \geq 1$, we have $F \leq \mathrm{e}^\lambda B_\lambda$ there. On the complement $\{L \leq T\}$, which is compact and disjoint from the pole fiber, F is essentially bounded, while $B_\lambda \geq q_\alpha \geq b_0 > 0$. Increasing the constant, we obtain $F \leq AB_\lambda$ almost everywhere on X. □

Theorem 14.34.3 *Let F_j, $j \geq 1$, be smooth strictly positive probability densities on X_0 with respect to $\mathrm{d}V_0 = V_0^{-1} h_0^m$, whose normalization scalars on X_0, relative to h_0 and $\mathrm{d}V_0$, satisfy $c_{h_0}(F_j) \leq 2^{-2j}/C$. There are smooth strictly positive probability densities g_j on Y with respect to κ^k such that the probability densities*

$$f_j = RF_j g_j, \qquad f = \sum_{j \geq 1} 2^{-j} f_j$$

on X satisfy $c_H(f_j) \leq 2^{-2j}$ and $b_H(f) = 0$. The function f is finite everywhere, smooth off the pole fiber $X_0 \times \{o\}$, has integral one and is bounded below by a positive constant. For every $\lambda > 0$, the equation $\mathrm{MA}_H^{\mathrm{ext}}(u) = \mathrm{e}^{\lambda u} f \, \mathrm{d}V$ has an exponential subsolution and a greatest solution, of finite mass, and every solution is unbounded.

Proof Put $w_j = 2^{-j}$ and $M_j = \max_{X_0} F_j$.

Step 1: a smooth baseline. Fix C^j norms $\| \cdot \|_{C^j}$ on X_0, computed in a fixed finite atlas, so that they increase with j. Choose $0 < \varepsilon_j \leq 1/2$ with

$$w_j \varepsilon_j M_j \leq b_0 2^{-j-2}, \qquad w_j \varepsilon_j \| F_j \|_{C^j} \leq 2^{-j}.$$

Then $E = \sum_j w_j \varepsilon_j F_j$ converges in every C^l norm, so E is smooth on X_0, and $0 < E \leq b_0/4$.

Step 2: bumps escaping to the pole. Choose a smooth function $\chi : \mathbb{R} \to [0,1]$, supported in $[0,1]$, positive on $(0,1)$ and flat at 0 and 1. Starting with $T_0 = 0$, choose inductively $T_j \geq 2$ with $T_j > T_{j-1} + 2$ and

$$Z_j = \int_{T_j}^{T_j+1} \chi(L - T_j) \mathrm{e}^{(L^\alpha - 1)/j} W(L) \, \mathrm{d}L \geq 2 w_j M_j.$$

This is possible because, by Lemma 14.34.1 with $\tau = 1/j$, the factor $\mathrm{e}^{(L^\alpha - 1)/j} W(L)$ is uniformly large on sufficiently distant intervals. On the annulus $\{T_j \leq L \leq T_j + 1\}$ put $\beta_j = \chi(L - T_j) B_{1/j} / Z_j$, extend β_j by zero, and set $g_j = \varepsilon_j + (1 - \varepsilon_j)\beta_j$. Since χ is flat at the endpoints, β_j is smooth; it vanishes near o and near the hyperplane $\{L = 1\}$. Its integral against κ^k is one, so g_j is a smooth strictly positive probability density with respect to κ^k. Moreover,

$$w_j M_j (1 - \varepsilon_j) \beta_j \leq B_{1/j}/2.$$

Step 3: the scalars $c_H(f_j)$. By Theorem 9.1.1 on Y, there is a smooth ϕ_j with $\kappa + \mathrm{dd^c} \phi_j > 0$ and $(\kappa + \mathrm{dd^c} \phi_j)^k = g_j \kappa^k$; the scalar is one because both sides have mass one. On X_0, the same theorem gives a smooth v_j with $h_0 + \mathrm{dd^c} v_j > 0$ and $(h_0 + \mathrm{dd^c} v_j)^m = c_{h_0}(F_j) F_j \, \mathrm{d}V_0$. Since only one term of the binomial expansion survives for dimensional reasons,

$$(H + \mathrm{dd^c}(v_j + \phi_j))^N = C c_{h_0}(F_j) F_j g_j \mu = C c_{h_0}(F_j) f_j \, \mathrm{d}V.$$

Uniqueness of the scalar gives $c_H(f_j) = C c_{h_0}(F_j) \leq 2^{-2j}$.

Step 4: properties of f. By Tonelli's theorem, $\int_X f\,\mathrm{d}V = \sum_j w_j = 1$. The density of $f\,\mathrm{d}V$ with respect to μ is

$$F = f/R = \sum_j w_j F_j g_j = E + \sum_j w_j(1-\varepsilon_j)F_j\beta_j.$$

The annuli are disjoint and escape to the pole, so only finitely many bumps meet any compact subset of $Y \setminus \{o\}$; hence F, and therefore f, is smooth off the pole fiber. On the pole fiber all bumps vanish and $F = E$, so f is finite everywhere. Also $f \geq w_1 f_1 \geq \frac{1}{2}\min_X f_1 > 0$. If $\mathrm{MA}_H^{\mathrm{ext}}(u) \geq af\,\mathrm{d}V$ with $a > 0$, then $\mathrm{MA}_H^{\mathrm{ext}}(u) \geq aw_j f_j\,\mathrm{d}V$, and Lemma 14.26.1 gives

$$aw_j \leq c_H(f_j) \leq 2^{-2j}, \quad \text{that is,} \quad a \leq 2^{-j}, \quad \text{for every } j.$$

This is impossible, so $b_H(f) = 0$ by Theorem 14.27.1.

Step 5: exponential subsolutions. Fix $\lambda > 0$, and choose J with $1/j \leq \lambda$ for $j \geq J$. Since $L^\alpha - 1 \geq 0$, we have $B_{1/j} \leq B_\lambda$ for these j. As the bumps have disjoint supports, Step 2 bounds their total contribution $\sum_{j\geq J} w_j(1-\varepsilon_j)F_j\beta_j$ by $B_\lambda/2$. The baseline satisfies $E \leq b_0/4 \leq B_\lambda/4$, because $B_\lambda \geq q_\alpha \geq b_0$. The remaining finitely many bumps are bounded by the constant

$$K_\lambda = \max_Y \sum_{j<J} w_j(1-\varepsilon_j)M_j\beta_j,$$

and $K_\lambda \leq (K_\lambda/b_0)B_\lambda$. Hence $F \leq A_\lambda B_\lambda$ with $A_\lambda = 3/4 + K_\lambda/b_0$, and Theorem 14.34.2 gives the exponential subsolution $u_\alpha + \lambda^{-1}\log(CV_0/A_\lambda)$ and the greatest solution. Finally, a bounded solution u would satisfy $\mathrm{MA}_H^{\mathrm{ext}}(u) \geq \mathrm{e}^{\lambda \inf_X u} f\,\mathrm{d}V$, a positive scaled subsolution, contradicting $b_H(f) = 0$. Hence every solution is unbounded. □

The density just constructed also satisfies the criterion in part (2) of Theorem 14.34.2: on the jth annulus, $F/q_\alpha \leq 1/4 + \frac{1}{2}\mathrm{e}^{(L^\alpha-1)/j}$, and away from all annuli the ratio is at most $1/4$. Approaching the pole through the annuli forces $j \to \infty$, so the required limit is zero. Since $b_H(f) = 0$, Proposition 14.27.2 also shows that f belongs to no L^p with $p > 1$.

Densities F_j as in the theorem exist whenever $v_-(h_0) = 0$, by Theorems 26.1.1 and 26.14.1. For instance, on the elliptic threefold, Theorem 26.18.1 gives smooth functions v_ℓ with $h_0 + \mathrm{dd}^{\mathrm{c}} v_\ell > 0$ and masses $\delta_\ell = \int_{X_0}(h_0 + \mathrm{dd}^{\mathrm{c}} v_\ell)^3 \to 0$. The probability densities $F_\ell = (h_0 + \mathrm{dd}^{\mathrm{c}} v_\ell)^3/(\delta_\ell\,\mathrm{d}V_0)$ satisfy $c_{h_0}(F_\ell) = \delta_\ell$ by uniqueness of the scalar, and a subsequence with $\delta_{\ell_j} \leq 2^{-2j}/C$ gives the required densities. Thus the construction applies to this threefold times $\mathbb{P}^k$ for every $k \geq 1$. With the balanced metric of Proposition 26.18.1, $V_0 = 24\pi$, so the explicit subsolutions have mass CV_0, equal to 96π on the fourfold ($k = 1$) and 240π on the fivefold ($k = 2$). These values concern the subsolutions; the greatest solutions have their own finite positive masses.

In this construction the projective components g_j are chosen after the densities F_j, to fit them. We do not know whether the exponential equation is solvable for every

prescribed concentration family of this kind, and we have no necessary criterion for solvability at zero threshold.

14.34.3 Solvable exponents and collapse at zero threshold

We return to a general Hermitian form h on X and a nonzero density $0 \le f \in L^1(\mathrm{d}V)$. Let $\Lambda_h(f)$ be the set of exponents $\lambda > 0$ for which (14.100) has a solution. By Theorem 14.34.1, $\lambda \in \Lambda_h(f)$ if and only if the equation has an exponential subsolution at exponent λ.

Proposition 14.34.2 *If $\lambda_0 \in \Lambda_h(f)$, then $[\lambda_0, +\infty) \subset \Lambda_h(f)$. Consequently, $\Lambda_h(f)$ is empty, or equals $(a, +\infty)$ for some $a \ge 0$, or equals $[a, +\infty)$ for some $a > 0$. If $b_h(f) > 0$, then $\Lambda_h(f) = (0, +\infty)$.*

Proof Let u be a solution at λ_0, and put $s = u - \max(0, \sup_X u)$. Then $s \le \min(u, 0)$, so for $\lambda \ge \lambda_0$,

$$\begin{aligned} \mathrm{MA}_h^{\mathrm{ext}}(s) &= \mathrm{e}^{\lambda_0 u} f \, \mathrm{d}V \\ &\ge \mathrm{e}^{\lambda_0 s} f \, \mathrm{d}V \ge \mathrm{e}^{\lambda s} f \, \mathrm{d}V. \end{aligned}$$

Thus s is an exponential subsolution at every $\lambda \ge \lambda_0$, and Theorem 14.34.1 gives a solution. Hence $\Lambda_h(f)$ contains $[\lambda_0, +\infty)$ together with each of its points λ_0. A nonempty subset of $(0, +\infty)$ with this property is determined by its infimum a and by whether a belongs to it, which gives the stated forms. If $b_h(f) > 0$, Corollary 14.34.1 gives $\Lambda_h(f) = (0, +\infty)$. □

Proposition 14.34.3 *Suppose $b_h(f) = 0$. Let $\lambda_j > 0$ decrease to zero, and let u_j be any solution of (14.100) at exponent λ_j. Put*

$$M_j = \sup_X u_j, \qquad v_j = u_j - M_j, \qquad c_j = \mathrm{e}^{\lambda_j M_j}.$$

Then

$$\begin{aligned} c_j &\longrightarrow 0, \qquad \lambda_j M_j \longrightarrow -\infty, \\ \|\mathrm{MA}_h^{\mathrm{ext}}(u_j)\|_{\mathrm{TV}} &= \|\mathrm{MA}_h^{\mathrm{ext}}(v_j)\|_{\mathrm{TV}} \longrightarrow 0. \end{aligned}$$

Moreover, $\mathrm{e}^{\lambda_j u_j} \to 0$ uniformly on X, where the exponential is zero on the pole set, and $u_j \to -\infty$ uniformly, that is, $\sup_X u_j \to -\infty$.

Proof Set $g_j = \mathrm{e}^{\lambda_j v_j} f$. By Lemma 1.23.2, applied to the finite non-pluripolar measure $f \, \mathrm{d}V$, $g_j \to f$ in L^1; each g_j is nonzero, since v_j is finite almost everywhere. Since the Monge–Ampère measure is unchanged by adding constants,

$$\mathrm{MA}_h^{\mathrm{ext}}(v_j) = c_j g_j \, \mathrm{d}V, \qquad \text{hence} \qquad 0 < c_j \le b_h(g_j)$$

by Theorem 14.27.1. The upper semicontinuity of the threshold, Theorem 14.31.1, gives $\limsup_j c_j \le b_h(f) = 0$. Since $0 \le g_j \le f$, the total masses are at most $c_j \|f\|_{L^1}$ and tend to zero. Moreover $\lambda_j M_j = \log c_j \to -\infty$, and $0 \le e^{\lambda_j u_j} \le e^{\lambda_j M_j} = c_j$. Finally, once $\lambda_j < 1$ and $\log c_j < 0$, we have $M_j = \lambda_j^{-1} \log c_j \le \log c_j$, so $M_j \to -\infty$. □

For the density of Theorem 14.34.3, solutions exist for every positive exponent, so the collapse applies as $\lambda \downarrow 0$ to every choice of solutions, in particular to the greatest ones. By contrast, the subsolutions of Theorem 14.34.2 keep the mass CV_0 for every exponent, while the masses of the solutions above them tend to zero: on a nonclosed background, the order of two potentials does not give an order of their total Monge–Ampère masses. Whether the normalized potentials converge in capacity, and which equation a normalized cluster limit satisfies at exponent zero, are not decided by this argument. Positive endpoints of $\Lambda_h(f)$ are governed instead by the compactness criterion below.

14.34.4 Positive endpoints and one-sided limits

For $\lambda \in \Lambda_h(f)$, write U_λ for the greatest solution given by Theorem 14.34.1. When the exponents stay above a fixed $\tau > 0$, the solution of a bounded truncated equation at exponent τ is a common upper barrier for all subsolutions. Together with the maximality of greatest solutions, this barrier gives an order estimate between U_{λ_1} and U_{λ_2}, which controls the positive endpoint of $\Lambda_h(f)$ and the limits of U_λ from the right.

Lemma 14.34.2 *For every $\tau > 0$, there is a nonnegative $t_\tau \in \mathrm{PSH}(X,h) \cap C(X)$ such that every exponential subsolution at an exponent $\lambda \ge \tau$ lies below t_τ. Put $K_\tau = \sup_X t_\tau$. If $\tau \le \lambda_1 \le \lambda_2$ belong to $\Lambda_h(f)$, then*

$$U_{\lambda_2} \ge U_{\lambda_1} - K_\tau \frac{\lambda_2 - \lambda_1}{\lambda_2}.$$

Consequently, $\lambda \mapsto U_\lambda + K_\tau \log(\lambda/\tau)$ is nondecreasing on $\Lambda_h(f) \cap [\tau, +\infty)$.

Proof Set $q = \min(f, 1)$, a nonzero bounded density. By Theorem 10.1.2, there is a continuous $w \in \mathrm{PSH}(X,h)$ with $\mathrm{MA}_h(w) = e^{\tau w} q\, dV$. Put $t_\tau = w + \max(0, -\inf_X w)$. Then $t_\tau \ge 0$ and $t_\tau \ge w$, so for $\lambda \ge \tau$,

$$\mathrm{MA}_h(t_\tau) = e^{\tau w} q\, dV \le e^{\lambda t_\tau} f\, dV.$$

Let u be an exponential subsolution at an exponent $\lambda \ge \tau$, and let $\epsilon > 0$. On $\{t_\tau < u - \epsilon\}$,

$$\mathrm{MA}_h(t_\tau) \le e^{\lambda(u-\epsilon)} f\, dV \le e^{-\lambda\epsilon} \mathrm{MA}_h^{\mathrm{ext}}(u - \epsilon).$$

The bounded function t_τ satisfies $P_{h/2}(t_\tau) \not\equiv -\infty$, and $u-\epsilon \preceq t_\tau$. Thus Theorem 14.1.1 gives $t_\tau \geq u-\epsilon$, and letting $\epsilon \downarrow 0$ gives $t_\tau \geq u$.

For the order estimate, put $\delta = K_\tau(\lambda_2-\lambda_1)/\lambda_2$. By the first part, $U_{\lambda_1} \leq t_\tau \leq K_\tau$, so $(\lambda_2-\lambda_1)U_{\lambda_1} \leq \lambda_2\delta$, that is, $\lambda_1 U_{\lambda_1} \geq \lambda_2(U_{\lambda_1}-\delta)$. Since the Monge–Ampère measure is unchanged by adding constants,

$$\begin{aligned} \mathrm{MA}_h^{\mathrm{ext}}(U_{\lambda_1}-\delta) &= \mathrm{e}^{\lambda_1 U_{\lambda_1}} f \,\mathrm{d}V \\ &\geq \mathrm{e}^{\lambda_2(U_{\lambda_1}-\delta)} f \,\mathrm{d}V. \end{aligned}$$

Thus $U_{\lambda_1}-\delta$ is an exponential subsolution at λ_2, and the maximality of U_{λ_2} gives $U_{\lambda_2} \geq U_{\lambda_1}-\delta$. Finally, $1-x^{-1} \leq \log x$ for $x \geq 1$; with $x = \lambda_2/\lambda_1$ this gives $\delta \leq K_\tau \log(\lambda_2/\lambda_1)$, which proves the monotonicity. □

Proposition 14.34.4 *Suppose $\Lambda_h(f) \neq \varnothing$ and $a = \inf \Lambda_h(f) > 0$. Then $a \in \Lambda_h(f)$ if and only if there are exponents $\lambda_j > a$ decreasing to a and solutions u_j at exponent λ_j with $\inf_j \sup_X u_j > -\infty$.*

If $a \notin \Lambda_h(f)$, then every sequence of solutions u_j at exponents $\lambda_j > a$ decreasing to a satisfies

$$\sup_X u_j \longrightarrow -\infty, \qquad \mathrm{e}^{\lambda_j u_j} \longrightarrow 0 \text{ uniformly on } X,$$
$$\|\mathrm{MA}_h^{\mathrm{ext}}(u_j)\|_{\mathrm{TV}} \longrightarrow 0,$$

where the exponential is zero on the pole sets.

Proof Suppose first that $a \in \Lambda_h(f)$, let u_a be a solution at a, and put $s = u_a - \max(0, \sup_X u_a)$. As in the proof of Proposition 14.34.2, s is an exponential subsolution at every $\lambda \geq a$, so $U_\lambda \geq s$. Hence the greatest solutions at any exponents $\lambda_j \downarrow a$ have suprema at least $\sup_X s > -\infty$.

Conversely, let λ_j and u_j be as in the statement. The lemma with $\tau = a$ gives the common upper bound $u_j \leq K_a$. Write $M_j = \sup_X u_j$. After extraction, $M_j \to M \in \mathbb{R}$ and, by Theorem 1.4.1, $u_j - M_j \to v$ in L^1 for some $v \in \mathrm{PSH}(X,h)$. Then $u_j \to u = v + M$ in L^1 and, after a further extraction, almost everywhere. Since $a \leq \lambda_j \leq \lambda_1$, $u_j \leq K_a$ and $K_a \geq 0$, the densities $\mathrm{e}^{\lambda_j u_j} f$ are bounded by $\mathrm{e}^{\lambda_1 K_a} f$, and dominated convergence gives

$$\mathrm{e}^{\lambda_j u_j} f \longrightarrow \mathrm{e}^{au} f \quad \text{in } L^1(\mathrm{d}V).$$

Lemma 14.27.1 now gives $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq \mathrm{e}^{au} f \,\mathrm{d}V$. Thus u is an exponential subsolution at a, and Theorem 14.34.1 gives a solution at a.

Finally, suppose $a \notin \Lambda_h(f)$, and let u_j be solutions at exponents $\lambda_j \downarrow a$. If $\sup_X u_j$ did not tend to $-\infty$, a subsequence would satisfy the condition just shown to imply $a \in \Lambda_h(f)$. Hence $M_j \to -\infty$. Once $M_j < 0$, since $\lambda_j \geq a > 0$,

$$0 \leq \mathrm{e}^{\lambda_j u_j} \leq \mathrm{e}^{\lambda_j M_j} \leq \mathrm{e}^{aM_j} \longrightarrow 0,$$

and the total mass $\int_X \mathrm{e}^{\lambda_j u_j} f \,\mathrm{d}V$ is at most $\mathrm{e}^{aM_j}\|f\|_{L^1}$. □

Proposition 14.34.5 *For every $a \in \Lambda_h(f)$, the greatest solutions satisfy*

$$U_\lambda \longrightarrow U_a \quad \text{in } L^1 \text{ and in capacity} \quad (\lambda \downarrow a),$$

and their Monge–Ampère measures converge in total variation to $\mathrm{e}^{aU_a} f \, \mathrm{d}V$.

Proof Let $K = K_a$ be the constant of the lemma with $\tau = a$, and let $\lambda_j > a$ decrease to a. By the lemma, the functions

$$V_j = U_{\lambda_j} + K \log(\lambda_j / a)$$

decrease and satisfy $V_j \geq U_a$. Their limit V therefore belongs to $\mathrm{PSH}(X, h)$ and satisfies $V \geq U_a$. Dominated convergence between the integrable bounds U_a and V_1 gives $V_j \to V$ in L^1, and Lemma 1.8.9 gives convergence in capacity. Since the added constants tend to zero, $U_{\lambda_j} \to V$ in both senses.

The nonpositive functions $U_{\lambda_j} - K$ satisfy

$$\mathrm{MA}_h^{\mathrm{ext}}(U_{\lambda_j} - K) = \mathrm{e}^{\lambda_j (U_{\lambda_j} - K)} \, \mathrm{e}^{\lambda_j K} f \, \mathrm{d}V,$$

and $\mathrm{e}^{\lambda_j K} f \to \mathrm{e}^{aK} f$ in L^1. Theorem 14.33.1 therefore gives $\mathrm{MA}_h^{\mathrm{ext}}(V) = \mathrm{e}^{aV} f \, \mathrm{d}V$, together with total-variation convergence of the measures $\mathrm{MA}_h^{\mathrm{ext}}(U_{\lambda_j})$. Hence V is a solution at a, so $V \leq U_a$ by maximality, while $V \geq U_a$ by construction. Thus $V = U_a$. Since every sequence of exponents converging to a from above has a decreasing subsequence, this proves the assertions. □

The corrected order also controls approach from the left. The limit solves the equation at the limiting exponent; maximality gives an inequality with the greatest solution there, but does not force equality.

Proposition 14.34.6 *Suppose $\Lambda_h(f) \neq \varnothing$, and put $a_0 = \inf \Lambda_h(f)$. For every $a > a_0$, there is $L_a \in \mathrm{PSH}(X, h)$ such that*

$$U_\lambda \longrightarrow L_a \quad \text{in } L^1 \text{ and in capacity} \quad (\lambda \uparrow a).$$

It satisfies

$$L_a \leq U_a, \qquad \mathrm{MA}_h^{\mathrm{ext}}(L_a) = \mathrm{e}^{aL_a} f \, \mathrm{d}V.$$

The equation measures converge in total variation to this finite measure. The left limit is independent of the auxiliary exponent and of the cofinal sequence used to construct it.

Proof Choose $\tau \in \Lambda_h(f)$ with $0 < \tau < a$; the upper-interval property gives such a choice. Put $K = K_\tau$ from Lemma 14.34.2 and

$$V_\lambda = U_\lambda + K \log(\lambda / \tau) \qquad (\lambda \in \Lambda_h(f),\ \lambda \geq \tau).$$

This family is increasing. For a sequence $\lambda_j \uparrow a$ with $\tau \leq \lambda_j < a$, its members lie between the integrable potentials V_τ and V_a. The upper-envelope construction in Section 1.19 gives

$$V_a^- = \left(\sup_{\tau \le \lambda < a} V_\lambda \right)^* = \left(\lim_j V_{\lambda_j} \right)^* \in \mathrm{PSH}(X, h).$$

Indeed cofinality and the order give the same pointwise supremum for every such sequence. Regularization changes it only on a pluripolar set. Dominated convergence between the integrable bounds gives L^1 convergence to V_a^-, and Lemma 1.8.9 gives convergence in capacity. Since the added constants converge, set

$$L_a = V_a^- - K \log(a/\tau).$$

Then $U_{\lambda_j} \to L_a$ in both topologies and $L_a \le U_a$; the latter inequality survives regularization because V_a is upper semicontinuous.

The potentials $U_{\lambda_j} - K$ and their limit $L_a - K$ are nonpositive. Apply Theorem 14.33.1 with exponents tending to $a > 0$ and densities $\mathrm{e}^{\lambda_j K} f \to \mathrm{e}^{aK} f$ in L^1. It proves the exact equation and total-variation convergence.

Every sequence approaching a from the left has a cofinal increasing subsequence. If potential convergence in either topology, or total-variation convergence of the equation measures, failed, a sequence staying outside a fixed neighbourhood of the proposed limit would therefore have an increasing subsequence, contrary to the preceding argument. This proves the full left limit and measure convergence. Repeating the construction with another τ gives the same L^1 limit; canonical quasi-plurisubharmonic representatives that agree almost everywhere agree everywhere. Thus the auxiliary choice does not change L_a. □

Proposition 14.34.7 *Suppose $\Lambda_h(f) \neq \varnothing$, put $a_0 = \inf \Lambda_h(f)$, and let L_a be the left limit of Proposition 14.34.6. The set*

$$D = \{a > a_0 : L_a \neq U_a\}$$

is at most countable. At every $a > a_0$ with $a \notin D$, the greatest solutions are continuous in L^1 and in capacity as $\lambda \to a$, and their equation measures converge in total variation to $\mathrm{e}^{aU_a} f \, \mathrm{d}V$.

Proof Fix $a_0 < \alpha < \beta$, choose an admitted $0 < \tau < \alpha$, and use the corrected family V_λ from the preceding proof on $[\alpha, \beta]$. Its integrals

$$I(\lambda) = \int_X V_\lambda \, \mathrm{d}V$$

form a finite bounded increasing real function. For $a \in (\alpha, \beta]$, the left-limit proposition gives

$$I(a) - I(a-) = \int_X (U_a - L_a) \, \mathrm{d}V.$$

If $L_a \neq U_a$, this quantity is positive: the integrable nonnegative difference cannot vanish almost everywhere without equality of the canonical potentials. For any finite ordered collection of such points, the sum of their jumps is at most $I(\beta) - I(\alpha)$.

Consequently there are only finitely many jumps at least $1/m$ for each positive integer m, and at most countably many positive jumps. A countable cover by intervals with rational endpoints inside $(a_0, +\infty)$ proves the assertion about D.

If $a \notin D$, the left limit is U_a, and Proposition 14.34.5 supplies the same right limit in both topologies and for the equation measures. Splitting an arbitrary approaching sequence into its two sides proves the stated two-sided convergence. □

Whether an actual jump occurs, or all left limits equal the greatest solution, remains undecided. An intrinsic criterion on f and the existence or nonexistence of a positive excluded endpoint remain separate questions. These one-sided limits concern greatest solutions at positive exponents; they do not identify limits of arbitrary solutions with other singularities or supply a zero-exponent limit.

14.35 Radial selection for integrable densities

The scalar and measure limits in Corollary 14.34.1 do not by themselves determine a limit potential. For the sublogarithmic densities of Lemma 14.29.1, the radial flux supplies the missing information. It also distinguishes convergence after subtracting the supremum from convergence after subtracting $\lambda^{-1}\log b$, where b is the critical scalar: the latter depends on a first moment of the limiting measure.

Use the product $X = X_0 \times Y$, $Y = \mathbb{P}^k$, $H = h_0 + \kappa$, and the probability volume $\mu = V_0^{-1} h_0^m \wedge \kappa^k$ of Section 14.29, with $\dim X_0 = m$, $\nu_-(h_0) = 0$ and $k \geq 2$. Put $b = \binom{N}{m} V_0$, where $N = m + k$. For $0 < \alpha < 1$, let $U_{\lambda,\alpha}$ be the greatest solution of

$$\mathrm{MA}_H^{\mathrm{ext}}(U_{\lambda,\alpha}) = \mathrm{e}^{\lambda U_{\lambda,\alpha}} q_\alpha \mu, \qquad \lambda > 0.$$

The threshold of this forcing measure is $b > 0$, by Theorem 14.29.1, so the solutions exist by Corollary 14.34.1.

14.35.1 Separation and the radial flux

Lemma 14.35.1 *There is a κ-plurisubharmonic function $w_{\lambda,\alpha}$ on Y such that*

$$U_{\lambda,\alpha} = \lambda^{-1}\log b + w_{\lambda,\alpha}, \qquad w_{\lambda,\alpha} \geq u_\alpha, \qquad \mathrm{MA}_\kappa^{\mathrm{ext}}(w_{\lambda,\alpha}) = \mathrm{e}^{\lambda w_{\lambda,\alpha}} q_\alpha \kappa^k.$$

The last measure has mass one. On the affine chart centered at o, set $s = \log|z|^2$, $\rho(s) = \log(1 + \mathrm{e}^s)$ and $m(s) = \rho'(s)$. The function $w = w_{\lambda,\alpha}$ is radial and satisfies

$$\begin{aligned} Q_{\lambda,\alpha}(s) &= \int_{-\infty}^{s} \mathrm{e}^{\lambda w(r)} q_\alpha(r)\, \mathrm{d}(m(r)^k), \\ w'(s) &= Q_{\lambda,\alpha}(s)^{1/k} - m(s), \qquad Q_{\lambda,\alpha}(-\infty) = 0, \quad Q_{\lambda,\alpha}(+\infty) = 1. \end{aligned} \tag{14.102}$$

Proof Choose a smooth nondecreasing concave function χ on $[0,+\infty)$, equal to the identity on $[0,1]$ and constant on $[2,+\infty)$, and put $q_j = j\chi(q_\alpha/j)$. Concavity gives $q_j \uparrow q_\alpha$ and

$$\min(q_\alpha, j) \le q_j \le \min(q_\alpha, 2j).$$

The functions q_j are smooth and positive on Y: near o they are constant, and elsewhere the density is smooth. Let w_j be the continuous solution of $\mathrm{MA}_\kappa(w_j) = \mathrm{e}^{\lambda w_j} q_j \kappa^k$ from Theorem 10.1.2. It is the greatest subsolution by Theorem 14.34.1 and bounded uniqueness. Since $u_\alpha \le 0$ and $\mathrm{MA}_\kappa^{\mathrm{ext}}(u_\alpha) = q_\alpha \kappa^k$, it is a subsolution for every q_j, whence $u_\alpha \le w_j$. Density comparison gives $w_j \downarrow w$.

The pullback $W_j = \lambda^{-1}\log b + w_j$ is a bounded solution on X, by the product expansion in Theorem 14.29.1. For the smooth density $q_j\mu$ it is therefore also the greatest subsolution. Every subsolution for $q_\alpha\mu$ is a subsolution for $q_j\mu$, so $U_{\lambda,\alpha} \le W_j$.

Monotone convergence in capacity and Theorem 14.33.1 on Y identify the equation for $w \ge u_\alpha$. Moreover, Stokes gives $\int_Y \mathrm{e}^{\lambda w_j} q_j \kappa^k = 1$. The integrands are dominated by $\mathrm{e}^{\lambda \sup_Y w_1} q_\alpha$, so dominated convergence gives the same identity for w. Its pullback is a product solution, hence lies below the greatest solution on X. Together with $U_{\lambda,\alpha} \le \lim_j W_j$, this proves separation and all measure assertions.

Uniqueness makes each w_j invariant under the unitary action on the affine coordinates $z \in \mathbb{C}^k$, and the limit has the same invariance. A radial κ-plurisubharmonic function has a convex nondecreasing profile $\rho + w$. Symmetric convolution of this convex profile on compact s intervals, decreasing as the scale decreases, and bounded-product continuity give its radial measure $\mathrm{d}((\rho+w)'^k)$, as in Lemma 14.29.1. The bound $w \ge u_\alpha$, whose growth is $o(|s|)$ at $-\infty$, forces the initial derivative to vanish. The positive density makes the flux continuous and positive at finite s, yielding (14.102). Its final value is the mass one already proved. The profile is consequently smooth on finite s intervals. □

14.35.2 The normalized limit

Set

$$a_{\lambda,\alpha} = \sup_Y w_{\lambda,\alpha}, \qquad v_{\lambda,\alpha} = w_{\lambda,\alpha} - a_{\lambda,\alpha}, \qquad c_{\lambda,\alpha} = \mathrm{e}^{\lambda \sup_X U_{\lambda,\alpha}} = b\mathrm{e}^{\lambda a_{\lambda,\alpha}}.$$

In particular $a_{\lambda,\alpha} \ge 0$.

Theorem 14.35.1 *Let $\alpha_j \to \alpha \in (0,1)$ and $\lambda_j \to 0$ with $\lambda_j > 0$, at arbitrary relative rates. Then*

$$v_{\lambda_j,\alpha_j} \longrightarrow u_\alpha \quad \text{in } L^1(Y), \text{ in capacity, and locally uniformly on } Y \setminus \{o\}.$$

Their pullbacks converge in $L^1(X)$, in capacity on X, and locally uniformly off $X_0 \times \{o\}$. Furthermore $q_{\alpha_j} \to q_\alpha$ in $L^1(\kappa^k)$, $c_{\lambda_j,\alpha_j} \to b$, and the equation measures converge in total variation to $bq_\alpha\mu$. The limiting pullback has finite mass b and belongs to $\mathcal{E}_{\mathrm{env}}(X,H,0)$.

Proof Choose $[\alpha_-,\alpha_+] \Subset (0,1)$ containing all late parameters. The density formula in Lemma 14.29.1 gives, uniformly for δ in this interval and $t = -s$ large,

$$q_\delta(s) \le Ce^{kt}(1+t)^{-1-k(1-\alpha_+)}.$$

Away from o the densities are jointly smooth, including on the hyperplane at infinity. Thus one integrable density g dominates all q_δ, and dominated convergence gives $q_{\alpha_j} \to q_\alpha$ in L^1.

For every normalized κ-plurisubharmonic v, Theorem 1.4.1 gives $\int_Y (-v)\kappa^k \le C_k$. Absolute continuity of the integral of g therefore implies

$$\sup_{\sup_Y v=0} \int_{\{v<-T\}} g\kappa^k \longrightarrow 0 \quad (T \to \infty).$$

Taking $T = \lambda^{-1/2}$ shows that

$$\int_Y (1-e^{\lambda v}) q_\delta \kappa^k \le \lambda T + \int_{\{v<-T\}} g\kappa^k \longrightarrow 0$$

uniformly in δ and v. Write $v_j = v_{\lambda_j,\alpha_j}$ and $a_j = a_{\lambda_j,\alpha_j}$. The exact mass identity of the lemma is

$$1 = e^{\lambda_j a_j} \int_Y e^{\lambda_j v_j} q_{\alpha_j} \kappa^k. \tag{14.103}$$

It gives $e^{\lambda_j a_j} \to 1$, hence $\lambda_j a_j \to 0$. The actual densities $e^{\lambda_j a_j} e^{\lambda_j v_j} q_{\alpha_j}$ converge in L^1 to q_α and are bounded by $2g$ for all late j.

Their cumulative radial fluxes Q_j consequently converge uniformly to the flux Q_α of u_α. By (14.102), $v_j' \to u_\alpha'$ uniformly on compact s intervals. The normalized L^1 bound controls one value of each profile on a fixed annulus; thus every sequence has a subsequence converging uniformly on compact s intervals to $u_\alpha + d$ for some finite constant d.

Near infinity the common bound for the densities is smooth and bounded. Hence $1 - Q_j(s) \le Ce^{-s}$ and $|v_j'(s)| \le Ce^{-s}$ for large s. Integrating gives uniform convergence up to the hyperplane at infinity. At the other end, monotonicity of $\rho + v_j$ gives, for $s < s_0$,

$$v_j(s) \le v_j(s_0) + \rho(s_0).$$

Choose s_0 so negative that the right side is negative for all late members of the subsequence. The supremum zero is then attained outside this inner ball. Uniform convergence on its compact complement gives $\sup_Y(u_\alpha + d) = 0$, so $d = 0$. Normalized compactness identifies every L^1 cluster limit with u_α; this proves convergence of the entire family and its local uniform convergence off o.

For capacity convergence, fix $T > 0$. The sublevel $\{u_\alpha < -T\}$ is a neighborhood of o, and its complement is a compact set on which convergence is uniform. Its capacity is at most C/T by (1.15). Let $j \to \infty$ and then $T \to \infty$. The same argument on X uses the normalized pullback of u_α and proves convergence in Hermitian capacity there; comparison sets omit pole sets. Pullback also preserves the L^1 and local uniform limits. The product expansion proves total-variation convergence of the measures, and Theorem 14.29.1 supplies the exact limiting mass and envelope class. □

14.35.3 Scalar centering and its moment boundary

Proposition 14.35.1 *The first moment*

$$M_\alpha = \int_Y u_\alpha q_\alpha \kappa^k$$

is finite exactly when $\alpha < k/(k+1)$. In this range,

$$-M_\alpha = \alpha \int_1^\infty x^{\alpha-1}\left[\alpha x^{\alpha-1} + (1-\alpha x^{\alpha-1})\mathrm{e}^{1-x}\right]^k \,\mathrm{d}x. \tag{14.104}$$

For the joint limits of Theorem 14.35.1, if $\alpha < k/(k+1)$, then

$$a_{\lambda_j,\alpha_j} \to -M_\alpha, \qquad U_{\lambda_j,\alpha_j} - \lambda_j^{-1}\log b \to u_\alpha - M_\alpha$$

in L^1, in capacity, and locally uniformly away from the pole fiber. If $\alpha \geq k/(k+1)$, then $a_{\lambda_j,\alpha_j} \to +\infty$ and the latter translated potentials tend to $+\infty$ locally uniformly off the pole fiber, although $\lambda_j a_{\lambda_j,\alpha_j} \to 0$. In both cases the exact scalar error is

$$\lambda_j^{-1}\log(c_{\lambda_j,\alpha_j}/b) = a_{\lambda_j,\alpha_j}.$$

Proof As $t = -s \to \infty$, the radial profile of Lemma 14.29.1 satisfies

$$u_\alpha \sim -t^\alpha, \qquad Q'_\alpha(s) \sim k(1-\alpha)\alpha^k t^{-1-k(1-\alpha)}.$$

Thus the first moment is finite precisely when $(k+1)\alpha < k$. In that case, write $x = 1 - \psi$. Its cumulative flux is

$$Q_\alpha = \left[\alpha x^{\alpha-1} + (1-\alpha x^{\alpha-1})\mathrm{e}^{1-x}\right]^k.$$

Integration by parts gives (14.104); the pole boundary term vanishes since $(k+1)\alpha - k < 0$.

Suppose $\alpha < k/(k+1)$ and choose the parameter interval in the preceding proof with $\alpha_+ < k/(k+1)$. Its dominating density g satisfies $(-u_{\alpha_+})g \in L^1$. Write $w_j = w_{\lambda_j,\alpha_j} = v_j + a_j$. Since $w_j \geq u_{\alpha_j} \geq u_{\alpha_+}$, the mass identity and $\mathrm{e}^r \geq 1 + r$ give $\int_Y w_j q_{\alpha_j} \kappa^k \leq 0$. On a fixed annulus A away from o, the normalized smooth-volume L^1 bound gives

$$\int_A w_j q_{\alpha_j} \kappa^k \geq a_j \int_A q_{\alpha_j} \kappa^k - C.$$

On the complement, use $w_j \geq u_{\alpha_+}$ and the integrable lower bound. The annulus has uniformly positive measure, so $0 \leq a_j \leq C_*$. Along any subsequence with $a_j \to a$, local uniform convergence gives $w_j \to u_\alpha + a$ off o. In the exact identity

$$\int_Y \frac{\mathrm{e}^{\lambda_j w_j} - 1}{\lambda_j} q_{\alpha_j} \kappa^k = 0,$$

the negative part is dominated by $(-u_{\alpha_+})g$ and the positive part by $C_* \mathrm{e}^{C_*} g$. Dominated convergence gives $M_\alpha + a = 0$. Every subsequence therefore has the asserted scalar limit. Adding these convergent constants to the normalized potentials gives all three claimed topologies.

If $\alpha \geq k/(k+1)$, use instead

$$\int_Y \frac{1 - \mathrm{e}^{\lambda_j v_j}}{\lambda_j} q_{\alpha_j} \kappa^k = \frac{1 - \mathrm{e}^{-\lambda_j a_j}}{\lambda_j} \leq a_j.$$

The integrands are nonnegative and tend off o to $(-u_\alpha) q_\alpha$. Fatou's lemma forces $a_j \to +\infty$. The preceding theorem gives $\lambda_j a_j \to 0$; local uniform convergence of v_j gives the stated divergence of w_j. This includes sequences approaching the moment boundary from below. □

For the elliptic fivefold of Corollary 14.29.1, $b = 240\pi$ and the moment boundary is $\alpha = 2/3$. The choice $\alpha = 1/2$ has a finite centering constant. For $2/3 \leq \alpha < 1$, the supremum-normalized family still converges to the exact threshold solution, while its scalar-centered version diverges off the pole fiber. Thus convergence of the normalization scalars alone does not give a bounded first-order scalar error.

14.35.4 Order in the separated class

We use here the closed-class uniqueness theorem: on a compact connected Kähler manifold, two potentials whose non-pluripolar measures have full mass and are equal differ by a constant. This is an external input; its source is identified in Section 34.11.

Corollary 14.35.1 *Every separated threshold subsolution $r = r(y)$ with $r \in \mathrm{PSH}(Y,\kappa)$ and $\mathrm{MA}_H^{\mathrm{ext}}(r) \geq b q_\alpha \mu$ equals $u_\alpha + d$ for some constant d. In particular u_α is its unique supremum-zero member. If $\alpha < k/(k+1)$, then $u_\alpha - M_\alpha$ is the greatest such subsolution whose q_α-mean on Y is nonpositive.*

Proof The product formula reduces the inequality to $\mathrm{MA}_\kappa^{\mathrm{ext}}(r) \geq q_\alpha \kappa^k$. Closed Stokes gives each bounded truncation mass one, so the extended measure of r has mass at most one. The inequality therefore gives equality and full mass. Closed-class uniqueness yields $r = u_\alpha + d$. In the finite-moment range its mean is $M_\alpha + d$, which is nonpositive exactly when $d \leq -M_\alpha$. □

At and beyond the moment boundary every constant translate has mean $-\infty$, so that mean condition no longer chooses a greatest translate. The order assertion concerns separated potentials. Selection for arbitrary integrable densities and uniqueness of arbitrary critical potentials on the nonclosed product remain the questions of Problem 33.1.1 and Section 14.33.

Chapter 15
Normalization and weak adjoint measures

Let X be a connected compact complex manifold of dimension $n \geq 1$ with a smooth positive volume form $\mathrm{d}V$. Function spaces are real, and Lebesgue norms are taken with respect to $\mathrm{d}V$. Until Section 15.8, θ is a smooth semipositive big real $(1,1)$-form and $\varphi \in \mathrm{PSH}(X,\theta)$ is a model reference in the sense of (13.20): it is a fixed point of the ordinary singularity envelope $P_\theta[\cdot]$ of Definition 1.19.1, and its envelope $P_{\varepsilon\theta}(\varphi)$ in a smaller background is not identically $-\infty$ for some $0 < \varepsilon < 1$. We write $u \sim \varphi$ when u has the ordinary singularity type of φ (Definition 1.12.1), and $\mathrm{MA}_\theta^{\mathrm{ext}}$ for the extended non-pluripolar Monge–Ampère measure of Theorem 6.1.1; when its total mass is finite, it is the usual non-pluripolar measure, which we also denote by MA_θ.

In the ordinary type of φ, the equation $\mathrm{MA}_\theta^{\mathrm{ext}}(u) = c\,\mathrm{e}^F \mathrm{d}V$ determines the constant $c > 0$ uniquely, even when it has several normalized solutions. As a function of the logarithmic density F, the logarithm of this constant is concave. Its supporting functionals are probability measures that describe the first-order response of the constant to a change of density; for smooth Hermitian equations they are the Gauduchon adjoint probabilities of the linearized operator. The convex dual of the functional controls the concentration of these measures through entropy, and this gives compactness when the density, the reference or the positive background varies. The same measures provide the integral normalizations that single out the limit of the exponential equations as the exponent tends to zero. The scalar functional does not, however, determine the singularities of the solutions: examples with moving divisors have identical functionals but different limiting potentials. On closed projective backgrounds, convex geometry gives quantitative criteria for varying references, including references with nonanalytic poles or degenerate residuals.

15.1 The scalar functional

The domination principle makes the constant decrease as the density increases, and mixed Monge–Ampère products strengthen this monotonicity to concavity in

the logarithmic density. Compactness of the solutions then gives continuity under uniformly bounded L^1 perturbations.

For a bounded real measurable function F, part (2) of Theorem 14.11.1, applied to the bounded density e^F, gives $u \in \mathrm{PSH}(X,\theta)$ with $u \sim \varphi$ and a unique constant $c_\varphi(F) > 0$ such that

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = c_\varphi(F)\mathrm{e}^F \,\mathrm{d}V. \tag{15.1}$$

The *normalization scalar* is

$$B_\varphi(F) = \log c_\varphi(F).$$

Since the constant is unique, B_φ is well defined; it depends on φ only through its ordinary singularity type.

Proposition 15.1.1 *Let $F, G \in L^\infty(\mathrm{d}V)$ be real. The functional B_φ is decreasing, and for every constant $a \in \mathbb{R}$,*

$$B_\varphi(F + a) = B_\varphi(F) - a.$$

Consequently

$$-\operatorname*{ess\,sup}_X(G - F) \le B_\varphi(G) - B_\varphi(F) \le -\operatorname*{ess\,inf}_X(G - F), \tag{15.2}$$

and $|B_\varphi(G) - B_\varphi(F)| \le \|G - F\|_\infty$.

Proof Suppose that $F \le G$ almost everywhere and, to reach a contradiction, that $c_\varphi(F) < c_\varphi(G)$. Let $u, v \sim \varphi$ solve the two equations. Since $F \le G$ and the extended measure is unchanged by adding constants, for every constant a,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) \le \frac{c_\varphi(F)}{c_\varphi(G)}\mathrm{MA}_\theta^{\mathrm{ext}}(v + a),$$

and the ratio is strictly less than one. As $u \sim \varphi$, the envelope $P_{\varepsilon\theta}(u)$ dominates a translate of $P_{\varepsilon\theta}(\varphi)$ and is therefore not identically $-\infty$; moreover $v + a \preceq u$. The singular strict domination principle, Theorem 14.1.1, gives $u \ge v + a$ for every a, which is impossible at any point where both potentials are finite. Thus $B_\varphi(F) \ge B_\varphi(G)$.

Replacing F by $F + a$ and the constant by $\mathrm{e}^{-a}c_\varphi(F)$ leaves the right-hand side of (15.1) unchanged, so uniqueness of the constant proves the translation rule. Finally, G lies between the constant translates $F + \operatorname{ess\,inf}_X(G - F)$ and $F + \operatorname{ess\,sup}_X(G - F)$; monotonicity and the translation rule give (15.2). □

The scalar does not depend on the smooth representative of the background: for a smooth real h, replacing θ by $\theta + \mathrm{dd}^{\mathrm{c}}h$ and each potential u, including φ, by $u - h$ preserves the currents and the prescribed ordinary type, and hence leaves the equation and its constant unchanged.

Concavity comes from mixed products. A convex combination of two solutions stays in the prescribed ordinary type, and Lemma 6.4.1 bounds its measure below by the corresponding mixed density.

Theorem 15.1.1 *The functional B_φ is concave on the real space $L^\infty(\mathrm{d}V)$: for F, G in that space,*

$$B_\varphi(tF + (1-t)G) \geq tB_\varphi(F) + (1-t)B_\varphi(G), \qquad 0 \leq t \leq 1.$$

Proof Let $u, v \sim \varphi$ solve the equations for F and G, and set $H = tF + (1-t)G$ and $D = c_\varphi(F)^t c_\varphi(G)^{1-t}$. Lemma 6.4.1 and the arithmetic–geometric mean inequality give

$$\begin{aligned} \mathrm{MA}_\theta^{\mathrm{ext}}(tu + (1-t)v) &\geq \bigl(t(c_\varphi(F)\mathrm{e}^F)^{1/n} + (1-t)(c_\varphi(G)\mathrm{e}^G)^{1/n}\bigr)^n \,\mathrm{d}V \\ &\geq D\mathrm{e}^H \,\mathrm{d}V. \end{aligned}$$

The averaged potential $tu + (1-t)v$ has the ordinary type of φ. If $c_\varphi(H) < D$, its measure dominates the measure of a solution $w \sim \varphi$ for H by the factor $D/c_\varphi(H) > 1$. Applying the singular strict domination principle to w and to every constant translate of the averaged potential, as in the proof of Proposition 15.1.1, leads to the same contradiction. Hence $c_\varphi(H) \geq D$, and taking logarithms proves concavity. □

For smooth Hermitian data, this concavity agrees with the second-variation formula of Theorem 9.7.1.

Uniformly bounded logarithmic densities give the solutions a common lower barrier, and compactness of the solutions identifies the limiting scalar even when the densities converge only in L^1.

Theorem 15.1.2 *If F_j, F are uniformly bounded real measurable functions and $F_j \to F$ in $L^1(\mathrm{d}V)$, then*

$$B_\varphi(F_j) \longrightarrow B_\varphi(F).$$

Proof Choose solutions $u_j \sim \varphi$ normalized by $\sup_X u_j = 0$, and write $c_j = c_\varphi(F_j)$. If $|F_j| \leq M$, monotonicity and the translation rule of Proposition 15.1.1 give

$$\mathrm{e}^{-M} c_\varphi(0) \leq c_j \leq \mathrm{e}^M c_\varphi(0).$$

In particular, the Monge–Ampère measures of the u_j are dominated by a fixed multiple of $\mathrm{d}V$, and Theorem 14.11.2 gives a constant C such that

$$\varphi - C \leq u_j \leq \varphi.$$

From any subsequence, extract a further subsequence with $c_j \to c > 0$ and $u_j \to u$ in $L^1(X)$. By Corollary 14.8.1, the convergence also holds in capacity, $u \sim \varphi$, and the measures converge weakly. On the other hand, the exponential function is Lipschitz on the common range of the F_j, so $c_j \mathrm{e}^{F_j} \to c\mathrm{e}^F$ in $L^1(\mathrm{d}V)$. Therefore

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = c\mathrm{e}^F \,\mathrm{d}V,$$

and uniqueness of the constant gives $c = c_\varphi(F)$. Since every subsequence has a further subsequence along which $c_j \to c_\varphi(F)$, the whole sequence converges, and so do the logarithms. □

15.2 Supporting probability measures

A supporting functional of the concave function B_φ describes the first-order response of the scalar to a change of logarithmic density. Monotonicity and the translation rule force such a functional to be minus the integral against a probability measure. We work first on the space $C(X)$ of continuous real functions, with the uniform norm. For $F \in C(X)$, let $\mathcal{A}_\varphi(F)$ be the set of Borel probability measures ν on X satisfying

$$B_\varphi(G) \le B_\varphi(F) - \int_X (G - F)\,\mathrm{d}\nu \qquad \text{for every } G \in C(X). \tag{15.3}$$

Thus $G \mapsto -\int_X G\,\mathrm{d}\nu$ is a supergradient of B_φ at F. We call the members of $\mathcal{A}_\varphi(F)$ the *supporting probabilities* at F.

Theorem 15.2.1 *For every $F \in C(X)$, the set $\mathcal{A}_\varphi(F)$ is nonempty, convex and weakly compact. Every one of its measures is absolutely continuous with respect to* $\mathrm{d}V$.

Proof The function $C_\varphi = -B_\varphi$ is convex and Lipschitz. Fix $F \in C(X)$. For a direction $h \in C(X)$, the limit

$$p(h) = \lim_{t \downarrow 0} \frac{C_\varphi(F + th) - C_\varphi(F)}{t}$$

exists and is finite: convexity makes the difference quotients monotone in $t > 0$, and their absolute values are at most $\|h\|_\infty$. Clearly p is positively homogeneous. Given another direction $k \in C(X)$, apply convexity at the midpoint of $F + 2th$ and $F + 2tk$ and let $t \downarrow 0$; this gives $p(h + k) \le p(h) + p(k)$. Thus p is sublinear.

By the Hahn–Banach theorem, the zero functional on $\{0\}$ extends to a linear functional $\ell \le p$. Since $p(h) \le \|h\|_\infty$, applying this bound to h and $-h$ shows that ℓ is continuous. Monotonicity of the convex difference quotients gives

$$C_\varphi(F + h) \ge C_\varphi(F) + \ell(h),$$

which is (15.3) once ℓ is represented by a probability. Testing the translation rule with positive and negative constants gives $\ell(1) = 1$. If $h \ge 0$, monotonicity of B_φ gives $C_\varphi(F - th) \le C_\varphi(F)$ for $t > 0$, whereas the inequality just proved gives the lower bound $C_\varphi(F) - t\ell(h)$. Hence $\ell(h) \ge 0$. By the Riesz representation theorem, $\ell(h) = \int_X h\,\mathrm{d}\nu$ for a probability measure ν, and $\nu \in \mathcal{A}_\varphi(F)$. Each inequality in (15.3) defines a weakly closed half-space in the compact space of probability measures, so their intersection is closed and convex, hence weakly compact.

It remains to prove absolute continuity. Let K be compact with $\mathrm{d}V(K) = 0$, and choose continuous functions $0 \le \chi_j \le 1$, equal to one on K, whose supports have volumes tending to zero. For any $\nu \in \mathcal{A}_\varphi(F)$, the supporting inequality with $G = F + \chi_j$ gives

$$0 \le \nu(K) \le \int_X \chi_j \,\mathrm{d}\nu \le B_\varphi(F) - B_\varphi(F + \chi_j).$$

The right-hand side tends to zero by Theorem 15.1.2, so $\nu(K) = 0$. By inner regularity of finite Borel measures on X, the same holds for every Borel set of zero volume. The Radon–Nikodym theorem now gives $\mathrm{d}\nu = h_\nu \mathrm{d}V$ with $h_\nu \ge 0$ and $\int_X h_\nu \mathrm{d}V = 1$. □

Proposition 15.2.1 *Let $F_j, F \in C(X)$ with $F_j \to F$ uniformly, and let $\nu_j \in \mathcal{A}_\varphi(F_j)$. Then every weak cluster point of (ν_j) belongs to $\mathcal{A}_\varphi(F)$. In particular, if the latter set consists of a single measure, ν_j converges weakly to it.*

Proof Take a weakly convergent subsequence and fix $G \in C(X)$. In the inequality

$$B_\varphi(G) \le B_\varphi(F_j) - \int_X (G - F_j) \,\mathrm{d}\nu_j,$$

the Lipschitz continuity of B_φ, the uniform convergence of F_j and the weak convergence of the probabilities allow passage to the limit. The limiting inequality holds for every G, so the limit measure belongs to $\mathcal{A}_\varphi(F)$. If that set is a singleton, every convergent subsequence has the same limit, and compactness of the space of probability measures proves the final assertion. □

15.2.1 Directional derivatives

As ν runs through the supporting probabilities at F, the integral $-\int_X G \,\mathrm{d}\nu$ ranges exactly between the two one-sided derivatives of B_φ at F in the direction G. Consequently, differentiability is equivalent to uniqueness of the supporting probability. For $F, G \in C(X)$, write $D^+B_\varphi(F)[G]$ and $D^-B_\varphi(F)[G]$ for the limits of the difference quotient $(B_\varphi(F + tG) - B_\varphi(F))/t$ as $t \downarrow 0$ and $t \uparrow 0$, respectively.

Proposition 15.2.2 *For $F, G \in C(X)$, the one-sided derivatives exist, and*

$$D^+B_\varphi(F)[G] = -\max_{\nu \in \mathcal{A}_\varphi(F)} \int_X G \,\mathrm{d}\nu,$$

$$D^-B_\varphi(F)[G] = -\min_{\nu \in \mathcal{A}_\varphi(F)} \int_X G \,\mathrm{d}\nu.$$

Consequently B_φ is Gâteaux differentiable at F if and only if $\mathcal{A}_\varphi(F)$ is a singleton. Its derivative is then $G \mapsto -\int_X G \,\mathrm{d}\nu$.

Proof The one-sided limits exist and are finite by concavity and the Lipschitz bound. For $t > 0$, every supporting probability ν at F gives

$$\frac{B_\varphi(F + tG) - B_\varphi(F)}{t} \le -\int_X G \, \mathrm{d}\nu.$$

Conversely, choose $\nu_t \in \mathcal{A}_\varphi(F + tG)$ and apply its supporting inequality with the test function F; this bounds the same quotient below by $-\int_X G \, \mathrm{d}\nu_t$. Along a sequence $t \downarrow 0$, the measures ν_t have a weak limit point, which belongs to $\mathcal{A}_\varphi(F)$ by Proposition 15.2.1. The two bounds identify the right derivative with minus the maximum. Applying this identity to $-G$ gives the formula for the left derivative.

If $\mathcal{A}_\varphi(F)$ is a singleton $\{\nu\}$, the two derivatives coincide for every G and equal $-\int_X G \, \mathrm{d}\nu$, a continuous linear functional of G. Conversely, if the two one-sided derivatives agree for every G, all supporting probabilities have the same integral against every continuous function, and the Riesz representation theorem shows that they coincide. □

15.2.2 Generic uniqueness

On every affine line in $C(X)$, the concave function B_φ is differentiable outside a countable set, so the gap between its two directional derivatives along the line vanishes on a dense subset. Upper semicontinuity of this gap and separability of $C(X)$ turn the one-dimensional fact into uniqueness of the supporting probability on a dense G_δ subset of $C(X)$.

Theorem 15.2.2 *The set*

$$\mathcal{U}_\varphi = \{F \in C(X, \mathbb{R}) : \mathcal{A}_\varphi(F) \text{ is a singleton}\}$$

is a dense G_δ subset of $C(X)$ with the uniform norm. At every $F \in \mathcal{U}_\varphi$, the functional B_φ is Gâteaux differentiable, and its derivative is minus the integral against the unique supporting probability. If $F_j \to F$ uniformly and $\nu_j \in \mathcal{A}_\varphi(F_j)$, then ν_j converges weakly to that probability.

Proof For $h \in C(X, \mathbb{R})$ define the width

$$w_h(F) = \max_{\nu \in \mathcal{A}_\varphi(F)} \int_X h \, \mathrm{d}\nu - \min_{\nu \in \mathcal{A}_\varphi(F)} \int_X h \, \mathrm{d}\nu \ge 0.$$

The extrema exist by weak compactness. We claim that the width is upper semicontinuous in F. Indeed, let $F_j \to F$ and choose maximizing and minimizing probabilities at each F_j. Along a subsequence realizing the upper limit of the widths, compactness of the space of probability measures gives weak limits of both choices. By Proposition 15.2.1, both limits belong to $\mathcal{A}_\varphi(F)$, so the difference of their integrals against h is at most $w_h(F)$.

Consequently, for every $\epsilon > 0$ the set $\{F : w_h(F) < \epsilon\}$ is open. It is also dense. If $h = 0$ there is nothing to prove. Otherwise fix F and an open ball about it. The function

$$b(t) = B_\varphi(F + th)$$

is finite and concave on the real line, so it is differentiable outside an at most countable set: its one-sided derivatives are finite and monotone, and the nonempty open intervals between unequal one-sided derivatives at distinct points are disjoint, so each contains a different rational number. Choose a point of differentiability t so close to zero that $F + th$ lies in the given ball. The derivative formulas of Proposition 15.2.2 give $w_h(F + th) = 0$, which proves density.

The compact manifold X is metrizable, so $C(X)$ is separable. Choose a countable uniformly dense family (h_j) in $C(X)$. By the Baire category theorem in the complete metric space $C(X)$, the set

$$\bigcap_{j,k\geq 1} \{F : w_{h_j}(F) < 1/k\}$$

is a dense G_δ. At every point of this intersection, all supporting probabilities have the same integral against every h_j. Since they have unit mass, uniform approximation gives equal integrals against every continuous function, and the Riesz representation theorem shows that the probabilities coincide. Conversely, a singleton has zero width in every direction, so the intersection is exactly $\mathscr{U}_\varphi$. The formula for the derivative follows from Proposition 15.2.2, and the approximation assertion from Proposition 15.2.1. □

15.2.3 Gauduchon adjoints

For a smooth Hermitian equation, differentiating the scalar identifies the supporting probability with the adjoint probability of the linearized operator.

Theorem 15.2.3 *Let $\theta = \omega$ be a Hermitian form, let $\varphi = 0$, and let F be a smooth real function. Let u be the smooth solution of (15.1), unique up to an additive constant by Corollary 11.4.1, and let μ_u be its Gauduchon adjoint probability from Proposition 4.8.1; for $n = 1$, this is $\mu_u = (\omega + \mathrm{dd}^c u)/\int_X \omega$. Then*

$$\mathscr{A}_0(F) = \{\mu_u\}.$$

Proof Suppose first that $n \geq 2$. By uniqueness of the constant, the normalization scalar of the smooth equation in Theorem 9.7.1 is B_0, and that theorem gives, for every smooth real G,

$$\frac{\mathrm{d}}{\mathrm{d}t}\bigg|_{t=0} B_0(F + tG) = -\int_X G \,\mathrm{d}\mu_u.$$

Let $\nu \in \mathcal{A}_0(F)$. Testing the supporting inequality at $F + tG$ for both signs of t and letting $t \to 0$ shows that G has the same integral against ν and μ_u. Since smooth functions are uniformly dense in $C(X)$, it follows that $\nu = \mu_u$, and the assertion follows from nonemptiness of $\mathcal{A}_0(F)$. In dimension one, Stokes' theorem gives $c_0(F) = \int_X \omega / \int_X \mathrm{e}^F \,\mathrm{d}V$; differentiating its logarithm in the same way yields the stated measure, since $\omega + \mathrm{dd}^{\mathrm{c}} u = c_0(F)\mathrm{e}^F \,\mathrm{d}V$. □

Consequently, in the Hermitian case the supporting probabilities at a continuous F can be approached through smooth data. If smooth F_j converge uniformly to F, then by Proposition 15.2.1 every weak cluster point of the Gauduchon adjoint probabilities of the solutions for F_j belongs to $\mathcal{A}_0(F)$, and is therefore absolutely continuous. If $\mathcal{A}_0(F)$ is a singleton, which holds in particular for every $F \in \mathcal{U}_0$ and under the continuous positive Hessian hypothesis of Theorem 15.2.4, these probabilities converge to its unique member, independently of the approximation. We do not know whether $\mathcal{A}_0(F)$ is a singleton for every continuous F, even in this Hermitian setting; the same question is open for the singular references considered above.

For $n \geq 2$, the Hermitian zero-reference case admits a quantitative strengthening: Corollary 26.8.1 bounds the densities of all supporting probabilities uniformly in L^q, for $1 < q < n/(n-1)$, when $\|F\|_\infty$ is bounded, and also for $q = n/(n-1)$ when ω has positive lower mass $\nu_-(\omega) > 0$ in the sense of Definition 6.5.1. The proof uses the Gauduchon-current formulation of Chapter 26, and we do not claim such a bound for an arbitrary singular reference.

A weak linearized operator requires more than a supporting probability. In the same Hermitian zero-reference setting, Theorem 26.7.1 represents each supporting probability by a determinant-weighted positive dd^{c}-closed current. Identifying that current with a scalar multiple of a weak power $(\omega + \mathrm{dd}^{\mathrm{c}} u)^{n-1}$ would require a well-defined product and its compatibility with approximation.

A similar representation holds for a functional defined by subsolutions rather than by an equation in a prescribed singularity type. Let $0 \leq f \in L^1(\mathrm{d}V)$ be nonzero with $f^{1/n} \in \mathcal{D}^0_\omega$, the space of densities with uniformly vanishing Gauduchon tails from Section 14.31.2. Then Proposition 26.9.3 describes the supporting probabilities of $F \mapsto \log b_\omega(\mathrm{e}^F f)$, where $b_\omega(\cdot)$ is the density threshold of Theorem 14.27.1.

15.2.4 Continuous positive complex Hessians

The smooth recovery theorem extends to a bounded solution whose complex Hessian is continuous and everywhere positive. In this case one can vary the potential in both directions, and the resulting densities force every supporting probability to annihilate the same elliptic operator. The Sobolev range theorem then gives uniqueness.

Theorem 15.2.4 *Let $n \geq 2$, let $\theta = \omega$ be a Hermitian form, and let $\varphi = 0$. Suppose $F \in C(X)$ and a bounded solution $u \in \mathrm{PSH}(X, \omega)$ of (15.1) has distributional complex Hessian represented by a continuous form*

$$\sigma = \omega + \mathrm{dd}^{\mathrm{c}} u > 0$$

everywhere on X. Then $\mathcal{A}_0(F)$ consists of one probability ν_F. It satisfies

$$\int_X L_\sigma h \, \mathrm{d}\nu_F = 0 \quad (h \in C^\infty(X)),$$
$$DB_0(F)[H] = -\int_X H \, \mathrm{d}\nu_F \quad (H \in C(X)).$$

The derivative is taken in the Gâteaux sense.

Proof The continuous trace of $\mathrm{dd}^{\mathrm{c}} u$ is the Euclidean Laplacian of u, up to the fixed normalization. Local constant-coefficient elliptic regularity gives $u \in W^{2,p}$ for every finite p. Indeed, subtract the Newtonian potential of a cutoff of this trace. Its second high-frequency derivatives are order-zero multipliers, and the low-frequency kernels are locally bounded; the remaining distribution is harmonic. Sobolev embedding gives a $C^{1,\alpha}$ representative for every $\alpha < 1$, which agrees with the quasi-psh representative.

On a coordinate ball choose smooth ρ with $\mathrm{dd}^{\mathrm{c}} \rho \geq \omega$. The radial regularizations of the bounded psh function $u + \rho$ decrease to it, and their complex Hessians converge uniformly on smaller balls. Continuity of bounded products and the finite smooth-background expansion identify $(\omega + \mathrm{dd}^{\mathrm{c}} u)^n$ with σ^n. For smooth real h, the same argument applies to $u + th$, which is admissible for all sufficiently small signed t by uniform positivity. Define

$$F_t = F + \log \frac{(\sigma + t\mathrm{dd}^{\mathrm{c}} h)^n}{\sigma^n}.$$

Its equation has the same normalization scalar as the equation for u, so $B_0(F_t) = B_0(F)$. The supporting inequality gives $\int_X (F_t - F) \, \mathrm{d}\nu \leq 0$ for each $\nu \in \mathcal{A}_0(F)$. Since $F_t - F = tL_\sigma h + O(t^2)$ uniformly, using both signs yields stationarity.

Choose $p = 4n + 1$ and $q = p/(p-1) = 1 + 1/(4n)$. By Corollary 26.8.1, every supporting probability has an L^q density, since $q < n/(n-1)$. Smooth density in $W^{2,p}$ extends its stationarity to every $W^{2,p}$ test. By Lemma 4.9.1, all these densities lie in a one-dimensional space. Their integrals equal one, so they coincide. Nonemptiness is Theorem 15.2.1, and the derivative formula follows from Proposition 15.2.2. □

15.2.5 Products with a Hermitian factor

An explicit product construction exhibits the criterion for densities with an arbitrary continuous modulus. Let (Y, κ) be a connected compact Hermitian k-fold, $k \geq 1$, with $\int_Y \kappa^k = 1$. Denote by ν_κ the smooth stationary probability of $L_\kappa = \mathrm{tr}_\kappa \, \mathrm{dd}^{\mathrm{c}}$,

given by the Gauduchon multiplier when $k \geq 2$; for $k = 1$ it is κ. Write w for the Fubini–Study area of mass one on $\mathbb{P}^1$. All factor forms and functions below are pulled back to $X = \mathbb{P}^1 \times Y$.

Proposition 15.2.3 *Let $a > 0$, let b be smooth and positive on $\mathbb{P}^1$, and let A be continuous and positive there, with $\int_{\mathbb{P}^1} Aw = a$. For*

$$\omega = aw + b\kappa, \qquad \mathrm{d}V = w \wedge \kappa^k, \qquad F = \log((k+1)Ab^k),$$

one has

$$c_0(F) = 1, \qquad \mathcal{A}_0(F) = \left\{ \frac{A}{a}\, w \otimes \nu_\kappa \right\}.$$

Proof The Green solution of $\mathrm{dd^c} u = (A - a)w$ on $\mathbb{P}^1$ has continuous complex Hessian and is bounded. Its pullback yields $\sigma = Aw + b\kappa > 0$, and $\sigma^{k+1} = (k+1)Ab^k w \wedge \kappa^k$. Thus scalar uniqueness gives $c_0(F) = 1$, and Theorem 15.2.4 gives a unique support. For every smooth h depending on all variables, the block decomposition

$$L_\sigma h = A^{-1} L_w h + b^{-1} L_\kappa h$$

shows that $(A/a)w \otimes \nu_\kappa$ is stationary: the first term integrates to zero by Stokes on $\mathbb{P}^1$, and the second by stationarity on Y and Fubini. This candidate has a bounded density with respect to $\mathrm{d}V$. The one-dimensional annihilator of Lemma 4.9.1 and probability normalization therefore identify it with the supporting probability. □

Example 15.2.1 There is a non-Kähler threefold with a nonclosed Hermitian background and a positive continuous density whose logarithm is neither Dini continuous nor Hölder continuous of any positive order, but whose supporting probability is explicit and unique.

Proof Take the Hopf surface $Y = (\mathbb{C}^2 \setminus \{0\})/\langle z \mapsto 2z \rangle$ and its unit-volume metric $\kappa = c|z|^{-2}\mathrm{dd^c}|z|^2$, where $c > 0$ is chosen so that $\int_Y \kappa^2 = 1$. Put $s = \log|z|^2$, $\alpha = \mathrm{dd^c} s$ and $\beta = \mathrm{d}s \wedge \mathrm{d^c} s$, so that $\kappa = c(\alpha + \beta)$. The differentiation in (8.1) applies in this dimension. Here α has rank one, so $\mathrm{dd^c}\kappa = -c\alpha^2 = 0$ and $\nu_\kappa = \kappa^2$. Polar coordinates identify Y with $S^3 \times S^1$, hence $H^2(Y, \mathbb{R}) = 0$. A closed positive form would be exact and have positive square integral, contradicting Stokes. Thus Y is non-Kähler, and so is $\mathbb{P}^1 \times Y$, by restriction.

Let $\tau \in [-1, 1]$ be the height on $\mathbb{P}^1$, set $b = 2 + \tau$, and put

$$f(t) = \begin{cases} 1/\log(e/|t|), & 0 < |t| \leq 1, \\ 0, & t = 0, \end{cases}$$

$$A = a + \varepsilon \left(f(\tau) - \int_{\mathbb{P}^1} f(\tau) w \right), \qquad 0 < \varepsilon < a.$$

Since $0 \leq f \leq 1$, this is a positive continuous function of mean a. Along a normal segment to the equator, $|\tau|$ is comparable to the distance r. The oscillation of A

is therefore bounded below by a positive multiple of $1/\log(e/r)$. Its Dini integral $\int_0^{r_0} \mathrm{d}r/(r\log(e/r))$ diverges, and this modulus is larger than every r^γ, $\gamma > 0$, as $r \downarrow 0$. The logarithm of A has the same lower bound, because A is uniformly positive and bounded. The smooth term $2\log b$ contributes only $O(r)$, so $F = \log(3Ab^2)$ has neither regularity. The mixed component $\mathrm{d}b \wedge \kappa$ shows that $\omega = aw + b\kappa$ is nonclosed. By Proposition 15.2.3, its supporting probability is $(A/a)w \wedge \kappa^2$. □

The theorem assumes a continuous positive complex Hessian for a bounded solution. It does not establish that hypothesis for every continuous F; the uniqueness question for arbitrary continuous data remains open.

15.2.6 Divisorial smoothing

For a singular reference, the supporting probability can be unique while smoothings of the solution have different limiting adjoint probabilities. The reason is that the non-pluripolar product discards the mass on a divisor that the smoothings keep. On a product of two projective lines, explicit formulas exhibit both the lost mass and its dependence on the smoothing.

In this subsection, $X = \mathbb{P}^1 \times \mathbb{P}^1$. Let ω_1 and ω_2 be the pullbacks of the Fubini–Study forms of the two factors, normalized to have integral one on their factors, and put

$$\theta = 2\omega_1 + 2\omega_2, \qquad \beta = \omega_1 + 2\omega_2, \qquad \omega = \omega_1 + \omega_2, \qquad \mathrm{d}V = \omega_1 \wedge \omega_2.$$

Thus $\mathrm{d}V$ is a probability volume form, $\theta^2 = 8\mathrm{d}V$ and $\beta^2 = 4\mathrm{d}V$. Let z be the affine coordinate on the first factor, and put

$$r = \frac{|z|^2}{1 + |z|^2}, \qquad \psi = \log r, \qquad D = \{0\} \times \mathbb{P}^1.$$

The function r extends smoothly to the first factor, with value one at infinity, and ψ is quasi-plurisubharmonic with value $-\infty$ exactly on D. The Poincaré–Lelong formula gives $\mathrm{dd^c}\psi = [D] - \omega_1$, so $\theta + \mathrm{dd^c}\psi = \beta + [D]$.

For a smooth positive $(1,1)$-form Ω on the surface X, the linearization $v \mapsto 2\mathrm{dd^c}v \wedge \Omega/\Omega^2$ of the logarithmic Monge–Ampère operator has the adjoint probability $\rho\Omega^2$, where the Gauduchon multiplier $\rho > 0$ satisfies $\mathrm{dd^c}(\rho\Omega) = 0$ and $\int_X \rho\Omega^2 = 1$ (Proposition 4.8.1). We call $Q = \rho\Omega$ the *adjoint cofactor* of Ω: it is $\mathrm{dd^c}$-closed, and $\Omega \wedge Q$ is the adjoint probability.

Lemma 15.2.1 *Write $x = \log|z|^2$ and $\chi(x) = \log(1+\mathrm{e}^x)$. The envelope $\varphi = P_\theta[\psi]$ is*

$$\varphi = W(x) - 2\chi(x), \qquad W(x) = \begin{cases} x + 2\log 2, & x \le 0, \\ 2\chi(x), & x \ge 0. \end{cases} \tag{15.4}$$

It satisfies $\psi \le \varphi \le 0$, $0 \le \varphi - \psi \le 2\log 2$, and the model condition (13.20) with $\varepsilon = 3/4$.

Proof The function W is convex: both one-sided derivatives at zero equal one, and the derivative of 2χ increases from one to two on $[0,\infty)$. Since $\omega_1 = \mathrm{dd^c}\chi(x)$ on the affine chart, $W - 2\chi$ is $2\omega_1$-plurisubharmonic there. Since W has slope one for $x \le 0$ and agrees with 2χ for $x \ge 0$, the function $W - 2\chi$ extends to a global $2\omega_1$-plurisubharmonic function, with a logarithmic pole along D and equal to zero where $|z| \ge 1$. The asserted bounds follow from $\psi = x - \chi$: the difference $\varphi - \psi$ equals $2\log 2 - \chi$ for $x \le 0$ and $\chi - x$ for $x \ge 0$.

For $C > 0$ write $v_C = P_\theta(\min\{\psi + C, 0\})$. Rotations of the first factor and the transitive unitary action on the second preserve the whole competitor class, so the envelope is radial and independent of the second factor. The function $V_C = 2\chi + v_C$ is then convex in x and satisfies $V_C \le \chi + x + C$. This upper bound as $x \to -\infty$ forces the slope of V_C at $-\infty$ to be at least one, and by convexity all its slopes are at least one. For $x < 0$,

$$V_C(x) \le V_C(0) + x \le 2\log 2 + x = W(x).$$

For $x \ge 0$, the zero obstacle gives $V_C \le 2\chi = W$. Consequently $v_C \le \varphi$. If $C \ge 2\log 2$, the bounds already proved make φ a competitor, so $v_C = \varphi$. Letting $C \to \infty$ proves $P_\theta[\psi] = \varphi$. Since $\varphi \sim \psi$ and the ordinary envelope depends only on the singularity type, also $P_\theta[\varphi] = \varphi$.

Finally

$$\tfrac{3}{4}\theta + \mathrm{dd^c}\psi = \tfrac{1}{2}\omega_1 + \tfrac{3}{2}\omega_2 + [D] \ge 0.$$

Since $\psi \le \varphi$, the function ψ is a competitor for $P_{(3/4)\theta}(\varphi)$, which is therefore not identically $-\infty$. □

Proposition 15.2.4 *Every $v \in \mathrm{PSH}(X,\theta)$ with $v \sim \varphi$ is uniquely of the form $v = \psi + w$, where $w \in \mathrm{PSH}(X,\beta)$ is bounded. Its non-pluripolar measure is*

$$\mathrm{MA}_\theta(v) = (\beta + \mathrm{dd^c}w)^2, \qquad \int_X \mathrm{MA}_\theta(v) = 4. \tag{15.5}$$

For every real continuous F,

$$B_\varphi(F) = \log 4 - \log \int_X \mathrm{e}^F \mathrm{d}V, \qquad \mathcal{A}_\varphi(F) = \left\{ \frac{\mathrm{e}^F \mathrm{d}V}{\int_X \mathrm{e}^F \mathrm{d}V} \right\}.$$

At $v = \psi$, the non-pluripolar part of $\theta + \mathrm{dd^c}\psi$ is β, whose adjoint cofactor is $Q = \beta/4$, with adjoint probability $\beta \wedge Q = \mathrm{d}V$.

Proof On $X \setminus D$, the function $w = v - \psi$ is bounded, because $v \sim \varphi \sim \psi$, and satisfies $\beta + \mathrm{dd^c} w \geq 0$. After adding local potentials of the closed form β, Lemma 1.3.7 extends w across D; the extensions agree on overlaps and give a bounded β-plurisubharmonic function on X. Conversely, for every bounded $w \in \mathrm{PSH}(X, \beta)$, the function $\psi + w$ is θ-plurisubharmonic with current $\beta + \mathrm{dd^c} w + [D]$, and it has the ordinary type of φ. The decomposition is unique, since two such functions w agree off D and hence everywhere.

Put $T = \beta + \mathrm{dd^c} w$. The bounded-product construction gives

$$T^2 - \beta^2 = \mathrm{dd^c}\big(w(T + \beta)\big),$$

and Stokes' theorem against the constant function yields $\int_X T^2 = 4$. The product gives no mass to D by Proposition 1.7.1; we also give a direct cutoff estimate, which will be used again below. Shift w so that $0 \leq w \leq M$, and set $f_t = \max\{\psi/t, -1\}$ for $t > 0$. Choose smooth convex functions σ_ϵ with derivative in $[0, 1]$, equal to -1 below $-1 - \epsilon$ and to the identity above $-1 + \epsilon$, converging uniformly to $\max\{\cdot, -1\}$. Then $f_{t,\epsilon} = \sigma_\epsilon(\psi/t)$ is globally smooth, constant near D, and

$$f_{t,\epsilon} \longrightarrow f_t \text{ uniformly}, \qquad \mathrm{dd^c} f_{t,\epsilon} \geq -\omega_1/t.$$

Testing the distributional identity against $f_{t,\epsilon}$, using positivity of $T + \beta$, and letting $\epsilon \to 0$, we obtain

$$\int_X (-f_t) T^2 \leq \int_X (-f_t)\beta^2 + \frac{M}{t} \int_X \omega_1 \wedge (T + \beta) = \int_X (-f_t)\beta^2 + \frac{4M}{t}. \tag{15.6}$$

Here the last integral equals four by Stokes' theorem. The right-hand side tends to zero as $t \to \infty$, since $f_t \to 0$ off D and $\beta^2(D) = 0$; as $-f_t = 1$ on D, this gives $T^2(D) = 0$. Off D the currents $\theta + \mathrm{dd^c} v$ and T agree, so locality and the fact that the extended measure puts no mass on the pole set prove (15.5).

For the Hermitian background β, Theorem 10.1.1 with density e^F gives a bounded solution w and a constant $c > 0$, and the correspondence above turns it into a solution $\psi + w$ in the ordinary type of φ. Every potential of that type has mass four, so integration forces $c = 4/\int_X \mathrm{e}^F \mathrm{d}V$, which is the formula for B_φ. Jensen's inequality for the probability $\nu_F = \mathrm{e}^F \mathrm{d}V / \int_X \mathrm{e}^F \mathrm{d}V$ gives

$$B_\varphi(G) \leq B_\varphi(F) - \int_X (G - F)\, \mathrm{d}\nu_F.$$

Thus ν_F is a supporting probability. For any supporting probability, testing its inequality at $G = F \pm th$ and differentiating at $t = 0$ shows that its integral against every $h \in C(X)$ equals that of ν_F.

For a smooth real h and sufficiently small $|t|$, we have $\beta + t\mathrm{dd^c} h > 0$, so $\psi + th$ stays in the same ordinary type and its residual measure is $(\beta + t\mathrm{dd^c} h)^2$, with derivative $2\mathrm{dd^c} h \wedge \beta$ at $t = 0$. Since β is closed, the constant weight $\rho = 1/4$ annihilates this derivative after integration, and $Q = \rho\beta$ gives the asserted probability. This

normalization uses the residual mass: since $\int_X \theta \wedge Q = 3/2$, the cofactor Q is not a normalized Gauduchon current for θ in the sense of Section 4.4. □

Theorem 15.2.5 *Let g be a smooth real function on the second factor with $\gamma = \mathrm{dd^c} g \geq -\omega_2$, regarded as a function on X. For $0 < \delta \leq 1$ put*

$$u_{\delta,g} = \log(r + \delta \mathrm{e}^g), \qquad \Omega_{\delta,g} = \theta + \mathrm{dd^c} u_{\delta,g}, \qquad F_{\delta,g} = \log \frac{\Omega_{\delta,g}^2}{4\mathrm{d}V}.$$

The forms satisfy $\Omega_{\delta,g} \geq \omega$ and $\int_X \Omega_{\delta,g}^2 = 8$. For each fixed g, as $\delta \downarrow 0$ the smooth potentials $u_{\delta,g}$ decrease pointwise to ψ, converge in L^1 and in the capacity Cap_ω, and converge smoothly off D. Moreover $F_{\delta,g} \to 0$ in $L^p(\mathrm{d}V)$ for every $1 \leq p < \infty$. The adjoint cofactors and adjoint probabilities of the forms $\Omega_{\delta,g}$ are

$$Q_{\delta,g} = \Omega_{\delta,g}/8, \qquad \nu_{\delta,g} = \Omega_{\delta,g}^2/8,$$

and they have the weak limits

$$\begin{aligned} Q_{\delta,g} &\longrightarrow (\beta + [D])/8, \\ \nu_{\delta,g} &\longrightarrow \tfrac{1}{2}\mathrm{d}V + \tfrac{1}{2}[D] \wedge \omega_2 + \tfrac{1}{8}[D] \wedge \mathrm{dd^c} g. \end{aligned} \tag{15.7}$$

The limiting probability has mass $1/2$ on D and depends on g, although $\mathcal{A}_\varphi(0) = \{\mathrm{d}V\}$. The cofactors do not approach $\beta/4$, and their limit is not $\rho\beta$ for any locally integrable scalar ρ.

Proof Smoothness and monotone convergence follow directly from the defining formula, also on D, where $\psi = -\infty$. Off D, set

$$\lambda = \frac{r}{r + \delta \mathrm{e}^g}, \qquad h = \psi - g - \log \delta.$$

The chain rule gives $\Omega_{\delta,g} = A_\delta + R_\delta$, where

$$A_\delta = (2 - \lambda)\omega_1 + 2\omega_2 + (1 - \lambda)\gamma, \qquad R_\delta = \lambda(1 - \lambda)\mathrm{d}h \wedge \mathrm{d^c} h.$$

Thus $A_\delta \geq \omega_1 + \omega_2$ and $R_\delta \geq 0$, and the inequality $\Omega_{\delta,g} \geq \omega$ extends across D by continuity. Closedness of θ and Stokes' theorem give the mass eight. Since $\Omega_{\delta,g}$ is closed, the Gauduchon condition $\mathrm{dd^c}(\rho\Omega_{\delta,g}) = 0$ reduces to the elliptic equation $\mathrm{dd^c}\rho \wedge \Omega_{\delta,g} = 0$ on the connected surface, whose smooth solutions are constant by the maximum principle. Normalization against $\Omega_{\delta,g}^2$ gives $\rho = 1/8$ and the stated adjoint cofactors and probabilities.

The rank-one form R_δ has square zero, hence $\Omega_{\delta,g}^2 = A_\delta^2 + 2A_\delta \wedge R_\delta$. The bounded coefficients of A_δ converge off D to those of β, which gives $A_\delta^2 \to 4\mathrm{d}V$. Write $N = \mathrm{d}\psi \wedge \mathrm{d^c}\psi$. In $A_\delta \wedge R_\delta$, the part in which R_δ contributes only derivatives along the first factor (the normal part) is

$$\lambda(1 - \lambda)N \wedge \big(2\omega_2 + (1 - \lambda)\gamma\big).$$

Terms mixing a derivative along the first factor with one along the second vanish for degree reasons. The remaining tangential term is $\lambda(1-\lambda)(2-\lambda)\omega_1 \wedge \mathrm{d}g \wedge \mathrm{d}^{\mathrm{c}}g$, which tends to zero by dominated convergence.

The normal coefficients can be computed in polar coordinates. Put $s = \delta \mathrm{e}^{g}$ and $t = |z|^2$. Then

$$\lambda = \frac{t}{s + (1+s)t}, \qquad N = \frac{\mathrm{i}\,\mathrm{d}z \wedge \mathrm{d}\bar{z}}{2\pi t(1+t)^2}.$$

After angular integration the radial measure of $\lambda(1-\lambda)N$ is

$$\frac{s\,\mathrm{d}t}{(1+t)(s+(1+s)t)^2} = \frac{\mathrm{d}y}{(1+sy)(1+(1+s)y)^2}, \qquad t = sy.$$

It is bounded by $\mathrm{d}y/(1+y)^2$ and tends to that measure, whose integral is one. With an additional factor $1-\lambda$, the rescaled measure becomes $\mathrm{d}y/(1+(1+s)y)^3$, which is bounded by $\mathrm{d}y/(1+y)^3$ and has limiting integral $1/2$. The mass of both measures outside every fixed tube around D tends to zero, uniformly in the point of the second factor because g is bounded. Testing against continuous functions therefore gives

$$\lambda(1-\lambda)N \longrightarrow [D], \qquad \lambda(1-\lambda)^2 N \longrightarrow \tfrac{1}{2}[D].$$

Combining the normal and the remaining terms proves

$$\Omega_{\delta,g}^2 \longrightarrow 4\mathrm{d}V + [D] \wedge (4\omega_2 + \gamma). \tag{15.8}$$

Dividing by eight gives the second line of (15.7). The limit is positive since $4\omega_2 + \gamma \geq 3\omega_2$, and its mass on D is $4/8 = 1/2$ by Stokes' theorem on the second factor. Taking $g = 0$ and a small nonconstant smooth g gives different limits, since $\mathrm{dd}^{\mathrm{c}}g$ vanishes identically only for constant g.

The difference of the potentials satisfies

$$0 \leq u_{\delta,g} - \psi \leq \log\bigl(1 + \delta \mathrm{e}^{\max g}/r\bigr)$$

off D. The right-hand side tends to zero and is dominated by an integrable logarithmic pole, which proves L^1 convergence. Continuity of distributional differentiation then gives the limit of the cofactors. A locally integrable function times the smooth form β has absolutely continuous coefficients, so it cannot produce the singular coefficients of $[D]$.

For convergence in capacity, use the capacity Cap_ω of Section 1.8; after subtracting one, its test potentials range over $v \in \mathrm{PSH}(X,\omega)$ with $-1 \leq v \leq 0$. For such v, apply the cutoff argument of (15.6) with β replaced by ω and $w = v + 1$. Stokes' theorem gives $\int_X \omega_1 \wedge (2\omega + \mathrm{dd}^{\mathrm{c}}v) = 2$, so

$$\mathrm{Cap}_\omega\{\psi < -t\} \leq \int_X (-f_t)\omega^2 + 2/t \longrightarrow 0.$$

The same bound shows that D has capacity zero. For $\eta > 0$, the set of points off D where $u_{\delta,g} - \psi > \eta$ is contained in

$$\left\{ r < \frac{\delta \mathrm{e}^{\max g}}{\mathrm{e}^{\eta} - 1} \right\}.$$

This is a sublevel set of ψ whose level tends to $-\infty$ as $\delta \downarrow 0$. The capacity bound for such sublevel sets, together with $\mathrm{Cap}_{\omega}(D) = 0$, proves convergence in capacity.

Finally, $\Omega_{\delta,g} \geq \omega$ gives $F_{\delta,g} \geq -\log 2$. In the affine chart $|\mathrm{d}\psi|^2_{\omega} \leq C/r$, while g and its first two derivatives are bounded. The decomposition above yields $\Omega_{\delta,g} \leq C_g(1 + r^{-1})\omega$, hence

$$|F_{\delta,g}| \leq C_g + 2|\log r|.$$

Every finite power of this logarithmic bound is integrable. Smooth convergence off D gives $F_{\delta,g} \to 0$ there, and dominated convergence proves convergence in L^p. □

The exponential densities satisfy $\int_X \mathrm{e}^{F_{\delta,g}} \mathrm{d}V = 2$ for every δ, whereas their pointwise limit has integral one; they are therefore not uniformly integrable. The smoothings leave the ordinary type of φ and keep the mass eight of bounded potentials instead of the mass four of that type. The example thus shows which concentration a recovery theorem must exclude. The hypotheses of Proposition 15.2.1 (uniform convergence) and of Theorem 15.1.2 (uniformly bounded logarithmic densities converging in L^1) are stronger than the convergence in every L^p obtained here. In the fixed divisorial type, a common bound on the residual potentials gives a direct recovery estimate instead.

Corollary 15.2.1 *Let $w_j, w \in \mathrm{PSH}(X, \beta)$ satisfy $|w_j|, |w| \leq M$ for a fixed $M \geq 1$, and suppose that $w_j \to w$ in capacity. Put*

$$T_j = \beta + \mathrm{dd}^{\mathrm{c}} w_j, \qquad T = \beta + \mathrm{dd}^{\mathrm{c}} w,$$
$$Q_j = T_j/4, \quad Q = T/4, \qquad \nu_j = T_j^2/4, \quad \nu = T^2/4.$$

Then $Q_j \rightharpoonup Q$ as currents and $\nu_j \rightharpoonup \nu$ as probability measures. More precisely, for real $f \in C^{\infty}(X)$ choose $C_f \geq 0$ with $-C_f\beta \leq \mathrm{dd}^{\mathrm{c}} f \leq C_f\beta$. For every $\eta > 0$, writing $E_{j,\eta} = \{|w_j - w| > \eta\}$, one has

$$\left| \int_X f \, (\mathrm{d}\nu_j - \mathrm{d}\nu) \right| \leq C_f \big(2\eta + 2M^2 \, \mathrm{Cap}_{\beta}(E_{j,\eta}) \big). \tag{15.9}$$

If T_j is smooth and strictly positive, then Q_j and ν_j are its adjoint cofactor and adjoint probability. If $\psi + w$ solves (15.1) for some $F \in C(X)$, the limit ν is the unique member of $\mathcal{A}_{\varphi}(F)$.

Proof The capacity is the one of Section 1.8, and $\beta \leq 2\omega$ gives $\mathrm{Cap}_{\beta} \leq 4\,\mathrm{Cap}_{\omega}$. Set $a_j = (w_j + M)/(2M)$ and $S_j = \beta + \mathrm{dd}^{\mathrm{c}} a_j$. Then $0 \leq a_j \leq 1$ and

$$S_j = \left(1 - \frac{1}{2M}\right)\beta + \frac{1}{2M}T_j,$$
$$S_j^2 \geq \left(\frac{1}{M} - \frac{1}{2M^2}\right)\beta \wedge T_j \geq \frac{1}{2M}\beta \wedge T_j.$$

Positivity of bounded mixed products justifies these inequalities. Thus $\int_E \beta \wedge T_j \leq 2M \operatorname{Cap}_\beta(E)$ for every Borel set E, and the same bound holds for T. By closedness and Stokes' theorem, $\int_X \beta \wedge (T_j + T) = 8$. Now test the identity

$$T_j^2 - T^2 = \mathrm{dd^c}\big((w_j - w)(T_j + T)\big)$$

against f. On $X \setminus E_{j,\eta}$ the potential difference has absolute value at most η, and on $E_{j,\eta}$ at most $2M$. Consequently

$$\begin{aligned}\left|\int_X f(T_j^2 - T^2)\right| &\leq C_f\left(8\eta + 2M\int_{E_{j,\eta}} \beta \wedge (T_j + T)\right)\\ &\leq C_f\left(8\eta + 8M^2 \operatorname{Cap}_\beta(E_{j,\eta})\right).\end{aligned}$$

Dividing by four proves (15.9). Letting first $j \to \infty$ with η fixed and then $\eta \downarrow 0$ shows that $\int_X f\,\mathrm{d}\nu_j \to \int_X f\,\mathrm{d}\nu$. All ν_j and ν have mass one by Proposition 15.2.4, and smooth functions are uniformly dense in $C(X)$, so $\nu_j \rightharpoonup \nu$.

The constant test potential in the definition of capacity gives $4\mathrm{d}V(E) \leq \operatorname{Cap}_\beta(E)$. Splitting the potential difference over the same sets yields

$$\|w_j - w\|_{L^1(\mathrm{d}V)} \leq \eta + \tfrac{M}{2}\operatorname{Cap}_\beta(E_{j,\eta}).$$

Taking the limits in the same order proves L^1 convergence, and hence convergence of the currents Q_j by continuity of distributional differentiation. The limiting cofactor satisfies $\mathrm{dd^c}Q = 0$, $\int_X \beta \wedge Q = 1$, and $T \wedge Q = \nu$ as a bounded product. For smooth real h, the signed measure $2\mathrm{dd^c}h \wedge T$ is the formal linearization of the residual operator at w in the direction h, and its integral against the constant $1/4$ vanishes by Stokes' theorem. It is the derivative of the residual measure along $w + th$ whenever these functions remain β-plurisubharmonic.

If T_j is smooth and strictly positive, the maximum principle on the connected surface makes its Gauduchon multiplier constant, and the mass four normalizes it to $1/4$. Finally, if $\psi + w$ solves the equation at F, then $\nu = T^2/4 = \mathrm{e}^F\mathrm{d}V/\int_X \mathrm{e}^F\mathrm{d}V$, which is the unique supporting probability by Proposition 15.2.4. □

In the corollary, the potentials $\psi + w_j$ keep their pole along D, and the adjoint objects refer to the smooth residual forms T_j. We do not know whether a similar recovery holds for more general singular references, for unbounded residual sequences, or when the Gauduchon multipliers are not constant.

15.3 A convex functional on probability measures

To pass to the limit in the supporting inequality, we need to control the mass that supporting probabilities can put on small sets. The convex dual of B_φ provides this control: the measures in each of its sublevel sets are uniformly absolutely continuous. This allows the logarithmic density and the supporting measure to vary simultaneously.

Let $\mathcal{P}(X)$ denote the set of Borel probability measures on X, with the weak topology. Define

$$H_\varphi(\nu) = \sup_{G \in C(X)} \left(B_\varphi(G) + \int_X G \, d\nu \right), \qquad \nu \in \mathcal{P}(X). \tag{15.10}$$

The value $+\infty$ is allowed, while taking $G = 0$ shows that $H_\varphi \geq B_\varphi(0) > -\infty$.

Proposition 15.3.1 *The functional H_φ is convex and weakly lower semicontinuous. For every $F \in C(X)$,*

$$B_\varphi(F) = \min_{\nu \in \mathcal{P}(X)} \left(H_\varphi(\nu) - \int_X F \, d\nu \right). \tag{15.11}$$

The minimizers are exactly $\mathcal{A}_\varphi(F)$.

Proof Each function of ν in the supremum defining H_φ is affine and weakly continuous, so their supremum is convex and lower semicontinuous. By definition, $H_\varphi(\nu) - \int_X F \, d\nu \geq B_\varphi(F)$, with equality precisely when

$$B_\varphi(G) + \int_X G \, d\nu \leq B_\varphi(F) + \int_X F \, d\nu \quad \text{for every } G \in C(X).$$

This is the defining inequality of $\mathcal{A}_\varphi(F)$, and the minimum is attained because $\mathcal{A}_\varphi(F)$ is nonempty by Theorem 15.2.1. □

Theorem 15.3.1 *For every finite real L, the set*

$$\mathcal{K}_L = \{\nu \in \mathcal{P}(X) : H_\varphi(\nu) \le L\}$$

is weakly compact. Its measures are uniformly absolutely continuous with respect to $\mathrm{d}V$*: for every $\epsilon > 0$ there is a $\delta > 0$ such that*

$$\mathrm{d}V(E) < \delta \quad \Longrightarrow \quad \sup_{\nu \in \mathcal{K}_L} \nu(E) < \epsilon \tag{15.12}$$

for every Borel set E. In particular, writing $\mathrm{d}\nu = h_\nu \mathrm{d}V$, the densities in this set are uniformly integrable in $L^1(\mathrm{d}V)$. On $\mathcal{K}_L$, weak convergence of measures also implies weak convergence of their densities in $L^1(\mathrm{d}V)$.

Proof Weak compactness follows from lower semicontinuity and compactness of $\mathcal{P}(X)$. We may assume that the sublevel set is nonempty, so that $L \ge B_\varphi(0)$. Fix $t > 0$. By Theorem 15.1.2, there is $\delta_t > 0$ such that

$$0 \le \chi \le 1, \quad \chi \in C(X), \quad \int_X \chi \,\mathrm{d}V < \delta_t \quad \Longrightarrow \quad B_\varphi(t\chi) > B_\varphi(0) - 1.$$

Indeed, otherwise there would be a sequence of such functions χ tending to zero in L^1 with $B_\varphi(t\chi) \le B_\varphi(0) - 1$, contrary to that theorem. For $\nu \in \mathcal{K}_L$, the defining supremum gives

$$t \int_X \chi \,\mathrm{d}\nu \le L - B_\varphi(t\chi) < L - B_\varphi(0) + 1.$$

Choose t so large that $(L - B_\varphi(0) + 1)/t < \epsilon/2$. If $\mathrm{d}V(E) < \delta_t/2$, outer regularity gives an open neighborhood O of E with $\mathrm{d}V(O) < \delta_t$. For any compact $K \subset E$, choose a continuous cutoff $0 \le \chi \le 1$ equal to one on K and supported in O. The last inequality gives $\nu(K) < \epsilon/2$, uniformly in $\nu \in \mathcal{K}_L$, and inner regularity yields $\nu(E) \le \epsilon/2 < \epsilon$. This proves (15.12).

In particular, every measure in the sublevel set is absolutely continuous, with a density of integral one. Together with the uniform small-set estimate, this is exactly uniform integrability on the finite measure space $(X, \mathrm{d}V)$.

Finally, suppose that $\nu_j \to \nu$ weakly within the sublevel set. For a bounded measurable G, choose continuous G_k with $|G_k| \le \|G\|_\infty$ and $G_k \to G$ in $\mathrm{d}V$-measure; such approximations exist by Lusin's theorem. Uniform absolute continuity gives

$$\sup_{\sigma \in \mathcal{K}_L} \int_X |G_k - G| \,\mathrm{d}\sigma \longrightarrow 0.$$

To see this, split X into $\{|G_k - G| \le a\}$ and its complement; the integral over the first set is at most a, and the integral over the second is at most $2\|G\|_\infty$ times a uniformly small measure. For fixed k, weak convergence applies to G_k. Letting first $j \to \infty$ and then $k \to \infty$ proves convergence of the integrals against G, which is exactly weak

$L^1(\mathrm{d}V)$ convergence of the densities. In particular, every sequence in the sublevel set has a subsequence whose densities converge weakly in L^1. □

15.4 Bounded measurable densities and stability

The supporting probabilities of continuous approximations of a bounded measurable logarithmic density lie in one sublevel set of H_φ. Uniform integrability then allows both the density and the supporting measure to vary when we pass to the limit in the supporting inequality.

Theorem 15.4.1 *For every $F \in L^\infty(\mathrm{d}V)$ there is a nonempty set of absolutely continuous probability measures, again denoted $\mathcal{A}_\varphi(F)$, characterized by*

$$B_\varphi(G) \le B_\varphi(F) - \int_X (G - F)\,\mathrm{d}\nu \qquad \text{for every } G \in L^\infty(\mathrm{d}V). \tag{15.13}$$

For continuous F, this set agrees with the one defined by (15.3). Formula (15.11) also holds for bounded measurable F, with these measures as its minimizers; there the objective is interpreted as $+\infty$ whenever $H_\varphi(\nu) = +\infty$, and otherwise ν is absolutely continuous, so that the integral of the L^∞ class F is well defined.

Suppose that $F_j, F \in L^\infty(\mathrm{d}V)$ are uniformly bounded and $F_j \to F$ in $L^1(\mathrm{d}V)$, and let $\nu_j \in \mathcal{A}_\varphi(F_j)$. Then the densities of the ν_j are uniformly integrable, and every weak L^1 cluster point belongs to $\mathcal{A}_\varphi(F)$. If the latter is a singleton, the whole sequence converges to it weakly in $L^1(\mathrm{d}V)$.

Proof First, if $H_\varphi(\nu) < \infty$, the measure ν is absolutely continuous by Theorem 15.3.1. A bounded measurable G admits uniformly bounded continuous approximations $G_k \to G$ in $L^1(\mathrm{d}V)$, and absolute continuity together with the common bound gives $\int_X G_k\,\mathrm{d}\nu \to \int_X G\,\mathrm{d}\nu$. Combined with Theorem 15.1.2, this proves

$$H_\varphi(\nu) = \sup_{G \in L^\infty(\mathrm{d}V)} \left(B_\varphi(G) + \int_X G\,\mathrm{d}\nu \right) \tag{15.14}$$

for such ν.

To construct supporting probabilities at F, choose continuous F_j with $|F_j| \le M = \|F\|_\infty$ and $F_j \to F$ in $L^1(\mathrm{d}V)$, and choose $\nu_j \in \mathcal{A}_\varphi(F_j)$. The minimum formula of Proposition 15.3.1 and the Lipschitz bound give

$$H_\varphi(\nu_j) = B_\varphi(F_j) + \int_X F_j\,\mathrm{d}\nu_j \le B_\varphi(0) + 2M.$$

By Theorem 15.3.1, a subsequence converges weakly in L^1 to a probability measure ν. Uniform absolute continuity gives

$$\int_X |F_j - F|\,\mathrm{d}\nu_j \longrightarrow 0,$$

by splitting again at a fixed small positive threshold: the sets where $|F_j - F|$ exceeds it have $\mathrm{d}V$-measure tending to zero. Since F is bounded and measurable, weak L^1 convergence applies to its integral. Lower semicontinuity of H_φ and continuity of B_φ yield

$$H_\varphi(\nu) \le \liminf_j H_\varphi(\nu_j) = B_\varphi(F) + \int_X F \,\mathrm{d}\nu.$$

The reverse inequality follows from (15.14) with $G = F$. Equality, combined with the same supremum formula, proves (15.13) for ν and the minimum formula.

For continuous F, every measure satisfying (15.3) has finite dual value by Proposition 15.3.1, so (15.14) extends its supporting inequality to all bounded measurable tests; the converse inclusion is trivial. Thus the two definitions agree. Finally, an absolutely continuous probability satisfying (15.13) has finite dual value and attains the minimum, so the characterization is exact.

For the stability assertion, we start from the given F_j and ν_j instead of an approximating construction. The common uniform bound again places all ν_j in a single finite sublevel set of H_φ, and the same compactness and limiting argument shows that every weak L^1 cluster point attains the minimum for F. If the set of minimizers is a singleton, compactness forces the whole sequence to converge to its member. □

15.5 Entropy and the closed case

In a closed background, all potentials of an ordinary singularity type have the same mass, and integrating the equation determines the scalar explicitly; its convex dual is then the relative entropy. The variational formula for the entropy also gives estimates in nonclosed backgrounds.

For a Borel probability measure ν absolutely continuous with respect to $\mathrm{d}V$, let h be its nonnegative density and define the *relative entropy*

$$\mathrm{Ent}_{\mathrm{d}V}(\nu) = \int_X h \log h \,\mathrm{d}V, \qquad 0 \log 0 = 0,$$

and set $\mathrm{Ent}_{\mathrm{d}V}(\nu) = +\infty$ if ν is not absolutely continuous. The integral is well defined in $(-\infty, +\infty]$, since $h \log h \ge -\mathrm{e}^{-1}$; it may be negative when $\mathrm{d}V(X) \ne 1$.

Lemma 15.5.1 *For every $\nu \in \mathcal{P}(X)$,*

$$\mathrm{Ent}_{\mathrm{d}V}(\nu) = \sup_{F \in C(X)} \left(\int_X F \,\mathrm{d}\nu - \log \int_X \mathrm{e}^F \,\mathrm{d}V \right).$$

Proof If ν is not absolutely continuous, choose a compact set K with $\mathrm{d}V(K) = 0$ and $\nu(K) > 0$. For $t > 0$, regularity gives a continuous cutoff $0 \le \chi_t \le 1$, equal to one on K, whose support has volume at most e^{-2t}. For $F = t\chi_t$, the expression in the supremum is at least

$$t\nu(K) - \log\bigl(\mathrm{d}V(X) + \mathrm{e}^{-t}\bigr),$$

which tends to infinity with t.

Suppose now that $\nu = h\,\mathrm{d}V$. If its entropy is finite, Jensen's inequality for the logarithm gives

$$\int_X F\,\mathrm{d}\nu - \mathrm{Ent}_{\mathrm{d}V}(\nu) \le \log \int_{\{h>0\}} \mathrm{e}^F\,\mathrm{d}V \le \log \int_X \mathrm{e}^F\,\mathrm{d}V.$$

For infinite entropy this upper bound is automatic. For the opposite inequality, set

$$F_k = \log\bigl(\max\{k^{-1}, \min\{h, k\}\}\bigr), \qquad k \ge 1.$$

Then $\int_X \mathrm{e}^{F_k}\,\mathrm{d}V \to 1$ and $\int_X F_k\,\mathrm{d}\nu \to \mathrm{Ent}_{\mathrm{d}V}(\nu)$, with the value $+\infty$ allowed: the positive parts of the integrands hF_k increase to that of $h\log h$, and their negative parts are dominated by the integrable negative part of $h\log h$. For each fixed k, approximate F_k in $L^1(\mathrm{d}V + \nu)$ by continuous functions with the same bounds; both integrals, including the exponential one, converge to those of F_k. Hence the supremum over continuous functions is at least the value of the expression at F_k, and letting $k \to \infty$ completes the proof. □

Suppose now that θ is a Kähler form. By the closed-background theory of [Xia], all potentials of the ordinary type of φ have the same non-pluripolar mass m_φ, which is positive under the standing hypotheses. For $F \in L^\infty(\mathrm{d}V)$, integrating the equation gives

$$B_\varphi(F) = \log m_\varphi - \log \int_X \mathrm{e}^F\,\mathrm{d}V, \qquad \mathcal{A}_\varphi(F) = \left\{ \frac{\mathrm{e}^F\,\mathrm{d}V}{\int_X \mathrm{e}^F\,\mathrm{d}V} \right\}. \tag{15.15}$$

For the second identity, Jensen's inequality shows, as in Proposition 15.2.4, that the normalized exponential measure is a supporting probability; differentiating in bounded directions and testing the supporting inequality with both signs of the parameter shows that it is the only one.

Proposition 15.5.1 *If θ is Kähler, then*

$$H_\varphi(\nu) = \log m_\varphi + \mathrm{Ent}_{\mathrm{d}V}(\nu).$$

Thus the minimum formula (15.11) *becomes the usual variational formula for the logarithmic integral in* (15.15).

Proof Substitute (15.15) into the defining supremum and apply Lemma 15.5.1. □

The dual functional depends on the reference volume. If $\mathrm{d}V$ is replaced by $\mathrm{d}V' = \mathrm{e}^a\mathrm{d}V$ for a continuous real a, the corresponding functionals satisfy

$$B'_\varphi(F) = B_\varphi(F + a), \qquad H'_\varphi(\nu) = H_\varphi(\nu) - \int_X a\,\mathrm{d}\nu.$$

The first identity follows from the equation, and the second, which also holds when the values are infinite, from the change of variable $G \mapsto G + a$ in the defining supremum. In a nonclosed background, H_φ is still defined by the same supremum, but the total mass need not be constant on an ordinary type, so the entropy computation no longer determines it.

15.6 Entropy bounds

For a Hermitian background and the zero reference, a lower bound for the L^q norm of the density in the equation and an upper bound coming from a Gauduchon trace place B_0 between two logarithmic integrals. Dualizing gives two-sided entropy estimates, which identify the set where H_0 is finite. Throughout this section, $\mathrm{d}V$ is normalized by $\mathrm{d}V(X) = 1$.

Proposition 15.6.1 *Let $\theta = \omega$ be a Hermitian form, and let $\varphi = 0$. There are real constants A and, for every $q > 1$, a_q such that every Borel probability measure ν satisfies*

$$a_q + \frac{1}{q}\operatorname{Ent}_{\mathrm{d}V}(\nu) \le H_0(\nu) \le A + n \operatorname{Ent}_{\mathrm{d}V}(\nu).$$

The inequalities include the value $+\infty$. Thus $H_0(\nu) < \infty$ if and only if ν has finite entropy, and a family of probability measures has uniformly bounded values of H_0 if and only if its entropies are uniformly bounded.

Proof In dimension one, ω is a Kähler form, and Proposition 15.5.1, which rests on (15.15), gives $H_0 = \log \int_X \omega + \operatorname{Ent}_{\mathrm{d}V}$, so the assertions follow. Suppose that $n \ge 2$.

For $G \in C(X)$, apply the lower bound for $\|F\|_q$ in Theorem 10.3.1 to a bounded solution with density $F = \mathrm{e}^{B_0(G)+G}$. It gives a constant $c_q > 0$, independent of G, such that

$$B_0(G) \ge \log c_q - \frac{1}{q}\log \int_X \mathrm{e}^{qG}\,\mathrm{d}V.$$

For the upper bound, fix a smooth Gauduchon metric γ, rescaled so that $\int_X \omega \wedge \gamma^{n-1} = 1$, and write

$$k_\gamma = \left(\frac{\gamma^n}{\mathrm{d}V}\right)^{(n-1)/n}, \qquad m = \min_X k_\gamma > 0.$$

For smooth G, the trace bound (4.3) gives

$$\mathrm{e}^{B_0(G)/n} \int_X \mathrm{e}^{G/n} k_\gamma \,\mathrm{d}V \le 1.$$

Uniform approximation and continuity of B_0 extend this inequality to continuous G. Consequently

$$B_0(G) \le -n \log m - n \log \int_X \mathrm{e}^{G/n}\,\mathrm{d}V.$$

Taking the defining suprema in the two scalar bounds and applying Lemma 15.5.1 with $F = qG$ and $F = G/n$, respectively, proves both inequalities for every probability measure, including infinite values, with $a_q = \log c_q$ and $A = -n \log m$. The finite-domain and bounded-family assertions follow by taking $q = 2$. □

15.6.1 The mass bounds as entropy differences

In a closed background the difference between H_0 and the entropy is constant. In general it measures how much the total Monge–Ampère mass of bounded potentials varies: its infimum and supremum recover the lower and upper masses $v_-(\omega)$ and $v_+(\omega)$ of Definition 6.5.1.

Let $\mathcal{P}_{\mathrm{ent}}(X)$ denote the set of probability measures of finite entropy relative to the fixed smooth probability volume $\mathrm{d}V$. By Proposition 15.6.1, the difference $H_0(\nu) - \mathrm{Ent}_{\mathrm{d}V}(\nu)$ is a finite real number for every ν in this set.

Proposition 15.6.2 *For every Hermitian background ω,*

$$\inf_{\nu \in \mathcal{P}_{\mathrm{ent}}(X)} \big(H_0(\nu) - \mathrm{Ent}_{\mathrm{d}V}(\nu)\big) = \log v_-(\omega),$$
$$\sup_{\nu \in \mathcal{P}_{\mathrm{ent}}(X)} \big(H_0(\nu) - \mathrm{Ent}_{\mathrm{d}V}(\nu)\big) = \log v_+(\omega).$$

The same extrema are obtained over smooth strictly positive probability measures. Here $\log 0 = -\infty$ and $\log(+\infty) = +\infty$. Thus the difference is bounded above if and only if X has the bounded mass property, and bounded below if and only if ω has positive lower mass.

Proof Write $Z_G = \int_X \mathrm{e}^G \,\mathrm{d}V$. A bounded solution for $G \in C(X)$ has mass $\mathrm{e}^{B_0(G)} Z_G$. If $v_-(\omega) > 0$, the lower mass bound gives

$$B_0(G) \geq \log v_-(\omega) - \log Z_G.$$

Taking the defining supremum for H_0 and using Lemma 15.5.1 gives $H_0 - \mathrm{Ent}_{\mathrm{d}V} \geq \log v_-(\omega)$ on $\mathcal{P}_{\mathrm{ent}}(X)$. In the same way, if $v_+(\omega) < \infty$, the upper mass bound gives $H_0 - \mathrm{Ent}_{\mathrm{d}V} \leq \log v_+(\omega)$. These bounds hold trivially when $v_-(\omega) = 0$ or $v_+(\omega) = +\infty$.

To prove sharpness, first take a smooth real G and its Gibbs probability $\nu_G = Z_G^{-1} \mathrm{e}^G \,\mathrm{d}V$, which has finite entropy. Testing the supremum defining H_0 with G gives

$$H_0(\nu_G) - \mathrm{Ent}_{\mathrm{d}V}(\nu_G) \geq B_0(G) + \log Z_G.$$

In the other direction, let σ_G be the smooth strictly positive Gauduchon adjoint probability of Theorem 15.2.3. It lies in $\mathcal{A}_0(G)$, so its dual value is $B_0(G) + \int_X G \,\mathrm{d}\sigma_G$, and Lemma 15.5.1 yields

$$H_0(\sigma_G) - \mathrm{Ent}_{\mathrm{d}V}(\sigma_G) \leq B_0(G) + \log Z_G.$$

As G runs over smooth real functions, the masses $\mathrm{e}^{B_0(G)}Z_G$ run over the masses $\int_X(\omega+\mathrm{dd^c}u)^n$ of all smooth u with $\omega+\mathrm{dd^c}u>0$, since such a u solves the equation for $G=\log((\omega+\mathrm{dd^c}u)^n/\mathrm{d}V)$. By Theorem 1.11.1, the mass of every bounded ω-plurisubharmonic function is a limit of such masses. Hence the infimum and supremum of $\mathrm{e}^{B_0(G)}Z_G$ over smooth G are $v_-(\omega)$ and $v_+(\omega)$. Since ν_G and σ_G are smooth and strictly positive, the last two inequalities prove sharpness on this smaller domain, including the cases $v_-(\omega)=0$ and $v_+(\omega)=+\infty$. The two equivalences follow. □

The difference does not depend on the smooth positive reference volume. For smooth real a, replacing $\mathrm{d}V$ by $\mathrm{d}V'=\mathrm{e}^a\mathrm{d}V$ changes both $H_0(\nu)$ and $\mathrm{Ent}(\nu)$ by $-\int_X a\,\mathrm{d}\nu$, by the transformation formula preceding Proposition 15.6.1, and finiteness of the entropy is unchanged because a is bounded. Similarly, if h is a smooth real function and $\omega+\mathrm{dd^c}h$ is also Hermitian, transporting bounded solutions by $u\mapsto u-h$ preserves B_0, and hence this difference. Finally, the difference is constant on $\mathcal{P}_{\mathrm{ent}}(X)$ exactly when $v_-(\omega)=v_+(\omega)$, that is, when all bounded ω-plurisubharmonic functions have the same mass.

15.6.2 Entropy for a prescribed ordinary type

Return to the standing setting: θ is semipositive and big, and φ is a model reference, with $\varepsilon\in(0,1)$ as in (13.20). The part $(1-\varepsilon)\theta$ of the background left over by the smaller-background envelope gives a uniform lower bound for the density norm, while comparison in a larger Hermitian background gives the upper bound. Together they extend the entropy estimates to the prescribed type.

Corollary 15.6.1 *For every $q>1$ there is a finite real a_q, and there is a finite real A, such that*

$$a_q+\frac{1}{q}\,\mathrm{Ent}_{\mathrm{d}V}(\nu)\le H_\varphi(\nu)\le A+n\,\mathrm{Ent}_{\mathrm{d}V}(\nu)$$

for every Borel probability measure ν, including infinite values. Thus $H_\varphi(\nu)$ is finite exactly when ν has finite entropy, and uniformly bounded dual values are equivalent to uniformly bounded entropies. For fixed θ and ε, the constants can be chosen independently of the model reference φ.

Proof For $G\in C(X)$, let $u\sim\varphi$ solve the equation with density $c\mathrm{e}^G$, where $c=\mathrm{e}^{B_\varphi(G)}$. The lower bound $b_q>0$ of Lemma 14.11.1 for the L^q norm of the density gives $c\|\mathrm{e}^G\|_q\ge b_q$, hence

$$B_\varphi(G)\ge\log b_q-\frac{1}{q}\log\int_X\mathrm{e}^{qG}\,\mathrm{d}V.$$

For the upper bound, choose a Hermitian form $\Omega\ge\theta$, and let $B_{\Omega,0}$ and $H_{\Omega,0}$ denote its normalization scalar and dual functional for the zero reference. Let v be a bounded solution for G in this background; being bounded, it has a smaller-background

envelope $P_{\delta\Omega}(v) \geq \inf_X v$ for every $0 < \delta < 1$. Moreover $u \in \mathrm{PSH}(X, \Omega)$, $u \preceq v$, and positivity gives

$$\mathrm{MA}^{\mathrm{ext}}_{\Omega}(u) \geq \mathrm{MA}^{\mathrm{ext}}_{\theta}(u) = c\mathrm{e}^{G}\,\mathrm{d}V.$$

If $c > \mathrm{e}^{B_{\Omega,0}(G)}$, the singular strict domination principle, applied in the background Ω to v and $u + t$ for every real t, would give $v \geq u + t$ for all t, which is impossible. Hence $B_{\varphi} \leq B_{\Omega,0}$, and therefore $H_{\varphi} \leq H_{\Omega,0}$; Proposition 15.6.1 now gives the upper bound.

Taking the defining supremum in the lower scalar estimate and applying Lemma 15.5.1 with $F = qG$ gives the lower bound for every probability measure, including infinite values, with $a_q = \log b_q$. The finite-domain and bounded-family assertions follow by taking $q = 2$. Finally, Lemma 14.11.1 is uniform in the reference for fixed θ and ε, and the upper bound uses only Ω, which proves the last assertion.□

This gives compactness when the reference varies. Let the model references φ_j satisfy the smaller-background condition with the same ε, let $G_j \in L^{\infty}(\mathrm{d}V)$ satisfy $\|G_j\|_{\infty} \leq M$ for a fixed constant M, and choose $\nu_j \in \mathcal{A}_{\varphi_j}(G_j)$. With Ω as in the proof,

$$H_{\varphi_j}(\nu_j) = B_{\varphi_j}(G_j) + \int_X G_j\,\mathrm{d}\nu_j \leq B_{\Omega,0}(0) + 2M.$$

The uniform lower estimate of Corollary 15.6.1 bounds their entropies, and the Hermitian upper estimate then places all ν_j in a single finite sublevel set of $H_{\Omega,0}$. Hence Theorem 15.3.1, applied in the background Ω, gives weak compactness and uniform integrability of their densities, and every weak limit has finite entropy. Identifying such a limit as a supporting probability for a limiting reference requires further information.

15.7 Changing the prescribed singularities

A more singular reference has a smaller normalization scalar. A competitor built from the smaller-background envelope also gives a quantitative comparison with the zero reference, uniform over all logarithmic densities. In this section the reference varies among the model potentials satisfying (13.20) for the fixed semipositive big background θ, and B_0, H_0 denote the functionals of the zero reference in the same background.

Proposition 15.7.1 *Let φ, ψ satisfy (13.20). If $\varphi \preceq \psi$, then $B_\varphi \le B_\psi$ and $H_\varphi \le H_\psi$. Moreover, if $0 < \varepsilon < 1$ and $P_{\varepsilon\theta}(\varphi) \not\equiv -\infty$, then*

$$B_0(G) + n\log(1-\varepsilon) \le B_\varphi(G) \le B_0(G) \qquad (G \in C(X)),$$

and

$$H_0(\nu) + n\log(1-\varepsilon) \le H_\varphi(\nu) \le H_0(\nu) \qquad (\nu \in \mathcal{P}(X)).$$

The dual inequalities include infinite values.

Proof Fix G, and let u_φ, u_ψ solve the equations in the ordinary types of φ and ψ, with constants c_φ, c_ψ. Then $u_\varphi \preceq u_\psi$. If $c_\varphi > c_\psi$, the singular strict domination principle applied to u_ψ and $u_\varphi + t$ would give $u_\psi \ge u_\varphi + t$ for every real t, which is impossible at a point where both are finite. This proves the monotonicity of B, and taking the defining supremum gives the monotonicity of H. Since $\varphi \preceq 0$ and the zero potential is itself a model reference, this also proves both upper bounds.

For the lower bound, let v be a bounded solution for G with the zero reference, with constant c_0, and put

$$h = P_{\varepsilon\theta}(\varphi) + (1-\varepsilon)v.$$

The two summands are $\varepsilon\theta$- and $(1-\varepsilon)\theta$-plurisubharmonic, respectively, so positivity and homogeneity give

$$\mathrm{MA}_\theta^{\mathrm{ext}}(h) \ge (1-\varepsilon)^n \mathrm{MA}_\theta(v) = (1-\varepsilon)^n c_0 \mathrm{e}^G \,\mathrm{d}V.$$

As in the proof of Lemma 14.11.1, this inequality is justified first on finite truncation levels and then off the pole set of $P_{\varepsilon\theta}(\varphi)$, which has zero smooth volume. Also $h \preceq u_\varphi$. If $c_\varphi < (1-\varepsilon)^n c_0$, strict domination would force $u_\varphi \ge h + t$ for every t. Thus $c_\varphi \ge (1-\varepsilon)^n c_0$. Taking logarithms proves the scalar bound, and taking the defining suprema proves the dual bound. □

15.7.1 Uniform comparison of the scalar functionals

When two scalar functionals are uniformly close, their supporting probabilities are close as well. To make this precise, define for two model references φ, ψ in the preceding setting

$$\Delta(\varphi, \psi) = \sup_{G \in C(X)} |B_\varphi(G) - B_\psi(G)|. \tag{15.16}$$

The comparison with B_0 in Proposition 15.7.1 makes this number finite for every such pair. It is a pseudometric: symmetry, vanishing on the diagonal and the triangle inequality follow from the properties of the uniform norm. Distinct singularity types can have distance zero, as Example 15.10.1 shows.

Proposition 15.7.2 *For these model references,*

$$\Delta(\varphi,\psi) = \sup_{\mathrm{Ent}_{\mathrm{d}V}(\nu)<\infty} |H_\varphi(\nu) - H_\psi(\nu)|,$$

where the supremum is over probability measures of finite entropy. The same value is obtained if (15.16) *uses all bounded measurable G, and it does not depend on the smooth positive reference volume.*

Proof By Corollary 15.6.1, both duals are finite exactly on the probability measures of finite entropy; rescaling the reference volume to have mass one does not affect finiteness. A uniform bound for $|B_\varphi - B_\psi|$ passes to the defining suprema, so the supremum in the statement is at most $\Delta(\varphi,\psi)$. Conversely, denote that supremum by D. If $\nu \in \mathcal{A}_\psi(G)$, then ν has finite entropy, and the dual minimum formula gives

$$B_\varphi(G) \le H_\varphi(\nu) - \int_X G\,\mathrm{d}\nu \le B_\psi(G) + D.$$

Interchanging the references gives the opposite inequality, so $\Delta(\varphi,\psi) \le D$.

For bounded measurable G, take continuous approximations with the same uniform bound converging in $L^1(\mathrm{d}V)$; the continuity theorem Theorem 15.1.2, applied to each of the two references, extends the scalar bound to G. Finally, a change of volume $\mathrm{d}V' = \mathrm{e}^a \mathrm{d}V$ replaces each $B(G)$ by $B(G+a)$, and translation by $a \in C(X)$ is a bijection of the space of tests, so the supremum is unchanged. □

Proposition 15.7.3 *Let φ_j, φ be model references in the same background with $\Delta(\varphi_j,\varphi) \to 0$. Let G_j, G be uniformly bounded measurable functions with $G_j \to G$ in $L^1(\mathrm{d}V)$, and choose $\nu_j \in \mathcal{A}_{\varphi_j}(G_j)$. Then the densities of the ν_j are uniformly integrable, every weak cluster point of (ν_j) belongs to $\mathcal{A}_\varphi(G)$, and a weakly convergent subsequence also converges weakly in L^1. If $\mathcal{A}_\varphi(G)$ is a singleton, the whole sequence converges to it in both senses.*

Proof Write $\delta_j = \Delta(\varphi_j,\varphi)$. The bounds $|B_{\varphi_j} - B_\varphi| \le \delta_j$ and $|H_{\varphi_j} - H_\varphi| \le \delta_j$, together with the identity $H_{\varphi_j}(\nu_j) = B_{\varphi_j}(G_j) + \int_X G_j\,\mathrm{d}\nu_j$, give

$$0 \le H_\varphi(\nu_j) - \int_X G_j\,\mathrm{d}\nu_j - B_\varphi(G_j) \le 2\delta_j.$$

If $\|G_j\|_\infty \le M$, then $H_\varphi(\nu_j) \le B_\varphi(0) + 2M + 2\delta_j$, so all the measures lie in one finite sublevel set of H_φ. By Theorem 15.3.1, their densities are uniformly integrable, and a weakly convergent subsequence also converges weakly in L^1.

Let ν be the limit of such a subsequence. Uniform integrability, the common bound and convergence in measure give $\int_X |G_j - G|\,\mathrm{d}\nu_j \to 0$; weak L^1 convergence applies to the bounded function G, and Theorem 15.1.2 gives $B_\varphi(G_j) \to B_\varphi(G)$. Lower semicontinuity of H_φ in the last inequality yields

$$H_\varphi(\nu) - \int_X G\,\mathrm{d}\nu - B_\varphi(G) \le 0.$$

The minimum formula for bounded measurable densities in Theorem 15.4.1 gives the reverse inequality, and equality means exactly that $v \in \mathcal{A}_\varphi(G)$. When this set is a singleton, compactness gives convergence of the whole sequence. □

The smaller-background comparison gives an explicit family of references converging to the zero reference.

Corollary 15.7.1 *Let the model references φ_j satisfy $P_{\varepsilon_j\theta}(\varphi_j) \not\equiv -\infty$, where $0 < \varepsilon_j < 1$ and $\varepsilon_j \to 0$. Then $B_{\varphi_j} \to B_0$ uniformly on $C(X)$. Let $G_j, G \in C(X)$ with $G_j \to G$ uniformly, and let $v_j \in \mathcal{A}_{\varphi_j}(G_j)$. Then every weak cluster point of (v_j) belongs to $\mathcal{A}_0(G)$, the densities of the v_j are uniformly integrable, and a weakly convergent subsequence also converges weakly in $L^1(\mathrm{d}V)$. If $\mathcal{A}_0(G)$ is a singleton, the whole sequence converges to it in both senses.*

Proof Put $\delta_j = -n\log(1-\varepsilon_j) \to 0$. Proposition 15.7.1 gives $\Delta(\varphi_j, 0) \le \delta_j$, which is the uniform convergence of B_{φ_j} to B_0 on $C(X)$. The assertions about supporting probabilities follow from Proposition 15.7.3 with the zero reference as limit. □

For ordinary divisorial types, a comparison of positive residual forms gives a geometric criterion for this convergence of functionals, as the next two sections show. We do not know general convergence criteria for references with degenerate residuals or with arbitrary singularities.

15.8 Varying positive backgrounds

A two-sided inequality between two Hermitian forms compares their normalization scalars uniformly in the logarithmic density. This turns geometric convergence of backgrounds into the uniform comparison of functionals used above.

From this section on, each section specifies its own background and reference. Here we vary a Hermitian form β on X and use the zero reference. Write B_β, H_β and $\mathcal{A}_\beta$ for the normalization scalar, its dual functional and the supporting sets, defined as above with $\theta = \beta$ and $\varphi = 0$. For two such backgrounds, set

$$d(B_\beta, B_{\beta'}) = \sup_{F \in L^\infty(\mathrm{d}V)} |B_\beta(F) - B_{\beta'}(F)|.$$

The supremum ranges over all bounded measurable tests, with no common bound on their norms.

Theorem 15.8.1 *Suppose $0 < \varepsilon < 1$ and $(1-\varepsilon)\beta \le \beta' \le (1+\varepsilon)\beta$. For every bounded measurable F,*

$$n\log(1-\varepsilon) \le B_{\beta'}(F) - B_\beta(F) \le n\log(1+\varepsilon). \tag{15.17}$$

In particular, $d(B_\beta, B_{\beta'}) \le -n\log(1-\varepsilon)$. The same conclusion holds if the two inequalities between forms are satisfied by positive representatives $\beta + \mathrm{dd^c}h$ and $\beta' + \mathrm{dd^c}h'$, with h, h' smooth real functions.

Proof First let F be smooth, and let v, v' be smooth solutions in the two backgrounds. At a maximum point of $v' - (1+\varepsilon)v$,

$$0 < \beta' + \mathrm{dd^c} v' \le (1+\varepsilon)(\beta + \mathrm{dd^c} v).$$

Taking determinants and canceling $\mathrm{e}^F \mathrm{d}V$ gives the upper bound. At a minimum point of $v' - (1-\varepsilon)v$, the reverse inequality between forms gives the lower bound. For bounded measurable F, choose smooth uniformly bounded approximations converging in L^1 and apply Theorem 15.1.2 in each of the two backgrounds. Finally, the correspondence $v \mapsto v - h$ preserves both boundedness and the current, so $B_{\beta+\mathrm{dd^c}h} = B_\beta$ whenever both backgrounds are positive. This proves the assertion about representatives. □

Corollary 15.8.1 *Let β_j be Hermitian forms with $(1-\varepsilon_j)\beta \le \beta_j \le (1+\varepsilon_j)\beta$, where $0 < \varepsilon_j < 1$ and $\varepsilon_j \to 0$. Suppose that $F_j \to F$ in $L^1(\mathrm{d}V)$ with a common L^∞ bound. Then $B_{\beta_j}(F_j) \to B_\beta(F)$. For any $\nu_j \in \mathcal{A}_{\beta_j}(F_j)$, the densities are uniformly integrable, and every subsequence has a further subsequence converging weakly in L^1 to an element of $\mathcal{A}_\beta(F)$. If this set is a singleton, which is the case in particular when F is smooth, the whole sequence converges to it weakly in L^1 and as probability measures.*

Proof Put $\delta_j = -n\log(1-\varepsilon_j)$. The scalar assertion follows from (15.17) and Theorem 15.1.2 in the fixed background β. Taking suprema over tests gives the inequalities, valid also for infinite values,

$$H_{\beta_j} \le H_\beta + \delta_j, \qquad H_\beta \le H_{\beta_j} + \delta_j.$$

In particular, the two duals are finite on the same measures, and the identity $H_{\beta_j}(\nu_j) = B_{\beta_j}(F_j) + \int_X F_j \,\mathrm{d}\nu_j$ gives

$$0 \le H_\beta(\nu_j) - B_\beta(F_j) - \int_X F_j \,\mathrm{d}\nu_j \le 2\delta_j.$$

If $\|F_j\|_\infty \le M$, this puts the measures in the fixed sublevel set $\{H_\beta \le B_\beta(0) + 2M + 2\sup_j \delta_j\}$, to which Theorem 15.3.1 applies. For a weak L^1 cluster point, uniform integrability gives $\int_X |F_j - F|\,\mathrm{d}\nu_j \to 0$, and lower semicontinuity in the last inequality, together with the minimum formula of Theorem 15.4.1, identifies the limit as a supporting probability at F. Compactness gives convergence of the whole sequence when that supporting probability is unique, and Theorem 15.2.3 gives uniqueness for smooth F. □

Smooth changes of the background also control the potentials, because the inverse of the linearized equation used in Proposition 9.3.1 remains available when the form itself is included among the parameters.

Proposition 15.8.1 *Let β_j, β be Hermitian forms and F_j, F smooth real functions with $\beta_j \to \beta$ and $F_j \to F$ in C^∞. Then the solutions v_j for (β_j, F_j) normalized by $\int_X v_j \, \mathrm{d}V = 0$ converge in C^∞ to the similarly normalized solution v for (β, F), and their scalars converge as well.*

Proof Fix $k \geq 0$ and $0 < \alpha < 1$. On the open set where $\eta + \mathrm{dd^c} w > 0$, consider the smooth map

$$(\eta, G, w, a) \longmapsto \log \frac{(\eta + \mathrm{dd^c} w)^n}{\mathrm{d}V} - a - G$$

defined for $C^{k,\alpha}$ forms η and functions G, mean-zero $C^{k+2,\alpha}$ potentials w and $a \in \mathbb{R}$, with values in $C^{k,\alpha}$. At the limiting solution its derivative in (w, a) is $(h, q) \mapsto \Delta_\Omega h - q$, where $\Omega = \beta + \mathrm{dd^c} v$ and $\Delta_\Omega h = n \mathrm{dd^c} h \wedge \Omega^{n-1}/\Omega^n$. Given a target g, choose $q = -\int_X g \, \mathrm{d}\mu_v$, where μ_v is the adjoint probability of Proposition 4.8.1. The Fredholm alternative then gives a unique mean-zero h with $\Delta_\Omega h = g + q$, and the inverse is bounded as in Proposition 9.3.1. In dimension one this is the Fredholm alternative for the Poisson equation.

The implicit function theorem gives a local branch of solutions depending continuously on the parameters in these spaces. For smooth parameters, uniqueness of bounded solutions modulo constants, Corollary 11.4.1, identifies this branch with the global smooth solution. Thus $v_j \to v$ in $C^{k+2,\alpha}$ for every k, which proves the assertion. □

The smooth adjoint probabilities determine the functional up to its value at zero. If $\nu_{\beta,F}$ denotes the unique supporting probability at a smooth F, integrating the derivative of Theorem 15.2.3 along the path $s \mapsto sF$ gives

$$B_\beta(F) = B_\beta(0) - \int_0^1 \int_X F \, \mathrm{d}\nu_{\beta, sF} \, \mathrm{d}s. \tag{15.18}$$

Here the derivative is continuous along the path by the implicit function theorem. Consequently, two Hermitian backgrounds on the same X, with the same $\mathrm{d}V$, have the same functional on bounded measurable tests if and only if their values at zero and all their adjoint probabilities at smooth tests agree. One direction follows by differentiation; the other follows from (15.18) for smooth tests and from bounded L^1 approximation for the remaining tests.

15.9 Divisorial types and moving sections

For a reference given by logarithms of holomorphic sections, removing its divisorial part identifies its ordinary singularity type with the bounded potentials of the residual background. The normalization scalar therefore depends only on the residual form, whereas convergence of the full potentials also requires control of the sections defining the divisors.

In this section, θ is a smooth real $(1,1)$-form on X. Fix finitely many holomorphic line bundles L_r on X with smooth Hermitian metrics h_r, nonzero holomorphic sections s_r, and weights $t_r > 0$. Put

$$\varphi = \sum_r t_r \log |s_r|^2_{h_r}, \qquad \Gamma = \sum_r t_r \operatorname{div}(s_r), \qquad \beta = \theta - \sum_r t_r c_1(L_r, h_r),$$

where $c_1(L_r, h_r)$ is the Chern curvature form, and assume that the residual form β is positive. The empty family is allowed, with $\varphi = 0$ and $\beta = \theta$.

Theorem 15.9.1 *The ordinary singularity type of φ is described by*

$$\{u \in \mathrm{PSH}(X,\theta) : u \sim \varphi\} = \{\varphi + w : w \in \mathrm{PSH}(X,\beta) \cap L^\infty(X)\},$$

and for each such w,

$$\mathrm{MA}^{\mathrm{ext}}_\theta(\varphi + w) = (\beta + \mathrm{dd^c} w)^n. \tag{15.19}$$

For every bounded measurable F, the equation (15.1) in this ordinary type has a unique constant and a solution unique modulo constants. Its normalization scalar $B_{\theta,[\varphi]}$ satisfies

$$B_{\theta,[\varphi]}(F) = B_\beta(F),$$

so its dual functional and supporting sets coincide with H_β and $\mathcal{A}_\beta$.

Proof The Poincaré–Lelong formula gives $\theta + \mathrm{dd^c}\varphi = [\Gamma] + \beta$, so every function on the right is θ-plurisubharmonic and has the type of φ. Conversely, let $u \in \mathrm{PSH}(X,\theta)$ with $u \sim \varphi$. Then u has the same generic Lelong numbers as φ along the components of Γ, namely the coefficients of Γ, and Lemma 1.17.1 gives

$$\theta + \mathrm{dd^c} u - [\Gamma] \geq 0.$$

The locally integrable difference $w = u - \varphi$ therefore has a β-plurisubharmonic representative. It is bounded off the divisor because $u \sim \varphi$, and the local submean property preserves both bounds across the divisor. Since u and $\varphi + w$ agree almost everywhere, they are equal as quasi-plurisubharmonic functions.

Off the divisor, the currents $\theta + \mathrm{dd^c}(\varphi + w)$ and $\beta + \mathrm{dd^c} w$ agree, and locality identifies their Monge–Ampère products there. The extended measure on the left gives the divisor zero mass, and so does the bounded product on the right, which is finite and charges no analytic set by Section 1.7. This proves (15.19). In the background β, the equation with bounded density has a continuous solution and a unique constant by Theorem 10.1.1 and Proposition 10.6.1. The density e^F is bounded above and below by positive constants, so Corollary 11.4.1 gives uniqueness modulo constants. The correspondence transfers these assertions to the whole ordinary type and identifies the functionals. □

In particular, the comparison of backgrounds and the stability of supporting probabilities in Theorem 15.8.1 and Corollary 15.8.1 apply whenever the positive residual forms satisfy the two-sided inequalities there; the location of the divisors

does not enter these estimates. This statement concerns ordinary types. To interpret it in terms of model references, one also needs the envelope $P_\theta[\varphi]$ to differ from φ by a bounded function. For a Hermitian θ, Lemma 15.9.1 below proves this bounded difference and the smaller-background model condition.

For a fixed positive residual β, uniformly bounded $F_j \to F$ in L^1 give uniform convergence of the residual solutions normalized by $\sup_X v_j = 0$. Indeed, continuity of the scalar gives uniformly bounded densities $e^{B_\beta(F_j)+F_j}$ converging in every L^p, $p < \infty$. The compactness theorem Theorem 10.3.2 gives uniform convergence of subsequences, continuity of bounded products identifies the limiting equation, and Corollary 11.4.1 identifies every limit. Subtracting the means gives the same conclusion for solutions normalized to have mean zero.

Theorem 15.9.2 *Keep the line bundles and metrics fixed. Let nonzero sections s_{jr} converge to $s_r \neq 0$ in the finite-dimensional spaces of global sections, and let positive weights satisfy $t_{jr} \to t_r > 0$. Given Hermitian forms β_j, define φ_j and $\theta_j = \beta_j + \sum_r t_{jr} c_1(L_r, h_r)$ by the preceding formulas. Suppose either that $\beta_j \to \beta$ in C^∞ for a Hermitian form $\beta > 0$ and $F_j \to F$ in C^∞, or that $\beta_j = \beta$ for all j and the tests F_j converge to F in L^1 with a common L^∞ bound. Then $\varphi_j \to \varphi$ in L^1, and the solutions $u_j \sim \varphi_j$ for (θ_j, F_j), normalized by $\sup_X u_j = 0$, converge in L^1 to the similarly normalized solution $u \sim \varphi$. For the residual solutions v_j normalized to have mean zero, one also has*

$$\sup_X(\varphi_j + v_j) \longrightarrow \sup_X(\varphi + v).$$

The residuals converge smoothly in the first regime and uniformly in the second.

Proof The convergence of the residual solutions follows from Proposition 15.8.1 in the first case and from the preceding compactness argument in the second. The fixed metrics and bounded weights give a common smooth lower bound for $\mathrm{dd}^c\varphi_j$. The convergent sections give a common upper bound for φ_j and convergence at a point outside all limiting divisors, so the suprema of the φ_j are bounded above and below. By Theorem 1.4.1, every subsequence has a further subsequence converging in L^1. Off the limiting divisors, convergence of the sections and weights gives local uniform convergence to φ; since those divisors have zero volume, every L^1 cluster point equals φ. Thus $\varphi_j \to \varphi$ in $L^1(X)$.

Put $C_j = \sup_X(\varphi_j + v_j)$ and $C = \sup_X(\varphi + v)$. The sums converge in L^1 and have a common smooth lower bound for their complex Hessians, since $\mathrm{dd}^c v_j \geq -\beta_j$ and the residual forms are uniformly bounded. Applying Lemma 1.4.1 at maximum points gives $\limsup_j C_j \leq C$. A maximum point of $\varphi + v$ lies off the poles of φ, and evaluation there, using local uniform convergence, gives $\liminf_j C_j \geq C$.

It follows that $u_j = \varphi_j + v_j - C_j \to \varphi + v - C = u$ in L^1. For an empty family of divisors, the assertion reduces to the convergence of the residual solutions and of their suprema. □

15.9.1 One-sided divisorial classes and sharp thresholds

The ordinary-type correspondence extends to potentials with additional poles. It then identifies the largest subsolution coefficient in the whole one-sided class, even for merely integrable data. For smooth positive data, the prescribed divisor causes a strict loss relative to the global coefficient.

Keep the divisorial setting above, assume also that θ is a Hermitian form and $n \geq 2$, and subtract a constant from φ so that $\sup_X \varphi = 0$. Write $S = \operatorname{Supp} \Gamma$ and $\psi = P_\theta[\varphi]$. For a nonempty class $\mathcal{A} \subset \mathrm{PSH}(X, \theta)$ and nonzero $0 \leq f \in L^1(\mathrm{d}V)$, define

$$b_{\theta,\mathcal{A}}(f) = \sup\{c \geq 0 : \text{some } u \in \mathcal{A} \text{ satisfies } \mathrm{MA}_\theta^{\mathrm{ext}}(u) \geq c f \, \mathrm{d}V\}.$$

The three classes considered here are

$$\begin{aligned} \mathcal{A}_{\preceq} &= \{u \in \mathrm{PSH}(X, \theta) : u \preceq \varphi\}, \\ \mathcal{A}_{\sim} &= \{u \in \mathrm{PSH}(X, \theta) : u \sim \varphi\}, \\ \mathcal{A}_{\mathrm{env}} &= \mathcal{E}_{\mathrm{env}}(X, \theta, \psi). \end{aligned}$$

The following lemma supplies the genuine reference ψ used in the last definition.

Lemma 15.9.1 *The map $w \mapsto \varphi + w$ is a bijection from $\mathrm{PSH}(X, \beta)$ onto $\mathcal{A}_{\preceq}$, and*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(\varphi + w) = \mathrm{MA}_\beta^{\mathrm{ext}}(w).$$

Its bounded members correspond to $\mathcal{A}_{\sim}$. The envelope ψ is genuine, satisfies $\varphi \leq \psi \leq \varphi + K$ for some finite K, meets the model condition (13.20), and

$$\mathcal{A}_{\sim} \subset \mathcal{A}_{\mathrm{env}} \subset \mathcal{A}_{\preceq}.$$

Proof If $u \preceq \varphi$, its generic Lelong numbers dominate the coefficients of Γ. By Lemma 1.17.1, $\theta + \mathrm{dd}^{\mathrm{c}} u - [\Gamma] \geq 0$. The locally integrable distribution $w = u - \varphi$ therefore has a canonical β-psh representative. Off S it equals the difference and is bounded above. The identity $u = \varphi + w$ holds almost everywhere, hence everywhere for the canonical quasi-psh functions. Conversely, $w \in \mathrm{PSH}(X, \beta)$ has finite supremum, and

$$\theta + \mathrm{dd}^{\mathrm{c}}(\varphi + w) = \beta + \mathrm{dd}^{\mathrm{c}} w + [\Gamma] \geq 0, \qquad \varphi + w \preceq \varphi.$$

These maps are inverse. The bounded correspondence is Theorem 15.9.1. Off S the currents agree; locality of the extended products identifies their measures there. Both measures give the analytic set S zero mass by Theorem 6.1.1, even when w has additional poles or infinite mass. This proves the measure identity on X without subtracting infinite pointwise values.

For an envelope competitor $v \le 0$ with $v \preceq \varphi$, the corresponding $w = v - \varphi$ satisfies $w \le -\varphi$ off S. Hence

$$\int_X w^+ \, \mathrm{d}V \le \int_X (-\varphi) \, \mathrm{d}V < \infty,$$

uniformly in v. On a fixed finite cover by inner and outer coordinate balls, add smooth quadratic corrections making w locally psh. Submean at a point attaining $\sup_X w$, with uniform correction and volume-ratio bounds, gives $\sup_X w \le C_1 \int_X w^+ \, \mathrm{d}V + C_2 \le K$. Thus $v \le \varphi + K$ canonically. The function φ itself is a competitor, so the ordinary envelope construction gives a genuine θ-psh function between φ and $\varphi + K$. The upper bound survives upper regularization because $\varphi + K$ is upper semicontinuous. Ordinary equivalence gives $P_\theta[\psi] = P_\theta[\varphi] = \psi$. For $\varepsilon < 1$ sufficiently close to one, $\beta - (1-\varepsilon)\theta > 0$, so φ is an $\varepsilon\theta$-psh competitor below ψ. Hence $P_{\varepsilon\theta}(\psi)$ is not identically $-\infty$, as required in (13.20).

If $u \sim \varphi \sim \psi$, choose $K_u \ge 0$ with $\psi - K_u \le u$. For each $t \ge 1$, the θ-psh function $a_t = \psi - tK_u$ obeys

$$t^{-1} a_t + (1 - t^{-1})\psi = \psi - K_u \le u.$$

This proves relative envelope-class membership in Definition 13.4.1, including the convention at $t = 1$ and common poles. The other containment follows from its defining order $u \preceq \psi \sim \varphi$. □

Theorem 15.9.3 *For every nonzero nonnegative $f \in L^1(\mathrm{d}V)$,*

$$b_{\theta,\mathcal{A}_\preceq}(f) = b_\beta(f),$$

and this coefficient is attained. If f is smooth and strictly positive, then

$$b_{\theta,\mathcal{A}_\sim}(f) = b_{\theta,\mathcal{A}_{\mathrm{env}}}(f) = b_{\theta,\mathcal{A}_\preceq}(f) = c_\beta(f),$$

with an exact finite equation attained in the ordinary type of φ. If also $\Gamma \ne 0$, then

$$0 < c_\beta(f) < c_\theta(f) = b_\theta(f).$$

Proof The correspondence lemma and Theorem 14.27.1 for the Hermitian form β prove the first assertion, including attainment. This assertion allows additional poles and excess or infinite mass. For smooth positive f, Theorem 9.1.1 gives a smooth w with $\beta + \mathrm{dd}^{\mathrm{c}} w > 0$ and $(\beta + \mathrm{dd}^{\mathrm{c}} w)^n = c_\beta(f) f \, \mathrm{d}V$. The potential $\varphi + w$ belongs to the ordinary type and hence to all three classes. The class containments and the first assertion give equality of their coefficients; bounded-data normalization identifies $b_\beta(f) = c_\beta(f)$. The exact measure is finite.

It remains to prove strictness. Let v be the smooth solution for θ, and put $\sigma = \theta + \mathrm{dd}^{\mathrm{c}} v, \eta = \beta + \mathrm{dd}^{\mathrm{c}} w$. The one-sided subsolution gives $c_\beta(f) \le b_\theta(f) = c_\theta(f)$. If equality held, then on $X \setminus S$ the smooth function $a = \varphi + w - v$ would satisfy

$$\mathrm{dd^c} a = \eta - \sigma, \qquad \mathrm{dd^c} a \wedge Q = 0, \qquad Q = \sum_{j=0}^{n-1} \eta^j \wedge \sigma^{n-1-j}.$$

The form Q is smooth and strictly positive, so it defines a real second-order operator L with positive definite principal matrix and no zeroth-order term. Also $a \to -\infty$ near S, so its maximum is attained inside a component U of $X \setminus S$. The strong maximum principle makes a constant on U. To recall its local argument, put $z = \max_U a - a \geq 0$. If a positive region of z had a boundary zero inside U, choose a ball in that region touching the zero set, with closure in a coordinate chart. On its outer half-annulus, the barrier $e^{-A|x-y|^2} - e^{-AR^2}$ has strictly positive L for large A. A sufficiently small multiple lies below z on the two boundary spheres. A negative interior minimum of the difference would have nonnegative L, whereas its equation gives strictly negative L. Thus the comparison holds throughout the annulus and gives a positive inward derivative at the touching zero, contradicting $\nabla z = 0$. Connectedness propagates the zero set to all of U. The boundary of U is nonempty and lies in S: otherwise U would be both open and closed in connected X, although $S \neq \varnothing$. Constancy then contradicts $a \to -\infty$ at that boundary. This proves strictness; no semipositivity of the divisor's smooth curvature representative is required. □

Corollary 15.9.1 *For smooth strictly positive f, no threshold subsolution has a nonzero divisorial component in $\theta + \mathrm{dd^c} u$.*

Proof If such a component existed, retain a sufficiently small positive multiple E of it. Choose a canonical logarithm ℓ_E and a smooth closed representative γ_E with $[E] = \gamma_E + \mathrm{dd^c}\ell_E$. The multiple can be chosen so that $\theta - \gamma_E > 0$. Divisorial removal gives a canonical $(\theta - \gamma_E)$-psh representative of $u - \ell_E$, whose finite supremum implies $u \preceq \ell_E$. The preceding theorem would then give

$$b_\theta(f) \leq c_{\theta-\gamma_E}(f) < c_\theta(f) = b_\theta(f),$$

a contradiction. □

The later rigidity result Corollary 26.9.1 strengthens this obstruction by determining every smooth-data threshold subsolution through the maximizing Gauduchon form.

Example 15.9.1 Let (X_0, h_0) be a connected compact Hermitian m-fold, let $k \geq 2$, and let κ be the mass-one Fubini–Study form on $\mathbb{P}^k$. On $X_0 \times \mathbb{P}^k$, choose a smooth positive volume form $\mathrm{d}V$. With pullbacks implicit, put

$$N = m + k, \quad C = \binom{N}{m}, \qquad V_0 = \int_{X_0} h_0^m,$$
$$H = h_0 + \kappa, \quad \mu = (h_0^m / V_0) \wedge \kappa^k, \quad R = \mu / \mathrm{d}V.$$

For $D = \{Z_0 = 0\}$ pulled back to the product, take $E = \lambda D$, $0 < \lambda < 1$, with

$$\ell_E = \lambda \log \frac{|Z_0|^2}{\sum_{i=0}^k |Z_i|^2}, \qquad H_E = h_0 + (1 - \lambda)\kappa.$$

The global threshold of R is CV_0, while its ordinary, relative envelope and one-sided thresholds prescribed by E are all $CV_0(1 - \lambda)^k$, attained by ℓ_E. If $v_-(h_0) = 0$, both H and H_E are nonclosed and have zero lower mass.

Proof The Poincaré–Lelong formula gives $[D] = \kappa + \mathrm{dd}^{\mathrm{c}}(\ell_E/\lambda)$. Dimensions and the mass-one projective factor give

$$H^N = CV_0 R \, \mathrm{d}V, \qquad H_E^N = CV_0(1 - \lambda)^k R \, \mathrm{d}V.$$

Thus the zero residual solves each smooth positive equation and fixes its unique scalar. The theorem identifies all three restricted coefficients, and the correspondence gives $\mathrm{MA}_H^{\mathrm{ext}}(\ell_E) = H_E^N$. Under the factor hypothesis, pullbacks of bounded h_0-psh potentials with mass tending to zero have masses multiplied respectively by C and $C(1 - \lambda)^k$. Bounded submersion pullback and the product expansion therefore give zero lower mass for both backgrounds. A closed positive h_0 would instead have every bounded mass equal to V_0 by Stokes, so both backgrounds are nonclosed. □

15.10 The mass determined by the functional

In a closed background, the information lost by the scalar functional can be described exactly: for the model references below, two functionals agree precisely when the masses agree. This also gives examples in which the supporting probabilities stay fixed while the potentials have different limits.

In this section X is a compact Kähler manifold and θ is any smooth closed big real $(1,1)$-form. Let $\varphi \in \mathrm{PSH}(X,\theta)$ satisfy $P_\theta[\varphi] = \varphi$, have small unbounded locus in the sense of Section 1.12, and have positive mass

$$m_\varphi = \int_X \mathrm{MA}_\theta(\varphi) > 0.$$

Write $B_{\theta,\varphi}$ and $\mathcal{A}_{\theta,\varphi}$ for the normalization scalar and the supporting sets of the equation (15.1) in the ordinary type of φ, and put $Z_F = \int_X \mathrm{e}^F \,\mathrm{d}V$.

Theorem 15.10.1 *For every such pair (θ,φ) and every bounded measurable F, the equation in the ordinary type of φ has a unique constant and a solution unique modulo constants. Its normalization scalar is*

$$B_{\theta,\varphi}(F) = \log m_\varphi - \log Z_F.$$

For continuous real F, its supporting set is

$$\mathcal{A}_{\theta,\varphi}(F) = \{\mathrm{e}^F \mathrm{d}V / Z_F\}.$$

For two such pairs on the same X, with the same $\mathrm{d}V$ and possibly in different classes,

$$\sup_{F\in L^\infty} |B_{\theta,\varphi}(F) - B_{\theta',\psi}(F)| = |\log m_\varphi - \log m_\psi|. \tag{15.20}$$

Thus an invariant of these pairs is determined by the whole functional if and only if it is constant on every fiber of the map $(\theta,\varphi) \mapsto m_\varphi$.

Proof Existence follows from Corollary 32.8.1. Indeed, a Kähler manifold has the bounded mass property by Lemma 21.4.1, and since in a closed background all potentials of the ordinary type of φ have the same mass $m_\varphi > 0$, the reference satisfies the positive-volume model condition (30.5). Uniqueness modulo constants is the classical theorem on equations with prescribed singularities in closed big classes, which applies under the model and small-unbounded-locus hypotheses; see the notes in Section 34.11.

Every potential of the ordinary type of φ has mass m_φ, so integrating the equation forces $cZ_F = m_\varphi$, which is the scalar formula. For continuous F, Jensen's inequality shows, as for (15.15), that the normalized exponential measure is a supporting probability, and differentiating at zero in both signs of every continuous direction shows that it is the only one. Subtracting the scalar formulas gives (15.20). Finally, $m_\varphi = \mathrm{d}V(X)\exp B_{\theta,\varphi}(0)$, so the functional and the mass determine each other, and an invariant factors through either one exactly when it is constant on the fibers of the mass map. □

For an ordinary divisorial type whose residual form β is positive and closed, Theorem 15.9.1 gives the same formula with mass $\int_X \beta^n$, since Stokes' theorem for bounded products in a closed background fixes the mass of every bounded β-plurisubharmonic function. This computation does not require the real weighted sum

of divisors to have a model representative. If $\beta_j \to \beta$ uniformly, the masses converge by continuity of $\beta \mapsto \int_X \beta^n$; under the two-sided bounds $(1-\varepsilon_j)\beta \le \beta_j \le (1+\varepsilon_j)\beta$ one has the sharper inequalities $(1-\varepsilon_j)^n \int \beta^n \le \int \beta_j^n \le (1+\varepsilon_j)^n \int \beta^n$.

Example 15.10.1 Let $X = \mathbb{P}^n$ with $n \ge 1$, let θ be the Fubini–Study form, normalized by $\int_X \theta^n = 1$, and let D be a hyperplane. Let s_D be a section of $\mathcal{O}(1)$ defining D, measured with the Fubini–Study metric and rescaled so that $a_D = \log|s_D|^2 \le 0$, and choose $t \in (0,1)$. Then

$$\mathrm{dd^c} a_D = [D] - \theta, \qquad \theta + \mathrm{dd^c}(t a_D) = (1-t)\theta + t[D].$$

Put $\varphi_{t,D} = P_\theta[t a_D]$. By Proposition 16.2.4, this envelope fixed point has the ordinary type of $t a_D$. Moreover $t a_D \in \mathrm{PSH}(X, t\theta)$ and $t a_D \le \varphi_{t,D}$, so $\varphi_{t,D}$ satisfies (13.20) with $\varepsilon = t$. Off D, the potential $t a_D$ has Monge–Ampère measure $(1-t)^n \theta^n$, and its non-pluripolar measure puts no mass on D.

Since mass is invariant under bounded changes of the potential in a closed background,

$$m_{\varphi_{t,D}} = (1-t)^n, \qquad B_{\varphi_{t,D}}(G) - B_0(G) = n\log(1-t) \quad (G \in C(X,\mathbb{R})).$$

Thus the constant in Proposition 15.7.1 is sharp.

Now let $n = 1$, and take for D two distinct points $p, q \in \mathbb{P}^1$. The corresponding references have distance zero, although $\varphi_{t,p}$ is unbounded near p and bounded near q, while $\varphi_{t,q}$ behaves in the opposite way; in particular they are not ordinarily equivalent. For every positive integer m,

$$\mathcal{I}(m\varphi_{t,p}) = \mathcal{O}(-\lfloor mt \rfloor p), \qquad \mathcal{I}(m\varphi_{t,q}) = \mathcal{O}(-\lfloor mt \rfloor q),$$

by Lemma 1.16.1, and for $mt \ge 1$ these ideals differ. Thus the distance Δ of (15.16) does not even separate multiplier-ideal types, and it determines neither the ordinary nor the ideal singularity type.

Fix a smooth real function F on $\mathbb{P}^1$, and let w_F be the solution of $\theta + \mathrm{dd^c} w_F = \mathrm{e}^F \mathrm{d}V / Z_F$ with $\int_X w_F \, \mathrm{d}V = 0$. The normalized solutions for $D = p$ and $D = q$ are

$$u_{t,D} = t a_D + (1-t) w_F - \sup_X \bigl(t a_D + (1-t) w_F \bigr).$$

Their difference satisfies $\mathrm{dd^c}(u_{t,p} - u_{t,q}) = t([p] - [q]) \ne 0$. Hence the sequence of solutions obtained by alternating between $D = p$ and $D = q$ has two different L^1 cluster points, although the scalar functional and all its supporting sets are the same at every step. Within this one-parameter family, the functional does recover t, since $t \mapsto (1-t)^n$ is injective.

Example 15.10.2 On $\mathbb{P}^n$, $n \ge 2$, let ω be the Fubini–Study form, normalized as in Example 15.10.1, and let f be a nonconstant smooth real function. Fix $0 < t < 1$ and put

$$\beta = \mathrm{e}^f \omega, \qquad \theta = \beta + t\omega, \qquad \varphi_D = t \log|s_D|^2.$$

Here s_D defines a hyperplane D as in Example 15.10.1, and $\theta + \mathrm{dd^c}\varphi_D = \beta + t[D]$, so every hyperplane has the same positive residual form β. This form is not closed: $\mathrm{d}\beta = \mathrm{e}^f \mathrm{d}f \wedge \omega \not\equiv 0$, since $\mathrm{d}f$ is nonzero somewhere and wedging a one-form with ω^{n-1} is injective. By Theorem 15.9.1, the ordinary types of all φ_D have the same functional B_β on bounded tests, hence the same supporting sets. At a smooth test, the common supporting probability is the Gauduchon adjoint probability of Theorem 15.2.3.

If v_F is the common smooth residual solution, the normalized solutions are the functions $\varphi_D + v_F - \sup_X(\varphi_D + v_F)$. Two distinct hyperplanes D_1, D_2 give different poles, different divisorial coefficients and, for sufficiently large k, different multiplier ideals $\mathcal{O}(-\lfloor kt \rfloor D_i)$, by the calculation in normal coordinates of Lemma 1.16.1. The potentials differ by more than a constant, since the difference of their complex Hessians is $t([D_1] - [D_2])$, and alternating between the two hyperplanes again produces two distinct L^1 limits. These conclusions come from the common residual form; for general nonclosed backgrounds we do not claim that the functional is determined by a mass.

15.11 Convex-body criteria for varying references

When the singularities of a torus-invariant reference are described by a convex body, the closed mass formula of Theorem 15.10.1 turns convergence of the convex bodies into convergence of the functionals. A translated simplex contained in all the bodies keeps the limiting reference solvable, and the Hausdorff distance then controls the functionals uniformly over all continuous tests, even though the ordinary types vary.

Let $n \geq 2$, and let ω_{FS} be the Fubini–Study form on $\mathbb{P}^n$, normalized by $\int_{\mathbb{P}^n} \omega_{\mathrm{FS}}^n = 1$. In homogeneous coordinates $[Z_0 : \cdots : Z_n]$, consider the torus $T = \{Z_0 \cdots Z_n \neq 0\}$, and put

$$x_i = \log |Z_i/Z_0|^2, \qquad L(x) = \log\bigl(1 + \textstyle\sum_i \mathrm{e}^{x_i}\bigr), \qquad \Sigma = \{p_i \geq 0 : \textstyle\sum_i p_i \leq 1\},$$

where $1 \leq i \leq n$ and $\Sigma \subset \mathbb{R}^n$ is the standard simplex. Functions of $x = (x_1, \ldots, x_n)$ are regarded as functions on T; thus $\omega_{\mathrm{FS}} = \mathrm{dd^c}L$ on T. Define the continuous function ℓ on Σ by

$$\ell(p) = \sum_i p_i \log p_i + (1 - \textstyle\sum_i p_i) \log(1 - \textstyle\sum_i p_i), \qquad 0 \log 0 = 0.$$

For a convex body $K \subset \Sigma$, that is, a compact convex set with nonempty interior, set

$$h_K(x) = \sup_{p \in K} p \cdot x, \qquad g_K(x) = \sup_{p \in K} \{p \cdot x - \ell(p)\}.$$

15.11.1 Canonical models and their mass

Lemma 15.11.1 *The functions $h_K - L$ and $g_K - L$ on T extend uniquely to ω_{FS}-plurisubharmonic functions ψ_K, Φ_K on $\mathbb{P}^n$. They satisfy*

$$\psi_K \le \Phi_K \le \psi_K + \log(n+1), \qquad \sup \Phi_K = 0,$$
$$P_{\omega_{\mathrm{FS}}}[\psi_K] = \Phi_K = P_{\omega_{\mathrm{FS}}}[\Phi_K].$$

If $p_* + \delta\Sigma \subset K$ for some $p_* \in \mathbb{R}^n$ and $0 < \delta < 1$, then $P_{(1-\delta)\omega_{\mathrm{FS}}}(\Phi_K) \not\equiv -\infty$.

Proof The Legendre transform of L is $L^* = \ell$ on Σ and $+\infty$ outside it. Since $-\log(n+1) \le \ell \le 0$,

$$h_K \le g_K \le h_K + \log(n+1), \qquad g_K \le L, \qquad h_K \le h_\Sigma \le L.$$

A finite convex function of the logarithmic moduli is plurisubharmonic: for a smooth convex function the complex Hessian is positive, and convolution gives the general case. On $T \cap \{Z_j \neq 0\}$, add the local Fubini–Study potential $\log \sum_i |Z_i/Z_j|^2$; the resulting functions are again convex functions of the logarithmic moduli of the affine coordinates, and they are bounded above by that smooth potential because $h_K, g_K \le L$. Lemma 1.3.7 therefore gives the extensions across the coordinate hyperplanes and the stated bounds. If $p \in \operatorname{int} K$, then $p \in \operatorname{int}\Sigma$, and at $x_i = \log(p_i/(1 - \sum_k p_k))$ the supremum defining $L = \ell^*$ is attained at $p \in K$, so $g_K(x) = L(x)$. This proves $\sup \Phi_K = 0$.

For $C \ge \log(n+1)$, let $v_C = P_{\omega_{\mathrm{FS}}}(\psi_K + C, 0)$, the envelope of the obstacle $\min(\psi_K + C, 0)$. Since Φ_K is a competitor, $\Phi_K \le v_C \le 0$. The obstacle is upper semicontinuous, so $v_C \le \psi_K + C$ everywhere. The compact torus acting by rotations of the coordinates preserves the obstacle, so v_C is invariant, and on T the function $f = v_C + L$ is a finite convex function of x with $f \le L$ and $f \le h_K + C$. The second inequality shows that the Legendre transform f^* is $+\infty$ outside K, and the first gives $f^* \ge \ell$. Thus

$$f(x) = \sup_{p \in \operatorname{dom} f^*} \{p \cdot x - f^*(p)\} \le g_K(x).$$

Hence $v_C \le \Phi_K$ on T, and since both functions are quasi-plurisubharmonic and T is the complement of an analytic set, $v_C = \Phi_K$ on $\mathbb{P}^n$. Letting $C \to \infty$ gives $P_{\omega_{\mathrm{FS}}}[\psi_K] = \Phi_K$. Since $\psi_K \le \Phi_K \le \psi_K + \log(n+1)$, the envelopes of $\min(\Phi_K + C, 0)$ and $\min(\psi_K + C, 0)$ interlace as $C \to \infty$, so also $P_{\omega_{\mathrm{FS}}}[\Phi_K] = \Phi_K$.

For the final assertion put $\varepsilon = 1 - \delta$, $b = \sum_i p_{*,i}$ and $\chi = p_* \cdot x - \varepsilon L$ on T. The inclusion $p_* + \delta\Sigma \subset \Sigma$ implies $p_{*,i} \ge 0$ and $b \le \varepsilon$, and the extension of χ to $\mathbb{P}^n$ satisfies

$$\varepsilon\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}}\chi = \sum_i p_{*,i}[Z_i = 0] + (\varepsilon - b)[Z_0 = 0] \ge 0.$$

Since $h_K \ge p_* \cdot x + \delta h_\Sigma$ and $L - h_\Sigma \le \log(n+1)$, one has $\chi - \delta\log(n+1) \le \Phi_K$. Thus $\chi - \delta\log(n+1)$ is an $\varepsilon\omega_{\mathrm{FS}}$-plurisubharmonic competitor for $P_{\varepsilon\omega_{\mathrm{FS}}}(\Phi_K)$, which proves the claim. □

In the rest of this section, either $X = \mathbb{P}^n$ and $\pi = \mathrm{id}$, or $\pi : X = \mathrm{Bl}_q \mathbb{P}^n \to \mathbb{P}^n$ is the blowup at a fixed point q, with exceptional divisor E_q; put $\Theta = \pi^* \omega_{\mathrm{FS}}$.

Lemma 15.11.2 *The manifold X is Kähler, and Θ is smooth, closed, semipositive and big. For $r > 0$, the reference $r\pi^*\Phi_K$ satisfies $P_{r\Theta}[r\pi^*\Phi_K] = r\pi^*\Phi_K$, has small unbounded locus, and satisfies*

$$\int_X \mathrm{MA}_{r\Theta}(r\pi^*\Phi_K) = r^n n! \,\mathrm{Vol}_n(K). \tag{15.21}$$

If $p_* + \delta\Sigma \subset K$ with $0 < \delta < 1$, then $P_{(1-\delta)r\Theta}(r\pi^*\Phi_K) \not\equiv -\infty$.

Proof On $\mathbb{P}^n$, the envelope identity is Lemma 15.11.1. In the blowup case, every $\pi^*\omega_{\mathrm{FS}}$-plurisubharmonic function descends to $\mathbb{P}^n$. Indeed, off E_q add a local potential of ω_{FS}; the resulting plurisubharmonic function is bounded above near q, because the original function is bounded above near the compact fiber E_q, and therefore extends across q. The pullback of the extension agrees with the original function off E_q, hence everywhere. Pullback is therefore a bijection from $\mathrm{PSH}(\mathbb{P}^n, \omega_{\mathrm{FS}})$ onto $\mathrm{PSH}(X, \Theta)$ preserving inequalities and envelopes, and positive scaling preserves them as well.

On projective space, $\Theta = \omega_{\mathrm{FS}}$ is Kähler. For bigness in the blowup case, choose unitary homogeneous coordinates $[W_0 : \cdots : W_n]$, used only in this paragraph, in which $q = [1 : 0 : \cdots : 0]$, set

$$\psi_q = \log \frac{\sum_{i=1}^n |W_i|^2}{\sum_{i=0}^n |W_i|^2},$$

and let $Q : X \to \mathbb{P}^{n-1}$ be the map induced by the linear projection from q. For $0 < t < 1$,

$$\Theta + \mathrm{dd^c}(t\pi^*\psi_q) = (1-t)\pi^*\omega_{\mathrm{FS}} + tQ^*\omega_{\mathrm{FS},n-1} + t[E_q].$$

The smooth part is a Kähler form, since (π, Q) embeds X as the incidence graph in $\mathbb{P}^n \times \mathbb{P}^{n-1}$ and both coefficients are positive. This proves the assertions about the manifold and the form Θ.

For a smooth convex g, the coordinates $z_i = \mathrm{e}^{x_i/2 + \mathrm{i}\vartheta_i}$ give

$$\mathrm{d^c} g = \frac{1}{2\pi} \sum_i g_i \,\mathrm{d}\vartheta_i, \qquad \int_T (\mathrm{dd^c} g)^n = n! \int_{\mathbb{R}^n} \det(D^2 g)\,\mathrm{d}x.$$

For a finite convex g, convolution and the continuity of bounded Monge–Ampère products under local uniform convergence identify $(\mathrm{dd^c} g)^n$ on T in the same way: its image under $z \mapsto x$ is $n! M_g$, where M_g is the Alexandrov measure, which assigns to a Borel set of $\mathbb{R}^n$ the Euclidean volume of its subgradient image. For g_K, the bound $g_K \le h_K + \log(n+1)$ and a separation argument put every subgradient in K. Conversely, if $p \in \operatorname{int} K$ and $p + c\mathbb{B} \subset K$, where $\mathbb{B}$ is the closed unit ball of $\mathbb{R}^n$ and $c > 0$, then $g_K(x) - p \cdot x \ge c|x|$; this function attains a minimum, so p is a subgradient of g_K at some point. Consequently

$$\operatorname{int} K \subset \partial g_K(\mathbb{R}^n) \subset K, \qquad M_{g_K}(\mathbb{R}^n) = \operatorname{Vol}_n(K),$$

since the boundary of a convex body has zero volume. The analytic complement of T receives no non-pluripolar mass, so this is the full mass. Locality off the exceptional divisor proves the formula after pullback, since the divisor and its image carry no non-pluripolar mass, and homogeneity gives the factor r^n. The reference is locally bounded off the coordinate hyperplanes and their inverse image, an analytic set, hence has small unbounded locus. Finally, scaling by r and pulling back the competitor found at the end of the proof of Lemma 15.11.1 gives the last assertion. □

15.11.2 Hausdorff control of the functional

Theorem 15.11.1 *Let convex bodies $P_j, P \subset \Sigma$ contain the same translated simplex $p_* + \delta\Sigma$, with $0 < \delta < 1$, and suppose that their Hausdorff distance $d_j = d_H(P_j, P)$ tends to zero. Let $r_j > 0$ tend to $r > 0$. On the fixed X above, set*

$$(\theta_j, \varphi_j) = (r_j\Theta, r_j\pi^*\Phi_{P_j}), \qquad (\theta, \varphi) = (r\Theta, r\pi^*\Phi_P).$$

For every bounded real Borel function F, the equation (15.1) is solvable in the ordinary type of each φ_j and of φ; these types have masses $m_j = r_j^n n!\operatorname{Vol}_n(P_j)$ and $m = r^n n!\operatorname{Vol}_n(P) > 0$. Fix a smooth positive volume form $\mathrm{d}V$ on X, put $Z_F = \int_X \mathrm{e}^F\,\mathrm{d}V$, and let B_j, B and $\mathcal{A}_j, \mathcal{A}$ be the corresponding normalization scalars and supporting sets. Then

$$B_j(F) = \log m_j - \log Z_F, \qquad B(F) = \log m - \log Z_F.$$

Writing $s = \delta/(n + \sqrt{n})$, one has

$$\sup_{G \in C(X,\mathbb{R})} |B_j(G) - B(G)| \le n|\log(r_j/r)| + n\log(1 + d_j/s). \tag{15.22}$$

Moreover, $n!\operatorname{Vol}_n(P_j) \ge \delta^n$ and $n!\operatorname{Vol}_n(P) \ge \delta^n$, the backgrounds converge smoothly, and the references converge in $L^1(X)$ and locally uniformly on $\pi^{-1}(T)$. For continuous real F, every supporting set at F equals $\{\nu_F\}$, where $\nu_F = \mathrm{e}^F\mathrm{d}V/Z_F$. If continuous F_j converge uniformly to F and $\nu_j \in \mathcal{A}_j(F_j)$, then

$$\int_X \left|\frac{\mathrm{d}\nu_j}{\mathrm{d}V} - \frac{\mathrm{d}\nu_F}{\mathrm{d}V}\right| \mathrm{d}V \le \mathrm{e}^{2\|F_j - F\|_\infty} - 1. \tag{15.23}$$

Proof By the two preceding lemmas, each φ_j and φ is an envelope fixed point with small unbounded locus and the stated positive mass, and it satisfies the smaller-background condition. Theorem 15.10.1 therefore gives solvability and the formulas for the scalars and supporting sets.

The common simplex contains a ball $c + s\mathbb{B}$ of radius s, the inradius of $\delta\Sigma$, where $\mathbb{B}$ is the closed unit ball. The Hausdorff distance gives $P_j \subset P + d_j\mathbb{B}$, while $s\mathbb{B} \subset P - c$

and convexity give

$$P + d_j\mathbb{B} \subset c + (1 + d_j/s)(P - c).$$

Exchanging the roles of P and P_j bounds both volume ratios by $(1 + d_j/s)^n$. Subtracting the scalar formulas and including the factor r_j^n/r^n gives (15.22). The volume bound holds because $\delta\Sigma$ has volume $\delta^n/n!$.

Let ω_ℓ be the modulus of uniform continuity of ℓ on Σ. Matching the maximizers in the definitions of g_{P_j} and g_P by points at distance at most d_j gives

$$|g_{P_j}(x) - g_P(x)| \le d_j|x| + \omega_\ell(d_j).$$

This proves local uniform convergence on T. The common lower bound $\chi - \delta\log(n+1) \le \Phi_{P_j}$ obtained at the end of the proof of Lemma 15.11.1 is integrable on X, also after pullback, so boundedness of r_j and dominated convergence off the coordinate hyperplanes give L^1 convergence. Finally, the ratio of the normalized exponential densities lies in $[\mathrm{e}^{-2\eta}, \mathrm{e}^{2\eta}]$, where $\eta = \|F_j - F\|_\infty$. This proves (15.23) and hence convergence in total variation. □

15.11.3 A family with nonanalytic isolated poles

The hypothesis of a common simplex allows ordinary singularity types that contain no potential with analytic singularities. Let $o = [1 : 0 : \cdots : 0]$ be the origin of the affine chart $Z_0 \neq 0$, with affine coordinates $z_i = Z_i/Z_0$. For $0 < a \le 1$, define

$$P_a = \{p \in \Sigma : \textstyle\sum_i \sqrt{p_i} \ge \sqrt{a}\}, \qquad \kappa_n = \frac{2^n n!}{(2n)!} = \frac{1}{(2n-1)!!}.$$

Proposition 15.11.1 *The function Φ_{P_a} is locally bounded outside the single point o, where it has a pole, and it does not have the ordinary singularity type of any function with analytic singularities. Its generic Lelong number along every prime divisor of $\mathbb{P}^n$ is zero, and*

$$\int_{\mathbb{P}^n} \mathrm{MA}_{\omega_{\mathrm{FS}}}(\Phi_{P_a}) = 1 - \kappa_n a^n > 0. \tag{15.24}$$

The same assertions about the pole, nonanalyticity and generic Lelong numbers hold for $\pi^*\Phi_{P_a}$ on the blowup $\mathrm{Bl}_q\,\mathbb{P}^n$ at a fixed point $q \neq o$.

Proof The function $p \mapsto \sum_i \sqrt{p_i}$ is concave, so P_a is convex. Set

$$b = \frac{n+1}{2n}, \qquad p_{*,i} = \frac{b}{n}, \qquad \delta = \frac{n-1}{4n}.$$

Then $b + \delta < 1$ and $\sum_i \sqrt{p_{*,i}} = \sqrt{(n+1)/2} > 1$. Adding a point of $\delta\Sigma$ preserves the last inequality and keeps the sum of the coordinates below one, so $p_* + \delta\Sigma$ lies in every P_a.

All the standard basis vectors e_i belong to P_a, and therefore

$$\psi_{P_a} \geq \log \frac{\max_{1\leq i\leq n} |Z_i|^2}{\sum_{i=0}^{n} |Z_i|^2}.$$

Hence the reference is locally bounded away from o. The Cauchy–Schwarz inequality gives $\sum_i p_i \geq a/n$ on P_a. When all $x_i < 0$, this yields $h_{P_a}(x) \leq (a/n)\max_i x_i$, which tends to $-\infty$ as $z \to o$, and Lemma 15.11.1 gives the pole at o. Local boundedness outside one point implies that all generic Lelong numbers along prime divisors vanish, and pulling back to the blowup at a different point introduces no pole.

To test analyticity, fix positive $\lambda_1, \ldots, \lambda_n$ and approach o along $|z_i|^2 = \mathrm{e}^{-R\lambda_i}$, $R \to \infty$. Writing $y_i = \sqrt{p_i}$, the Cauchy–Schwarz inequality gives

$$\min_{p\in P_a} \sum_i \lambda_i p_i = \frac{a}{\sum_i \lambda_i^{-1}} =: d_a(\lambda), \qquad y_i = \frac{\sqrt{a}}{\lambda_i \sum_k \lambda_k^{-1}}, \tag{15.25}$$

where the minimizer satisfies $\sum_i p_i \leq a \leq 1$, so that it lies in P_a. Since $L(-R\lambda) \to 0$ and $\Phi_{P_a} - \psi_{P_a}$ is bounded, $-\Phi_{P_a}/R \to d_a(\lambda)$ along these curves.

Suppose that the type were that of $c \log \sum_k |f_k|^2$ near o, with $c > 0$ and holomorphic germs $f_k = \sum_\alpha c_{k,\alpha} z^\alpha$. Exponentiating the two inequalities expressing this equivalence and averaging over the arguments of the z_i gives the positive series

$$\sum_{k,\alpha} |c_{k,\alpha}|^2 \mathrm{e}^{-R\alpha\cdot\lambda},$$

whose exponential decay rate in R must be $d_a(\lambda)/c$. That rate is the minimum of $\alpha\cdot\lambda$ over the monomials with nonzero coefficients: a minimizing term gives one bound, and convergence at a fixed R_0 bounds the series above by a constant times $\mathrm{e}^{-(R-R_0)\min \alpha\cdot\lambda}$. Near any λ with positive coordinates, only finitely many monomials can attain the minimum, because these coordinates have a common positive lower bound and any one nonzero coefficient bounds the degree of the minimizing monomials. The rate is therefore locally piecewise linear in λ. But

$$d_a(s, 1, \ldots, 1) = \frac{as}{1 + (n-1)s}, \qquad \frac{\mathrm{d}^2}{\mathrm{d}s^2} d_a(s, 1, \ldots, 1) = -\frac{2a(n-1)}{(1 + (n-1)s)^3} < 0.$$

This contradiction proves nonanalyticity. The assertion persists on a blowup at a point different from o, which does not change a neighborhood of the pole.

The removed corner $C_a = \{p \in \mathbb{R}^n : p_i \geq 0,\ \sum_i \sqrt{p_i} < \sqrt{a}\} = aC_1$ lies in Σ. The substitution $p_i = y_i^2$ gives

$$\mathrm{Vol}_n(C_1) = 2^n \int_{y_i\geq 0,\, \sum y_i < 1} \prod_i y_i \,\mathrm{d}y = \frac{2^n}{(2n)!}.$$

The last equality follows by iterated integration of monomials over a simplex. Removing the corner from Σ, whose volume is $1/n!$, and applying (15.21) gives (15.24). Since $n \geq 2$, one has $\kappa_n < 1$. □

Corollary 15.11.1 *Put $a_j = 1 - 1/(j+2)$ and $r_j = 1 + 1/(j+2)$ for $j \geq 1$. On $\mathbb{P}^n$, or on its blowup at a fixed point $q \neq o$, the references $r_j \pi^* \Phi_{P_{a_j}}$ satisfy the hypotheses of Theorem 15.11.1, with limit $\pi^* \Phi_{P_1}$. Their ordinary types and masses vary with j, and*

$$\sup_G |B_j(G) - B(G)| \leq n |\log r_j| + \frac{n\kappa_n}{1-\kappa_n} |1 - a_j| \longrightarrow 0.$$

The equation is solvable in the limiting ordinary type, whose mass is $1 - \kappa_n$; for $n = 2$ this mass is $2/3$.

Proof If $p \in P_{a_j} \setminus P_1$, then $u = (\sum_i \sqrt{p_i})^2 \in [a_j, 1)$ and $p/u \in P_1$. Since $|p| \leq \sum_i p_i \leq u$, one has $|p/u - p| \leq 1 - u \leq 1 - a_j$. Thus $d_H(P_{a_j}, P_1) \leq 1 - a_j$, and the hypotheses of the theorem hold with the simplex found in the proof of Proposition 15.11.1. The mass formula (15.24) and the derivative bound $|\mathrm{d} \log(1 - \kappa_n a^n)/\mathrm{d}a| \leq n\kappa_n/(1-\kappa_n)$ give the estimate for the functionals. By (15.25), the directional coefficients of the jth reference are multiplied by $r_j a_j = 1 - (j+2)^{-2}$, which strictly increases with j, so the ordinary types are distinct, while the masses $r_j^n (1 - \kappa_n a_j^n)$ strictly decrease to $1 - \kappa_n > 0$. □

15.11.4 Positive mass with a degenerate smooth residual

A second family has a logarithmic pole whose resolution leaves a smooth residual form degenerating along a different exceptional divisor. Let $o = [1 : 0 : \cdots : 0]$ as in Section 15.11.3, and fix $q \neq o$ in $\mathbb{P}^n$. On $X = \mathrm{Bl}_q \mathbb{P}^n$, keep $\Theta = \pi^* \omega_{\mathrm{FS}}$. For $0 < t < 1$, put

$$\psi_t = t \log \frac{\sum_{i=1}^n |Z_i|^2}{\sum_{i=0}^n |Z_i|^2}, \qquad K_t = \{p \in \Sigma : \textstyle\sum_i p_i \geq t\}.$$

On T, the function $\psi_t + L$, a potential of $\omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}} \psi_t$, equals $(1-t)L + t \log \sum_i \mathrm{e}^{x_i}$. It differs by a bounded function from

$$(1-t) h_\Sigma + t \max_i x_i = h_{K_t}, \qquad K_t = (1-t)\Sigma + t \,\mathrm{conv}(e_1, \ldots, e_n).$$

Thus $\psi_t \sim \psi_{K_t} \sim \Phi_{K_t}$, and $n! \,\mathrm{Vol}_n(K_t) = 1 - t^n$. We call ψ_t the prototype of this ordinary type.

Proposition 15.11.2 *Let $\tau : Z \to X$ be the blowup of the point of X above o, with exceptional divisor E_o, and denote the inverse image of E_q in Z again by E_q. There is a smooth semipositive closed form α_t on Z such that*

$$(\pi \circ \tau)^* \omega_{\mathrm{FS}} + \mathrm{dd}^{\mathrm{c}}(\psi_t \circ \pi \circ \tau) = \alpha_t + t[E_o]. \tag{15.26}$$

It is positive away from E_q, has rank exactly one at every point of E_q, and satisfies $\int_Z \alpha_t^n = 1 - t^n > 0$. Moreover, for every $u \in \mathrm{PSH}(X, \Theta)$ with the ordinary type of $\pi^* \Phi_{K_t}$, in particular for every solution of the equation in this type, the function $u \circ \tau - \psi_t \circ \pi \circ \tau$ extends from $Z \setminus E_o$ to a bounded α_t-plurisubharmonic function on Z.

Proof On $Y = \mathrm{Bl}_o \mathbb{P}^n$, let π_o be the blowdown map and $Q_o : Y \to \mathbb{P}^{n-1}$ the map induced by the linear projection from o. As in the proof of Lemma 15.11.2, the incidence graph embedding shows that

$$\beta_t = (1 - t)\pi_o^* \omega_{\mathrm{FS}} + t Q_o^* \omega_{\mathrm{FS},n-1}$$

is a Kähler form, where $\omega_{\mathrm{FS},n-1}$ is the Fubini–Study form of $\mathbb{P}^{n-1}$. Since the two centers are distinct, Z is also the blowup $\sigma : Z \to Y$ of the point above q. Put $\alpha_t = \sigma^* \beta_t$. The Poincaré–Lelong formula gives (15.26); there is no term along E_q, since ψ_t is locally bounded near q.

In a blowup chart, σ is $(s, w_2, \dots, w_n) \mapsto (s, sw_2, \dots, sw_n)$. At $s = 0$ its differential has rank one and kills the $n - 1$ tangent directions of E_q. Positivity of β_t therefore gives the assertion about the rank; off E_q the map is biholomorphic.

Write $H = \pi_o^*[\omega_{\mathrm{FS}}]$ and $E = [E_o]$ for the cohomology classes on Y. The current identity gives $[\beta_t] = H - tE$. Since $H|_{E_o} = 0$, all mixed top intersections vanish. The normal bundle of $E_o \cong \mathbb{P}^{n-1}$ is $\mathcal{O}_{\mathbb{P}^{n-1}}(-1)$, so $\int_Y E^n = (-1)^{n-1}$. Therefore

$$\int_Z \alpha_t^n = \int_Y (H - tE)^n = 1 - t^n.$$

The first equality holds because σ has degree one. Finally, if $u \sim \pi^* \Phi_{K_t} \sim \pi^* \psi_t$, then $u \circ \tau$ differs from the pulled-back prototype $\psi_t \circ \pi \circ \tau$ by a bounded function off E_o. By (15.26), after adding a local potential of α_t this bounded difference becomes plurisubharmonic off E_o, and it extends across E_o by Lemma 1.3.7. No Monge–Ampère product of unbounded potentials is involved. □

Corollary 15.11.2 *Let $t_j, t \in [t_{\min}, t_{\max}] \subset (0, 1)$ with $t_j \to t$, and let $r_j > 0$ tend to $r > 0$. The references $r_j \pi^* \Phi_{K_{t_j}}$ satisfy the hypotheses of Theorem 15.11.1, so in particular the equation is solvable in the limiting ordinary type, and*

$$\sup_G |B_j(G) - B(G)| \le n |\log(r_j/r)| + \frac{n t_{\max}^{n-1}}{1 - t_{\max}^n} |t_j - t|.$$

At continuous tests, all supporting sets consist of the normalized exponential probabilities of that theorem. At the endpoint $t = 1$, where the mass vanishes, no equation with a positive bounded density is solvable in the ordinary type of the prototype $\pi^* \psi_1$.

Proof Choose $p_{*,i} = t_{\max}/n$ and $\delta = (1 - t_{\max})/2$; then $p_* + \delta\Sigma$ lies in every K_t with $t \le t_{\max}$. For $s \ge t$, moving a point of K_t toward a vertex e_i until its coordinate sum reaches s gives

$$d_H(K_s, K_t) \le \frac{\sqrt{2}}{1 - t_{\max}}|s - t|.$$

Hence the stability theorem applies. Instead of its general bound, the derivative bound for $\log(1 - t^n)$ on $[t_{\min}, t_{\max}]$ and the mass formula give the sharper estimate for the functionals.

At $t = 1$, the resolved residual form α_1 is pulled back from $\mathbb{P}^{n-1}$, so $\int_Z \alpha_1^n = 0$. The argument of Proposition 15.11.2 shows that every potential of the ordinary type of $\pi^*\psi_1$ has a bounded α_1-plurisubharmonic remainder. Stokes' theorem for bounded products in a closed background gives this remainder mass zero, and positivity forces its Monge–Ampère measure to vanish. Thus no such potential can solve the equation with density $ce^F\mathrm{d}V$ for bounded F and $c > 0$. In contrast, the endpoint $a = 1$ in Corollary 15.11.1 has positive mass and remains solvable. □

Scaling by $r > 0$ multiplies both the resolved residual form and the divisor coefficient by r. Solvability is obtained on X through the criterion of Theorem 15.10.1, without requiring the resolved residual form to be strictly positive. These criteria use closed projective backgrounds and fixed modifications; we do not know analogous convergence criteria for general nonclosed Hermitian backgrounds, for moving modifications, or for unrestricted degenerations of the singularities. Moreover, the supporting probabilities here only identify the limiting functional: we make no claim about convergence of the solutions or of weighted adjoint products.

15.12 Selection by a vanishing exponential parameter

The equation with exponent zero can have several normalized solutions. Nevertheless, the solutions of the equations with positive exponent select one of them in the limit: the scalar functional provides a family of integral normalizations, and the selected potential is the greatest subsolution of the critical equation satisfying all of them. To prove that it is the greatest, we use supporting probabilities of a second functional, obtained by varying the forcing term in the subsolution inequality.

In this section, θ is an arbitrary smooth big real $(1,1)$-form on X, not necessarily semipositive. Fix a strict analytic barrier $\rho \le 0$ as in Section 14.12, and put $\Omega = X \setminus \{\rho = -\infty\}$. A potential has *minimal type* if it has the ordinary singularity type of the envelope $V_\theta = P_\theta(0)$, which has minimal singularities (Section 1.19). Fix a nonzero $0 \le f \in L^p(\mathrm{d}V)$, with $1 < p < \infty$. For a nonzero nonnegative density g in some L^q, $q > 1$, let $c(g) > 0$ be the unique constant of Theorem 14.15.2 for which the equation $\mathrm{MA}_\theta(v) = c(g)g\,\mathrm{d}V$ has a solution v of minimal type. We call $c(g)$ the *critical scalar* of g and such solutions *critical potentials* for g; they are continuous on Ω by Theorem 14.16.1. Here MA_θ is the extended measure $\mathrm{MA}_\theta^{\mathrm{ext}}$. On Ω it is the

locally bounded product for every potential of minimal type, and it gives zero mass to the analytic set $X \setminus \Omega$.

Put $c = c(f)$ and define

$$\begin{aligned} \kappa(r) &= \log c - \log c(\mathrm{e}^r f), \\ \mathcal{P}_f &= \left\{ \nu \in \mathcal{P}(X) : \int_X r \, \mathrm{d}\nu \le \kappa(r) \text{ for every } r \in C(X) \right\}. \end{aligned} \tag{15.27}$$

When θ is semipositive and $f = \mathrm{e}^F$ with $F \in C(X)$, we have $\kappa(r) = B_0(F) - B_0(F+r)$, and $\mathcal{P}_f$ is the set $\mathcal{A}_0(F)$ of supporting probabilities. The definition also applies when f vanishes on a set of positive measure and when θ is not semipositive.

Theorem 15.12.1 *For $\lambda > 0$, let u_λ be the solution of minimal type of*

$$\mathrm{MA}_\theta(u_\lambda) = \mathrm{e}^{\lambda u_\lambda} f \, \mathrm{d}V$$

given by Theorem 14.15.1 and unique by Corollary 14.12.1. The set $\mathcal{P}_f$ is nonempty and weakly compact, and every potential of minimal type is integrable against all its measures. As $\lambda \downarrow 0$,

$$w_\lambda = u_\lambda - \lambda^{-1} \log c$$

converges locally uniformly on Ω and in $L^1(X)$ to a potential w of minimal type, continuous on Ω. It is the greatest among the potentials s of minimal type, continuous on Ω, satisfying

$$\mathrm{MA}_\theta(s) \ge c f \, \mathrm{d}V, \qquad \int_X s \, \mathrm{d}\nu \le 0 \quad (\nu \in \mathcal{P}_f). \tag{15.28}$$

Moreover,

$$\mathrm{MA}_\theta(w) = c f \, \mathrm{d}V, \qquad \max_{\nu \in \mathcal{P}_f} \int_X w \, \mathrm{d}\nu = 0.$$

Consequently, $u_\lambda - \sup_X u_\lambda$ converges to $w - \sup_X w$ in the same two topologies. For a Hermitian θ, one may take $\Omega = X$, and both convergences of potentials are uniform.

15.12.1 A norm defined by the critical scalar

Mixed products turn the comparison of critical scalars into a triangle inequality for nth roots of densities, and the subsolution estimate associated with the strict barrier gives continuity in the corresponding Lebesgue norm.

Fix $1 < q < p$ and set $\ell = nq$. On real $L^\ell(\mathrm{d}V)$ define

$$N(a) = \begin{cases} c(|a|^n)^{-1/n}, & a \ne 0, \\ 0, & a = 0. \end{cases}$$

Proposition 15.12.1 *The function N is a lattice norm on $L^\ell(\mathrm{d}V)$, that is, a norm satisfying $N(a) \le N(b)$ whenever $|a| \le |b|$. There is $C_q < \infty$, depending only on $X, \theta, \mathrm{d}V$ and q, such that*

$$N(a) \le C_q \|a\|_\ell, \qquad |N(a) - N(b)| \le C_q \|a - b\|_\ell. \tag{15.29}$$

Consequently, for nonzero $g, h \ge 0$ in L^q,

$$|c(g)^{-1/n} - c(h)^{-1/n}| \le C_q \|g - h\|_q^{1/n}.$$

Proof If a potential v of minimal type satisfies $\mathrm{MA}_\theta(v) \ge dg\,\mathrm{d}V$, then $d \le c(g)$, since otherwise comparison with a critical potential for g contradicts part (1) of Corollary 14.12.1. Hence $g \le h$ implies $c(g) \ge c(h)$. Uniqueness of the critical scalar also gives $c(tg) = c(g)/t$ for $t > 0$. These facts prove that N is monotone and absolutely homogeneous, and positivity follows from $0 < c(g) < \infty$.

For the triangle inequality, let $a, b \ge 0$ be nonzero, put $A = N(a)$ and $B = N(b)$, and choose critical potentials v_a, v_b with measures $(a/A)^n \mathrm{d}V$ and $(b/B)^n \mathrm{d}V$. On every relatively compact subset of Ω, (1.12) gives

$$\mathrm{MA}_\theta\left(\frac{Av_a + Bv_b}{A + B}\right) \ge \left(\frac{a + b}{A + B}\right)^n \mathrm{d}V,$$

where both potentials are locally bounded. Exhausting Ω gives the inequality on X, since $X \setminus \Omega$ has zero smooth volume. The averaged potential has minimal type, so the first paragraph gives $N(a + b) \le A + B$. The cases where a or b vanishes are trivial, and for real functions we use $|a + b| \le |a| + |b|$ and monotonicity.

Next, apply Lemma 14.13.1 with $\eta = V_\theta$ to nonnegative densities of L^q norm at most one. It gives a uniform $m > 0$ and subsolutions of minimal type, hence $c(g) \ge m$ for each such nonzero density. For $a \ne 0$, take $g = |a|^n / \|a\|_\ell^n$, which has L^q norm one. Homogeneity gives $N(a) \le m^{-1/n} \|a\|_\ell$, which is the first bound in (15.29), and the reverse triangle inequality gives the second. Applying the second bound to $g^{1/n}, h^{1/n}$ and using $|g^{1/n} - h^{1/n}|^n \le |g - h|$ proves the last assertion. □

15.12.2 Norming probabilities and integral bounds

Set $a = f^{1/n} \in L^\ell(\mathrm{d}V)$ and $A = N(a) = c^{-1/n}$. The probabilities in (15.27) come from positive linear functionals that norm N at a, that is, functionals dominated by N and equal to $N(a)$ at a. This representation will control integrals of unbounded potentials as well as bounded logarithmic perturbations.

With $\ell' = \ell/(\ell - 1)$, define

$$\mathcal{H}_a = \left\{ \eta \in L^{\ell'}(\mathrm{d}V) : \eta \ge 0,\ \int_X a\eta\,\mathrm{d}V = A,\ \int_X b\eta\,\mathrm{d}V \le N(b) \text{ for every } b \in L^\ell \right\}. \tag{15.30}$$

Proposition 15.12.2 *The set $\mathcal{H}_a$ is nonempty and weakly compact in $L^{\ell'}$. The function κ of (15.27) is given by*

$$\kappa(r) = n \log \frac{N(a\mathrm{e}^{r/n})}{A},$$

and it is convex, increasing and 1-Lipschitz for the uniform norm on $C(X)$, with $\kappa(0) = 0$ and $\kappa(r + b) = \kappa(r) + b$ for constants b. Its subdifferential at zero is

$$\mathcal{P}_f = \{\nu_\eta : \eta \in \mathcal{H}_a\}, \qquad \mathrm{d}\nu_\eta = A^{-1} a\eta \,\mathrm{d}V. \tag{15.31}$$

If z is measurable and $az \in L^\ell$, then

$$\sup_{\nu \in \mathcal{P}_f} \int_X |z| \,\mathrm{d}\nu \le C_q A^{-1} \|az\|_\ell. \tag{15.32}$$

If also $a\mathrm{e}^{tz/n} \in L^\ell$ and $N(a\mathrm{e}^{tz/n}) = A$ for some $t > 0$, then $\int_X z \,\mathrm{d}\nu \le 0$ for every $\nu \in \mathcal{P}_f$.

Proof The formula for κ follows from $N(a\mathrm{e}^{r/n}) = c(\mathrm{e}^r f)^{-1/n}$. The Hahn–Banach theorem gives a linear functional that norms N at a. By (15.29) it is continuous on L^ℓ, and hence is represented by some $\eta_0 \in L^{\ell'}$. For $b \ge 0$, testing on $\operatorname{sgn}(\eta_0) b$ gives

$$\int_X b|\eta_0| \,\mathrm{d}V \le N(b).$$

Since $a \ge 0$ and $\int_X a\eta_0 \,\mathrm{d}V = A = N(a)$, the same equality holds with $|\eta_0|$ in place of η_0. Monotonicity of N extends the domination to real b, so $|\eta_0| \in \mathcal{H}_a$. The defining conditions of $\mathcal{H}_a$ are weakly closed and give $\|\eta\|_{\ell'} \le C_q$, so reflexivity proves weak compactness.

For nonzero nonnegative b_0, b_1, the weighted arithmetic–geometric mean inequality applied to $b_j / N(b_j)$, together with monotonicity and the triangle inequality, gives

$$N(b_0^{1-t} b_1^t) \le N(b_0)^{1-t} N(b_1)^t, \qquad 0 \le t \le 1.$$

Taking $b_j = a\mathrm{e}^{r_j/n}$ proves convexity of κ. Monotonicity and the translation rule follow from the corresponding properties of N, and together they imply the Lipschitz bound.

Every ν_η is a probability and satisfies

$$\frac{N(a\mathrm{e}^{r/n})}{A} \ge \int_X \mathrm{e}^{r/n} \,\mathrm{d}\nu_\eta.$$

Jensen's inequality gives $\kappa(r) \ge \int_X r \,\mathrm{d}\nu_\eta$, which proves one inclusion in (15.31). The map $\eta \mapsto \nu_\eta$ is weakly continuous, since $ar \in L^\ell$ for $r \in C(X)$.

Conversely, let $\nu \in \mathcal{P}_f$ and put $L(r) = \int_X r \,\mathrm{d}\nu$. Differentiating the curve $t \mapsto a\mathrm{e}^{tr/n}$ in L^ℓ at $t = 0$ gives

$$N(ae^{tr/n}) = N(a) + \frac{t}{n}N'_+(a;ar) + o(t), \qquad t \downarrow 0.$$

Here the one-sided derivative $N'_+(a;\cdot)$ of the continuous convex function N exists, and the error estimate follows from its Lipschitz bound. The inequality $L \le \kappa$, applied to tr and $-tr$, therefore gives

$$|AL(r)| \le C_q \|ar\|_\ell, \qquad AL(r) \le N'_+(a;ar) \le N(a+ar) - A. \tag{15.33}$$

Thus $T(ar) = AL(r)$ defines a continuous linear functional on the space of products ar, $r \in C(X)$. These products are dense in

$$S_a = \{b \in L^\ell : b = 0 \text{ almost everywhere on } \{a = 0\}\} :$$

indeed, it suffices to approximate b/a in $L^\ell(a^\ell \,\mathrm{d}V)$ by continuous functions. If $ar \ge 0$, then $ar = ar_+$ almost everywhere, and the first inequality in (15.33) gives $L(r - r_+) = 0$, so $T(ar) \ge 0$. Approximating nonnegative elements of S_a by products ar with $r \ge 0$ continuous shows that the continuous extension of T to S_a is positive.

Represent this extension by some $\eta \ge 0$ in $L^{\ell'}$ vanishing on $\{a = 0\}$. Since $T(a) = A$, extending the second inequality in (15.33) to S_a and applying it to $b - a$ gives $T(b) \le N(b)$ for $b \in S_a$. For general $b \in L^\ell$,

$$\int_X b\eta \,\mathrm{d}V \le N(b\mathbf{1}_{\{a>0\}}) \le N(b).$$

Thus $\eta \in \mathcal{H}_a$, and ν_η agrees with ν on all continuous functions. This proves the representation (15.31), and weak compactness of $\mathcal{P}_f$ follows from that of $\mathcal{H}_a$.

The bound (15.32) follows from Hölder's inequality and $\|\eta\|_{\ell'} \le C_q$. Under the last hypothesis, the norming inequality gives $\int_X e^{tz/n} \,\mathrm{d}\nu \le 1$. Since z is ν-integrable by (15.32), Jensen's inequality implies $\int_X z \,\mathrm{d}\nu \le 0$. □

These estimates apply uniformly to all $\nu \in \mathrm{PSH}(X,\theta)$ with $\sup_X \nu = 0$. Indeed, Lemma 1.5.1, applied in a Hermitian background larger than θ, gives uniform bounds for all finite moments of $|\nu|$, and Hölder's inequality gives

$$\int_X |\nu|^{nq} f^q \,\mathrm{d}V \le \|f\|_p^q \left(\int_X |\nu|^{nqp/(p-q)} \,\mathrm{d}V \right)^{(p-q)/p}. \tag{15.34}$$

Consequently, (15.32) gives a uniform bound for $\int_X |\nu| \,\mathrm{d}\nu$ over all such ν and all $\nu \in \mathcal{P}_f$; constant translates of such ν are integrable as well. The representation also shows that these probabilities charge neither $\{f = 0\}$ nor $X \setminus \Omega$.

15.12.3 Bounds for the centered potentials

We call the potentials w_λ of Theorem 15.12.1 the *centered potentials*. Choose a critical potential ψ for f with $\sup_X \psi = 0$, so that $\mathrm{MA}_\theta(\psi) = c\,f\,\mathrm{d}V$. The integral normalizations prevent the centered potentials from drifting upward by constants.

Lemma 15.12.1 *There is $K < \infty$, independent of $0 < \lambda \le 1$, such that*

$$\psi \le w_\lambda, \qquad 0 \le k_\lambda := \sup_X w_\lambda \le K, \qquad \psi - K \le v_\lambda := w_\lambda - k_\lambda \le V_\theta. \quad (15.35)$$

Moreover $\int_X w_\lambda \,\mathrm{d}\nu \le 0$ for every $\nu \in \mathcal{P}_f$. The family w_λ is relatively compact for locally uniform convergence on Ω; every such cluster also converges in $L^1(X)$ to a potential of minimal type.

Proof The centered potential satisfies $\mathrm{MA}_\theta(w_\lambda) = ce^{\lambda w_\lambda} f\,\mathrm{d}V$, while $\psi \le 0$ gives $\mathrm{MA}_\theta(\psi) \ge ce^{\lambda\psi} f\,\mathrm{d}V$. Part (2) of Corollary 14.12.1 therefore gives $\psi \le w_\lambda$, hence $k_\lambda \ge 0$. For each fixed λ, the density $e^{\lambda w_\lambda} f$ lies in L^p, and its critical scalar is c. Therefore

$$N(ae^{\lambda w_\lambda/n}) = A.$$

The moment estimate above gives $aw_\lambda \in L^\ell$, so Proposition 15.12.2, with $z = w_\lambda$ and $t = \lambda$, gives the asserted integral inequalities. Fix one $\nu \in \mathcal{P}_f$. Then

$$k_\lambda \le -\int_X v_\lambda \,\mathrm{d}\nu \le C_q A^{-1} \|a v_\lambda\|_\ell \le K$$

by (15.34), with K independent of λ. The normalization $\sup_X v_\lambda = 0$ gives $v_\lambda \le V_\theta$, and subtracting k_λ from the lower bound $\psi \le w_\lambda$ proves (15.35).

The potentials $v_\lambda = u_\lambda - \sup_X u_\lambda$ form the normalized exponential family of Proposition 14.16.1, which gives subsequences converging locally uniformly on Ω and in $L^1(X)$ to potentials of minimal type. Extracting a convergent subsequence of $k_\lambda \in [0, K]$ gives the same compactness for $w_\lambda = v_\lambda + k_\lambda$. The bound $|w_\lambda| \le |\psi| + K$ also gives L^1 convergence along every subsequence converging locally uniformly on Ω, since $X \setminus \Omega$ has zero volume. □

In particular,

$$e^{\lambda \sup_X u_\lambda} = ce^{\lambda k_\lambda} \longrightarrow c.$$

Moreover, for $0 < \lambda \le 1$ the densities of the equations satisfy $\|ce^{\lambda w_\lambda} f\|_p \le ce^K \|f\|_p$. It matters that this bound includes the scalar factor: an L^p bound on the data alone, after an arbitrary rescaling, does not bound the normalized potentials. For example, on $\mathbb{P}^1$, with $\omega_{\mathrm{FS}} = \mathrm{dd^c} \log(1 + |z|^2)$ and $0 < \epsilon < 1$, the function

$$\psi_\epsilon = \log \frac{|z|^2 + \epsilon^2}{1 + |z|^2}$$

is smooth and ω_{FS}-plurisubharmonic, with supremum zero and infimum $\log \epsilon^2$. Write $\mathrm{MA}_{\omega_{\mathrm{FS}}}(\psi_\epsilon) = g_\epsilon \omega_{\mathrm{FS}}$, and take L^p norms with respect to ω_{FS} in this example. The data $g_\epsilon / \|g_\epsilon\|_p$ have norm one, and ψ_ϵ solves the equation with these data and scalar $\|g_\epsilon\|_p$; but the densities g_ϵ of the equations themselves are not bounded in L^p, and the potentials are not uniformly bounded.

15.12.4 Scalar envelopes of subsolutions

To compare a cluster potential with every member of the class (15.28), fix a point $x \in \Omega$ and add a continuous forcing term r to the subsolution inequality. Let $\mathcal{S}$ be the convex set of potentials of minimal type that are continuous on Ω, and define

$$\mathcal{F}_{\lambda,x}(r) = \sup\{s(x) : s \in \mathcal{S},\ \mathrm{MA}_\theta(s) \ge ce^{\lambda s + r} f \, \mathrm{d}V\}. \tag{15.36}$$

Lemma 15.12.2 *The functional $\mathcal{F}_{\lambda,x}$ is finite, concave, decreasing and λ^{-1}-Lipschitz for the uniform norm on $C(X)$. It satisfies*

$$\mathcal{F}_{\lambda,x}(0) = w_\lambda(x), \qquad \mathcal{F}_{\lambda,x}(r + b) = \mathcal{F}_{\lambda,x}(r) - b/\lambda.$$

There is a probability measure $\nu_{\lambda,x}$ such that, for every $r \in C(X)$ and every s admissible for r in (15.36)*,*

$$\lambda s(x) + \int_X r \, \mathrm{d}\nu_{\lambda,x} \le \lambda w_\lambda(x). \tag{15.37}$$

Proof By part (2) of Corollary 14.12.1, w_λ is the greatest admissible potential for $r = 0$. If $m = \min_X r$ and $M = \max_X r$, then $w_\lambda - M/\lambda$ is admissible for r, and translating any potential admissible for r by m/λ makes it admissible for $r = 0$. Hence

$$w_\lambda(x) - M/\lambda \le \mathcal{F}_{\lambda,x}(r) \le w_\lambda(x) - m/\lambda.$$

The mixed density inequality on Ω and the arithmetic–geometric mean inequality show that a convex combination of potentials admissible for r_0 and r_1 is admissible for the same convex combination of the forcing terms. Approximating the two suprema at x proves concavity. Inclusion of the admissible classes proves monotonicity, and translation by constants proves the translation rule and the Lipschitz bound.

Now apply the Hahn–Banach construction in the proof of Theorem 15.2.1 to $-\lambda\mathcal{F}_{\lambda,x}$ at zero. This functional is finite, continuous, convex and increasing, and it satisfies $-\lambda\mathcal{F}_{\lambda,x}(r+b) = -\lambda\mathcal{F}_{\lambda,x}(r) + b$ for constants b. The same tests with nonnegative functions and constants show that its subgradient is a probability measure $\nu_{\lambda,x}$. The resulting supporting inequality, combined with $s(x) \le \mathcal{F}_{\lambda,x}(r)$, gives (15.37); it is not necessary that the supremum be attained. □

Proof (of Theorem 15.12.1) By Proposition 15.12.2 and the moment bound following it, $\mathcal{P}_f$ has the stated properties, and Lemma 15.12.1 gives precompactness of the centered potentials. It remains to identify every cluster potential.

Step 1: limits of the forcing probabilities. Fix $x \in \Omega$. For $r \in C(X)$, choose a critical potential ψ_r for $\mathrm{e}^r f$ with supremum zero. By the definition of κ,

$$\mathrm{MA}_\theta(\psi_r) = c\mathrm{e}^{-\kappa(r)+r} f \, \mathrm{d}V.$$

Since $\psi_r \le 0$, the potential $\psi_r - \kappa(r)/\lambda$ is admissible in (15.36). Thus

$$\int_X r \, \mathrm{d}\nu_{\lambda,x} \le \kappa(r) + \lambda\big(w_\lambda(x) - \psi_r(x)\big). \tag{15.38}$$

For fixed x and r, the values $w_\lambda(x)$ are uniformly bounded by Lemma 15.12.1, and $\psi_r(x)$ is finite. Hence every weak cluster point of $\nu_{\lambda,x}$ as $\lambda \downarrow 0$ belongs to $\mathcal{P}_f$.

Step 2: a pointwise comparison. Let s satisfy (15.28). The function $-\lambda s$ is lower semicontinuous and bounded below on X, with the value $+\infty$ allowed, so metric inf-convolution and truncation give continuous functions $r_j \uparrow -\lambda s$. Since $r_j \le -\lambda s$, the potential s is admissible for every r_j, and (15.37) bounds the integrals of the r_j from above. Monotone convergence, after subtracting a common lower bound, shows that s is integrable against $\nu_{\lambda,x}$ and gives

$$w_\lambda(x) \ge s(x) - \int_X s \, \mathrm{d}\nu_{\lambda,x}. \tag{15.39}$$

Step 3: cluster potentials belong to the class (15.28). Take a sequence $\lambda_j \downarrow 0$ with $w_{\lambda_j} \to z$ locally uniformly on Ω and in $L^1(X)$. The bounds (15.35) show that z has minimal type, and z is continuous on Ω. Since $c\mathrm{e}^{\lambda_j w_{\lambda_j}} f \to c f$ in L^p, by dominated convergence and the common bound $w_\lambda \le K$, continuity of local bounded products gives $\mathrm{MA}_\theta(z) = c f \, \mathrm{d}V$ on Ω, and then on X because neither side charges $X \setminus \Omega$.

For each $\nu \in \mathcal{P}_f$, the bound $|w_\lambda| \le |\psi| + K$ has a ν-integrable right-hand side, and ν charges only Ω. Dominated convergence in $\int_X w_\lambda \, \mathrm{d}\nu \le 0$ therefore gives $\int_X z \, \mathrm{d}\nu \le 0$. Hence z belongs to the class (15.28).
