

Singularities in Hermitian pluripotential theory

Working draft, October 2, 2026

Introduction

In a fixed Kähler class, all bounded potentials have the same Monge–Ampère mass. This consequence of Stokes’ theorem makes mass a tool for studying singularities: the mass lost at the poles of a potential can be compared with its growth and with the integrability of holomorphic functions against its exponential weight. For a Hermitian background, the mass can change even among smooth potentials, so one singularity type can have representatives of different masses.

This book studies singularities in the Hermitian setting, taking the theory developed in *Singularities in global pluripotential theory* [Xia] as its starting point. The central question is how ordinary singularity types, multiplier ideals and Monge–Ampère measures are related when the background is not closed. Envelopes remain useful, but the mass identities and variational arguments that connect these notions in Kähler theory have to be reconsidered: some arguments admit a replacement, while others require additional hypotheses or fail in explicit examples.

Two departures from Kähler geometry must be distinguished, one concerning the manifold and one concerning the background form. A non-Kähler manifold may carry closed positive currents, whereas a Kähler manifold may be equipped with a nonclosed Hermitian form; we keep these two situations separate. Let X be a connected compact complex manifold of dimension $n \geq 1$, and let θ be a smooth real $(1, 1)$ -form on X . A function u is θ -plurisubharmonic if it is locally the sum of a plurisubharmonic function and a smooth function and the current $\theta_u = \theta + dd^c u$ is positive. If θ is closed, this current is locally a complex Hessian. For a general background, a smooth local correction still makes u plurisubharmonic, but it leaves a smooth remainder in the current. Local potential theory therefore still provides compactness, regularization and multiplier ideals; the difference appears when one integrates over X .

Closedness, mass and energy

Let ω be a Hermitian form on X , that is, a smooth strictly positive $(1, 1)$ -form. If ω is Kähler, every smooth real potential u with $\omega + \text{dd}^c u > 0$ satisfies

$$\int_X (\omega + \text{dd}^c u)^n = \int_X \omega^n.$$

The identity extends to bounded ω -plurisubharmonic potentials. For singular potentials, the non-pluripolar product can have smaller total mass, and closedness provides the fixed total mass against which this loss is measured.

If ω is only Hermitian, integration by parts gives instead, for every smooth potential u ,

$$\int_X (\omega + \text{dd}^c u)^n - \int_X \omega^n = \sum_{k=1}^{n-1} \binom{n}{k} \int_X u (\text{dd}^c u)^{k-1} \wedge \text{dd}^c (\omega^{n-k}).$$

Mass conservation thus fails before any singularity appears. [Chapter 2](#) derives this formula and shows that mass invariance is equivalent to the vanishing of $\text{dd}^c(\omega^j)$ for $1 \leq j \leq n-1$. Since the usual global comparison inequality would force mass invariance, comparison estimates for a general Hermitian form must take the derivatives of the background into account.

Upper and lower bounds for the mass are separate questions. Call a smooth potential u *admissible* if $\omega + \text{dd}^c u > 0$. On the standard Hopf threefold, the masses of admissible potentials are unbounded, although their infimum is positive. Another compact threefold carries a balanced metric whose admissible potentials have bounded masses but include sequences with masses tending to zero. These examples, given in [Chapter 8](#) and [Section 25.17](#), show that a general Hermitian theory can assume neither bound. [Part IX](#) develops the theory under explicit upper and lower bounds.

Even constant mass does not recover the Kähler energy. At an admissible potential u , the Monge–Ampère operator defines the one-form

$$\alpha_u(v) = \int_X v (\omega + \text{dd}^c u)^n,$$

where the tangent direction v is a smooth real function. For a Kähler form, this is the differential of the Monge–Ampère energy. In dimension at least two, however, a primitive of this one-form even on a neighborhood of the zero potential forces $d\omega = 0$, by [Theorem 3.1.1](#). On a non-Kähler surface, a Gauduchon metric, that is, a Hermitian form γ with $\text{dd}^c(\gamma^{n-1}) = 0$, conserves mass but has no such primitive. This is one reason to distinguish constructions by envelopes from arguments that depend on an energy functional. Perron interpolation and Legendre duality remain available, but their relation to metric geodesics changes with the background.

A linear conservation law does survive. For a Gauduchon form γ , the equation $\text{dd}^c(\gamma^{n-1}) = 0$ gives, for every θ -plurisubharmonic u ,

$$\int_X (\theta + \text{dd}^c u) \wedge \gamma^{n-1} = \int_X \theta \wedge \gamma^{n-1}.$$

The trace measure on the left determines u up to an additive constant. Fix a smooth positive volume form dV on X . For potentials in a fixed background normalized by $\int_X u \, dV = 0$, weak convergence of the trace measures is equivalent to L^1 convergence of the potentials, as proved in [Chapter 5](#). The trace therefore controls the potential even when it does not control the nonlinear mass: every potential has finite trace mass, but its Monge–Ampère mass can be infinite. To handle such potentials we construct extended non-pluripolar measures and finite damped measures; removing the damping requires a separate estimate of the tails near the pole set.

Equations and singularity types

Since the mass varies, the normalization of a Monge–Ampère equation becomes part of the problem. Given a smooth real function F on X , we seek a smooth pair (u, c) satisfying

$$(\omega + \text{dd}^c u)^n = c \, e^F \, dV, \quad \omega + \text{dd}^c u > 0, \quad \sup_X u = 0.$$

Here the constant $c > 0$ is part of the unknown. In the Kähler case, integrating the equation determines c before one solves for u ; in the Hermitian case, the integral of the left-hand side depends on u . The equation nevertheless has a unique smooth solution (u, c) . Its linearization produces an adjoint Gauduchon probability measure, which describes how $\log c$ changes with the density. This dependence leads to a variational volume defined by Gauduchon test forms, which remains finite even on manifolds whose upper Monge–Ampère mass is unbounded. A projective example has a nef nonclosed background θ that has positive variational volume but is not big, that is, admits no θ -plurisubharmonic ρ with $\theta + \text{dd}^c \rho \geq \delta \omega$ for some $\delta > 0$ ([Theorem 25.12.1](#)). Up to a smooth change of representative, the same background occurs at the finite maximal time of a Chern–Ricci flow ([Theorem 25.19.3](#)). Positive variational volume alone therefore does not provide the bigness needed to apply geometric convergence theorems.

When e^F is replaced by a nonnegative density in $L^p(X, dV)$, $p > 1$, that is not almost everywhere zero, continuous solutions still exist and the positive constant c is still unique. Uniqueness of the potential requires more care. A smooth density with zeros can admit distinct normalized smooth solutions. For a smooth nonnegative density whose positive set is connected and dense, however, bounded solutions are unique up to an additive constant, by [Theorem 11.4.1](#). We therefore keep uniqueness of the constant, uniqueness of the potential and selection by an approximation procedure separate. Equations with a prescribed singularity type impose further conditions on the reference potential.

For such equations, the constant c depends on the density through a normalization functional, and this functional does not recover all the singularity data: distinct divisorial types can have the same normalization functional and the same supporting Gauduchon probabilities, as shown in [Chapter 14](#). To distinguish such types, we turn to envelopes.

Ordinary singularity type identifies potentials whose difference is bounded. Multiplier ideals instead record which holomorphic functions are locally square integrable against the weights e^{-ku} , $k > 0$. Two envelopes compare these descriptions. The *ordinary envelope* $P_\theta[u]$ is the upper semicontinuous regularization of the supremum of all θ -plurisubharmonic $h \leq 0$ with $h \leq u + C$ for some constant C . The *multiplier-ideal envelope* $P_\theta[u]_I$ is defined in the same way from the θ -plurisubharmonic $h \leq 0$ that have the same multiplier ideals as u at all weights $k > 0$. In a closed big class on a compact Kähler manifold, and for potentials of positive mass, the equality $P_\theta[u] = P_\theta[u]_I$ characterizes I -good singularities and is equivalent to a mass identity and to approximation by analytic singularities. We examine which parts of this relation persist for a nonclosed background.

Analytic approximation remains possible in a positive Hermitian background. After their curvature errors are corrected, dyadic approximants stay in the original space of potentials, and their envelopes decrease to the multiplier-ideal envelope. A uniform topology on ordinary singularity classes then characterizes the closure of the analytic classes by equality of the two envelopes, even for classes with infinite-mass representatives ([Theorem 15.6.1](#)). This topology can identify distinct ordinary classes. The envelopes above use the obstacle 0, that is, the constraint $h \leq 0$ on their competitors. If this obstacle is kept fixed, the topology changes under a smooth change of representative $\theta \mapsto \theta + \text{dd}^c \chi$, with the potentials transformed by $u \mapsto u - \chi$; including all smooth obstacles $h \leq \psi$ restores invariance under this change. In a smooth big background with bounded mass, if the multiplier-ideal envelope has positive lower volume in the sense of the next paragraph, equality of the envelopes at the obstacle 0 implies equality at every smooth obstacle. The same implication holds without these volume conditions on curves and for certain product constructions ([Proposition 29.8.1](#) and [Corollaries 15.6.8](#) and [29.13.1](#)). Whether it holds in general at zero volume remains open.

To attach a volume to an ordinary singularity type, we take the infimum and the supremum of the mass over all its representatives. These lower and upper singularity volumes need not agree. Call u an *ordinary model* if $P_\theta[u] = u$. In a smooth big background with bounded mass, volume comparison gives a completely metrizable topology on the ordinary models of positive lower volume. At zero volume, the same comparison can fail to distinguish different models.

On a curve, an ordinary model is determined by its polar curvature, the part of $\theta + \text{dd}^c u$ carried by the pole set of u . Total variation of polar curvature gives a complete metric that includes the models of zero volume, and in this metric the models with $P_\theta[u] = P_\theta[u]_I$ form the closure of the analytic models. In higher dimensions, residual mass in top degree can lie on a diffuse pole set while the polar parts of the curvature currents vanish on every modification; this happens already for Kähler forms. Even the whole residual measure, together with both volumes,

can fail to determine the model: different weights in an anisotropic maximum give the same residual measure but a positive comparison distance ([Proposition 15.6.29](#)). The curve construction nevertheless gives complete loci of zero-volume models on higher-dimensional products without an ambient mass bound, by [Proposition 15.6.18](#). A general extension must keep the singularity information that these volumes and polar currents lose.

Equations whose right-hand side is a general finite non-pluripolar measure require their own existence hypotheses. [Part IX](#) treats two regimes: semipositive big backgrounds with positive lower mass, with a model reference that admits a competitor in a smaller background; and arbitrary smooth big backgrounds with bounded mass, with a model reference of positive lower volume. The resulting solution lies in a relative envelope class; that it differs from the reference by a bounded function requires a further argument. The envelope and trace constructions described above provide the tools for both regimes.

Geometric constructions

Logarithmic poles provide concrete tests of the singularity theory. After resolution, a prescribed pole can leave a strictly positive residual form, and a bounded equation then determines the residual potential. A divisor forced by the background behaves differently: its coefficient belongs to the type of minimal singularities, and removing it can force the remaining current to descend. The residual in a prescribed-pole construction need not have this descent property. The constructions in [Sections 13.21](#) and [13.22](#) make the distinction explicit.

A current that is smooth and strictly positive off an analytic set defines a Hermitian metric there, and one may ask whether the analytic set lies at finite distance. If the potential is Hölder continuous, local trace estimates show that it does; in particular, the metric is incomplete when the analytic set is nonempty ([Theorem 1.18.1](#)). Boundedness of the potential alone gives no such conclusion: radial examples, already in closed Kähler classes, have continuous minimal residuals and complete regular ends. In these examples the integral that controls the potential differs from the integral that controls path length. They concern the strength of regularity assumptions rather than the loss of closedness.

Restriction and modification provide further ways to examine a singularity. A potential may be identically $-\infty$ on the subspace to which one wishes to restrict it, while restricted ideals and trace envelopes still carry data there. Realizing these data by a current or by a single ordinary singularity type requires compatibility conditions beyond those of numerical classes. We develop trace envelopes and divisorial representatives with this problem in view.

Holomorphic sections of line bundles connect singularities with geometry, but the curvature of a line bundle is closed. Counting sections therefore cannot measure an arbitrary Hermitian Monge–Ampère mass. Gauduchon degrees control sections and flag valuations, and fibrations explain examples whose section growth and equilibrium

measures live on a lower-dimensional base. Partial Bergman kernels relate these spaces of sections to envelopes defined by singular weights. Closed Bott–Chern classes and locally conformally Kähler structures provide further geometric settings in which the differential constraints can be used more precisely.

Reading the book

We assume familiarity with complex manifolds, differential forms and currents. **Chapter 1** develops the plurisubharmonic tools used throughout. On a first reading, the maximum principle, normalized compactness and exponential integrability are the main starting points; the longer approximation and descent arguments can be consulted when needed. The mass and energy calculations explain the obstructions described above, and Gauduchon traces, non-pluripolar products and the Hopf construction complete the foundations.

From there, the chapters on equations lead to prescribed singularities, while the chapters on envelopes lead to interpolation, restriction and holomorphic sections. **Part IX** develops volume comparison and equations with general measures under explicit mass hypotheses. The appendix treats descent, measures and equations on compact unibranch spaces, including projective cones. Open questions are collected in **Chapter 32**, and **Chapter 33** gives the sources in the literature and the precise dependencies on them. References to monographs also appear in the text where they are used.

Contents

Introduction	v
Part I The Hermitian foundations	
1 Plurisubharmonic functions and singularities	3
1.1 Plurisubharmonic potentials	3
1.2 Changes of background	5
1.3 Maxima and the maximum principle	6
1.4 Normalized compactness	10
1.5 Uniform exponential integrability	12
1.6 Local products and capacity	13
1.6.1 Polar parts on curves	19
1.6.2 Products at small pole sets	20
1.6.3 Sobolev regularity at divisorial poles	21
1.6.4 Measure concentration under integrable convergence	26
1.6.5 Adding a prescribed local measure	28
1.6.6 Full cluster sets at the zero potential	32
1.6.7 Cluster sets at a bounded background	35
1.7 Products with smooth backgrounds	37
1.8 Hermitian capacity	42
1.8.1 Capacity estimates	43
1.8.2 Convergence of potentials and measures	45
1.8.3 Vanishing area on curves	48
1.9 Comparing local regularizations	49
1.10 Gluing with a small curvature error	51
1.11 Regularization in a fixed Hermitian background	53
1.12 Singularity type and multiplier ideals	54
1.13 Analytic types and restriction	56
1.13.1 Lelong level sets	57
1.14 The local Bergman estimates	59
1.15 The global curvature bound	62

1.15.1	Regularization of closed currents	62
1.15.2	Smooth remainders after resolution	63
1.16	Multiplier ideals and logarithmic poles	64
1.16.1	Weighted distance from a sum of multiplier ideals	67
1.16.2	The optimal constant in dimension one	71
1.16.3	Distance for several hyperplane weights	75
1.17	Lelong numbers and divisorial estimates	76
1.18	Potential regularity and metric distance	83
1.18.1	Dini moduli and limits of distances	85
1.19	Obstacle envelopes	88
1.19.1	A hyperplane Green envelope on the ball	92
1.20	The minimum principle	95
1.20.1	Pointwise Legendre transforms	96
1.21	Chern-connection regularization	98
1.21.1	The general curvature modulus	101
1.21.2	A linear error for a smooth background	103
1.22	Pullback and descent	105
1.22.1	Holomorphic disks	106
1.22.2	Compact fibers	107
1.22.3	Modifications	108
1.22.4	Multiplier ideals under modifications	110
1.22.5	Restriction of analytic approximants	113
1.23	Integration against non-pluripolar measures	114
1.23.1	A fixed measure	114
1.23.2	Vanishing exponents	115
1.23.3	Measures with bounded potentials	116
1.23.4	Smoothing the measure	118
1.24	Curvature of line bundles	120
1.25	Polar curvature	121
2	Torsion and the variation of mass	127
2.1	Integration by parts with a nonclosed form	127
2.2	The mass polynomial	128
2.3	Mass variation on a complex torus	131
2.4	Comparison and mass invariance	132
2.5	Uniform mass bounds	133
3	Monge–Ampère energy and torsion	135
3.1	Primitives of the Monge–Ampère one-form	135
3.2	Radial energy and closed backgrounds	137
3.3	First variation in a nonclosed background	138
3.4	Symplectic completions and potential variations	139
3.4.1	Completion energy on products of complex tori	143

4	Gauduchon metrics and linear mass	147
4.1	Conformal Gauduchon metrics	148
4.2	Conservation of the trace mass	149
4.3	The Gauduchon criterion for positivity	150
4.4	Compactness and duality of Gauduchon currents	153
4.5	Convex norms and Gauduchon degrees	155
4.5.1	Homogeneous convex regularization	159
4.5.2	Strict positivity from the tautological metric	163
4.5.3	Polar norms of semipositive Finsler metrics	165
4.5.4	Ample comparison quotients on Hirzebruch surfaces	168
4.5.5	Stable extensions approaching the split comparison bundle	173
4.5.6	Deforming to stable ample bundles	175
4.5.7	A fixed Stein hypersurface for all Finsler metrics	179
4.5.8	Concave neighborhoods and dual norms	182
4.5.9	Curvature and projective complement exhaustions	186
4.5.10	External tensor products and complement convexity	189
4.5.11	Homogeneous plurisubharmonic functions and Hopf complements	191
4.6	Pluriharmonic currents	195
4.7	The adjoint measure of the linearization	198

15.4.2	Mass and capacity convergence	643
15.4.3	Comparison with scalar normalization	645
15.5	Limits of analytic envelopes	645
15.5.1	Dyadic regularization	648
15.5.2	Absorbing the curvature error	649
15.6	A topology on ordinary singularity types	650
15.6.1	Analytic closure	652
15.6.2	Separation and mass	653
15.6.3	Transport with an obstacle	654
15.6.4	All smooth obstacles	656
15.6.5	Relative divisors and fiber obstacles	660
15.6.6	Divisorial products and zero volume	673
15.6.7	Several curve factors	680
15.6.8	Varying the curve coefficients	686
15.6.9	Arbitrary curve backgrounds	691
15.6.10	Equality below all obstacles on separated products	695
15.6.11	Auxiliary compact complex factors	697
15.6.12	A polar metric in a background with unbounded mass	701
15.6.13	Complete model topologies	702

Part IV Interpolation and restriction

16	Perron interpolation and the geodesic equation	733
16.1	Subgeodesics and endpoint bounds	734
16.2	Perron segments	735
16.3	The smooth product equation	737
16.4	The L^2 action and torsion	738
17	Test curves and Legendre duality	741
17.1	Envelope test curves and rays	741
17.2	Perron maximality	742
17.3	Recovering the singularity envelopes	743
17.4	A logarithmic pole on the projective line	745
18	Restriction and intrinsic trace data	749
18.1	Restricted ideals and trace data	750
18.2	Comparison with ordinary restriction	752
18.3	Realization on a compact curve	753
18.4	The Poisson equation in the atomic trace type	755
18.5	Singularity distance on a curve	756
18.5.1	Total variation of the atomic data	757
18.6	The trace envelope	759
18.6.1	Limits of restricted analytic envelopes	760
18.6.2	Envelopes on modifications	762
18.6.3	Exact realization on a Kähler submanifold	763
18.6.4	Positive mass and prescribed equations	764
18.7	Exact traces over a curve	765
18.8	Product realizations and their measures	767

Part V Holomorphic sections and geometric models

19	Holomorphic sections and Hermitian mass	773
19.1	Weighted sections and Bergman currents	774
19.2	Gauduchon degree and vanishing	776
19.3	Restricted sections and trace data	777
19.4	Bounded weighted sections	779
19.5	Section growth on a curve	780
19.6	Homogeneous sections on a Hopf manifold	781
19.7	Section counts and infinite Hermitian mass	783
20	Flags, convex bodies and section growth	785
20.1	Flag valuations and degree bounds	785
20.2	The body of a graded section algebra	787
20.3	Intrinsic dimension, lattice and growth	788
20.4	Moishezon manifolds and bounded mass	791
20.5	Flags on a point blowup	792

20.6	The Hopf flag and its lower-dimensional body	794
21	Hopf fibrations and toric potentials	797
21.1	Weighted sections on the projective base	797
21.2	Descended measures and equations	798
21.3	Logarithmic coordinates and the gradient simplex	800
22	Divisorial currents on compact modifications	803
22.1	Divisorial trace currents	804
22.2	Compatibility between models	805
22.3	The trace envelope as a common majorant	806
22.4	Bott–Chern classes and closed currents	807
22.5	The b-divisor class of a closed positive current	809
22.6	Nef Cartier realizations	810
22.7	Continuous representatives and pullback	812
22.8	Exceptional divisors between trace models	815
23	Classes with a nonclosed background	819
23.1	Affine classes with prescribed derivative	819
23.2	Residual trace classes	820
23.3	Nef realizations and residual-current limits	822
23.4	Divisorial classes and infinite mass	824
24	Envelope systems over Hermitian perturbations	825
24.1	Curves constant on a left half-line	825
24.2	Transition maps and envelope systems	826
24.3	The limiting curve and recovery	828
24.4	Changes of representative and limiting mass	830
24.5	Failure of recovery in a positive background	831
Part VI Gauduchon duality and finite volumes		
25	A Gauduchon variational volume	839
25.1	The quotient and the smooth equation	840
25.2	The equality case of concavity and the first variation	843
25.3	Second variation on background classes	844
25.4	Recovering a positive class from its Gauduchon derivative	846
25.5	The Hessian metric and its completion	847
25.5.1	Product and blowup examples	849
25.5.2	Invariant backgrounds on compact Lie-group quotients	850
25.5.3	Warped product cones and flat completion	861
25.6	A compact dual problem over Gauduchon currents	874
25.7	Supporting probabilities represented by maximizing currents ..	877
25.8	Integrability of Gauduchon determinant measures	879
25.8.1	Uniform bounds near a smooth density	882
25.9	Integrable densities in the compact Gauduchon problem	887

25.9.1	The tail condition and perturbations of the density . . .	888
25.9.2	Supporting probabilities for an integrable density	890
25.9.3	Trace inequalities at the subsolution threshold	892
25.9.4	A smooth maximizing form with an analytic degeneracy set	896
25.9.5	The limit of the exponential equations	898
25.9.6	Envelope criteria and extension across the degeneracy set	899
25.9.7	A full-mass point pole without a smooth maximizing test	904
25.9.8	Quantitative convergence of the currents	907
25.9.9	The classes of the divisorial components	908
25.9.10	A branched projective example	910
25.9.11	A moment condition on maximizing tests	911
25.10	Nef limits and nonattainment	913
25.11	Subtraction with a closed nef core	915
25.12	Positive volume without bigness	919
25.12.1	Volume tests and threshold tests	923
25.13	Varying the probability measure	926
25.13.1	Upper and lower masses	927
25.14	Curvature conditions for mass extrema	929
25.15	Curvature pairs and positive lower mass	931
25.15.1	The bounded cubic identity	932
25.15.2	The curvature criterion	933
25.15.3	Negative-line-bundle quotients	935
25.15.4	A Calabi–Eckmann family without LCK metrics	936
25.16	Geometric bounds and determinant concentration	937
25.17	Vanishing lower mass	940
25.17.1	The elliptic quotient	940
25.17.2	Averaging the trace and compact curves	942
25.17.3	The volume of the positive root	945
25.17.4	Consequences for dimension and equations	947
25.17.5	A balanced metric and a finite upper mass	948
25.18	Orders of degeneration at the nef boundary	951
25.18.1	Elliptic surface volumes and order spectra	954
25.18.2	Comparison under an arbitrary modification	957
25.18.3	Strict changes under one blowup	960
25.18.4	Positive-current subtraction and divisorial residuals . .	963
25.18.5	Integer orders in fixed projective cones	965
25.18.6	A maximum-rank comparison criterion	972
25.18.7	Flat anticanonical curves	974
25.18.8	Flat divisors and Hartogs extension	981
25.18.9	Punctured line bundles and elliptic quotients	984
25.18.10	Cotangent torsors on split elliptic ruled surfaces	988
25.18.11	Symmetric tensors on split elliptic ruled surfaces	992

25.18.12	Section algebras of cotangent extensions	996
25.18.13	Cotangent extensions with zero ruling component	999
25.19	Current tests for smooth positivity	1001
25.19.1	Maximal time of the Chern–Ricci flow	1003
25.19.2	A positive-volume endpoint that is not big	1007
25.19.3	Twisting and distance bounds	1009
25.20	Divisorial constraints and residual volume	1011
25.20.1	Varying divisorial coefficients	1014
25.21	A divisorial threshold on the Hopf threefold	1016

Part VII Partial kernels and equilibrium

26	Partial kernels and quotient equilibrium	1021
26.1	Selected spaces and partial Bergman kernels	1023
26.2	A local Bernstein–Markov estimate	1023
26.3	Partial envelopes on a weighted compact set	1025
26.4	An upper bound for partial Fubini–Study limits	1027
26.5	The determinant functional	1029
26.5.1	Dependence on the continuous weight	1031
26.5.2	Stability of normalized kernels	1035
26.6	Partial kernels under a modification	1040
26.6.1	Convergence with a Kähler modification	1042
26.7	Kernels on a fibration	1043
26.7.1	The quotient equilibrium measure	1045
26.7.2	The Hopf equilibrium measure	1046
26.8	Isolated logarithmic poles on a fibration	1046
26.9	A point pole on the Hopf manifold	1050
26.10	Singularities along a section over a divisor	1055
26.10.1	A bounded divisorial band from fiber integrability	1059
26.10.2	Several crossing base divisors	1063
26.10.3	Fiber integrability on a modified base	1067
26.10.4	Semipositive residuals with positive volume	1070
26.10.5	Fixed exceptional orders and coefficient thresholds	1072
26.10.6	A semipositive residual with nonzero defect	1075
26.11	Horizontal poles over projective space	1078
26.11.1	The domination envelope	1079
26.11.2	Binomial kernels	1080
26.11.3	Changing the integration volume	1082
26.12	Degenerate curvature and growing vanishing orders	1084
26.12.1	A uniform tail estimate	1085
26.12.2	The limiting envelope and the transition scale	1086
26.13	Localization on curves	1090
26.13.1	Curvature quadrature domains	1096
26.13.2	Gaussian transitions at curvature boundaries	1098
26.13.3	Growth ranges and compact examples	1104

26.13.4	Corrections from the smooth weight	1105
26.14	A logarithmic kernel scale in two dimensions	1107
26.15	Anisotropic point jets and isolated poles on fibrations	1109
26.15.1	Corrected and homogeneous centers	1113
26.15.2	An isolated selecting potential on a submersion	1114
26.16	Newton selection and moment-shell limits	1116
26.16.1	The growth constraint and its envelope	1117
26.16.2	Norms, lattice growth and the lower bound	1119
26.16.3	The limit measure and the ambient metric	1120
26.16.4	A rank-one selection with nonclosed sampling	1121
26.17	Rounding in multiplier-ideal kernel families	1122
26.18	Three monomial bands from a multiplier-ideal selection	1125

Part VIII Closed classes and locally conformally Kähler geometry

27	Bott–Chern classes and singular loci	1135
27.1	Closed classes with Hermitian lower bounds	1136
27.2	Minimal multiplicities and the non-nef locus	1138
27.3	The non-Kähler locus	1139
27.4	Null loci and numerical restricted volumes	1141
27.5	Restricted volumes and Hermitian perturbations	1142
27.6	Finite restricted masses of closed classes	1143
27.7	Divisorial traces with bounded remainder	1147
27.8	Divisorial components at the threshold	1151
27.9	Currents on the elliptic threefold	1155
27.9.1	Potentials and envelopes from the base	1157
27.9.2	Sections selected by multiplier ideals	1158
27.9.3	The boundary volume and section growth	1159
27.9.4	Limits of the minimizing Gauduchon forms	1161
27.10	Smooth equations on the ample locus	1162
27.11	Density zeros and metric degeneration	1164
27.11.1	Determinant and normal distance	1166
27.11.2	Smoothness of exceptional residuals	1167
27.12	Radial densities and metric completeness	1169
27.13	Equations on products with a curve	1172
27.14	An incomplete metric in a big class	1174
27.14.1	A nef class with an incomplete null end	1178
27.14.2	An incomplete metric with compatible flow data	1183
27.15	Normal length near a divisor	1189
27.15.1	The critical exponent on a compact torus	1191
27.16	Rigid boundary classes on a torus	1194
27.17	Nonrigid classes on a quotient resolution	1197
27.18	Semipositive metrics in a four-point blowup family	1199
27.18.1	The image of metric restriction	1202
27.19	Oeljeklaus–Toma manifolds	1206

27.19.1	The construction	1206
27.19.2	Potentials of the transverse form	1207
27.19.3	Monge–Ampère masses on threefolds	1210
27.19.4	Hermitian metrics whose dd^c has a sign	1213
28	Locally conformally Kähler geometry	1215
28.1	The Lee form and the Kähler covering	1216
28.2	Gauduchon representatives and the Lee class	1217
28.3	Ordinary and twisted potentials	1219
28.3.1	The Vaisman metric on the Hopf manifold	1220
28.4	Volume equations in Gauduchon gauge	1221
28.4.1	Invariant volumes on Vaisman manifolds	1222
28.4.2	Radial volumes on scalar Hopf manifolds	1225
28.5	Chern–Ricci flatness and Vaisman rigidity	1229
28.5.1	A flat conformal gauge that is not Gauduchon	1231
28.6	The Lee–Gauduchon cone	1233
28.6.1	Bimeromorphic invariance	1235
28.6.2	Balanced metrics and the Hopf cone	1237
28.7	Strongly Gauduchon metrics	1238
Part IX Theory under mass bounds		
29	Volumes under bounded mass	1245
29.1	Comparison of singularity volumes	1247
29.2	Volume deficits and relative full mass	1248
29.3	Domination and ordinary envelopes	1250
29.4	Strict barriers and background variation	1255
29.5	Monotone limits	1259
29.5.1	Recovery of envelope systems	1265
29.6	Cauchy convergence of model potentials	1267
29.7	Rooftops and capacity convergence	1271
29.8	Volumes of multiplier-ideal envelopes	1275
29.9	Model comparison under background changes	1279
29.10	Two-sided background perturbations	1282
29.11	A complete metric on positive-volume models	1286
29.12	Model potentials on curves	1290
29.12.1	The ordinary-type topology on a curve	1295
29.12.2	Concentration of diffuse polar curvature	1296
29.12.3	Convergence for all obstacles	1298
29.13	Background changes on curves	1301
29.14	A complete space over varying curve backgrounds	1306

30	Relative equations under positive lower mass	1311
30.1	Equations for finite measures	1313
30.2	Domination	1313
30.2.1	Domination for extended measures	1314
30.3	Common envelopes and dominated continuity	1317
30.3.1	Convergence under a fixed measure	1320
30.4	Moving bounded carrier measures	1320
30.4.1	Convergence with a common envelope	1322
30.5	General measures in the minimal envelope class	1323
30.6	Equations with a model reference	1325
30.7	Normalization at exponent zero	1328
30.7.1	Nonuniqueness in the minimal envelope class	1329
31	Big backgrounds under bounded mass	1331
31.1	Equations for finite measures	1333
31.2	Convergence under a fixed measure	1333
31.3	Relative moments	1335
31.3.1	Higher moments in the minimal singularity type	1338
31.4	General measures in the minimal class	1341
31.4.1	Exponential and normalized equations	1342
31.5	Relative projection and supersolutions	1343
31.5.1	Varying model references	1345
31.6	Weighted measure addition	1347
31.6.1	Ordinary types and bounded carriers	1350
31.7	General measures with a model reference	1354
31.7.1	Stability under changes of reference	1356
31.7.2	Arbitrary weighted sums	1358
31.8	Relative boundedness for L^p data	1360

Part X Problems and historical notes

32	Problems in Hermitian pluripotential theory	1367
32.1	Threshold equations and singular limits	1367
32.1.1	Individual density thresholds	1368
32.1.2	Dual attainment and exact equations	1370
32.1.3	Regularity of singular solutions	1372
32.1.4	Uniqueness and selection	1373
32.2	Positive Gauduchon volume and bigness	1374
32.2.1	Collapse of normalized Gauduchon tests	1375
32.3	Closed positivity and geometric equations	1377
32.3.1	Nef classes, bigness and the Fujiki class	1377
32.3.2	Positive lower mass and concentration	1378
32.3.3	Primitive elliptic bundles	1379
32.3.4	Null loci and the singularities of the Chern–Ricci flow	1385
32.3.5	Balanced and pluriclosed metrics	1387

32.3.6	Pluriclosed metrics under deformation	1391
32.3.7	Morse inequalities and the choice of volume	1393
32.3.8	Oeljeklaus–Toma manifolds	1394
32.4	Closed and twisted classes	1395
32.5	Degeneration orders and finite-distance boundaries	1397
32.6	Weak Gauduchon adjoints	1398
32.7	Topologies on singularity types	1400
32.7.1	Weak convergence and singularity data	1401
32.7.2	Volume comparison and analytic approximation	1402
32.7.3	Polar curvature	1404
32.8	Trace realization and recovery	1407
32.8.1	Recovery of compatible divisor systems	1408
32.9	Sections, kernels and the dimension of growth	1410
32.9.1	Growing vanishing orders on curves	1413
32.10	Equations on singular spaces	1415
33	Historical notes	1417
33.1	Plurisubharmonic functions and regularization	1417
33.2	Mass and energy	1421
33.3	Gauduchon metrics and positivity	1422
33.4	Bounded products and extended measures	1427
33.5	Envelopes and comparison	1427
33.6	Smooth and continuous equations	1430
33.7	Uniqueness and selection	1431
33.8	Volumes under mass bounds	1432
33.8.1	Singularity volumes and relative classes	1432
33.8.2	Model topology and analytic approximation	1434
33.8.3	Curves and zero-volume limits	1436
33.9	Equations with prescribed singularities	1437
33.9.1	Equations of prescribed ordinary type	1437
33.9.2	General measures in semipositive backgrounds	1439
33.9.3	Big backgrounds under mass bounds	1440
33.10	Normalization and adjoint measures	1441
33.11	Singularity classes and traces	1444
33.12	Section growth and partial kernels	1444
33.13	Gauduchon variational volume	1447
33.14	Closed classes and singular loci	1452
33.15	Closed classes and metric completeness	1454
33.16	Locally conformally Kähler geometry	1455
33.17	Regularity and singular spaces	1456
33.18	Geometric problems	1458

A	Potentials and equations on unibranch spaces	1461
A.1	Potentials and disk tests	1462
A.2	Descent through a resolution	1462
A.3	Envelopes and normalized compactness	1464
A.4	Ideal envelopes defined on resolutions	1464
A.5	Extended measures and finite damping	1465
A.6	Equations on projective cones	1467
A.6.1	Logarithmic poles at the vertex	1468
A.6.2	The bounded equation	1472
A.6.3	The quadric cone	1473
A.7	Logarithmic equations on normalized curves	1474
A.7.1	A projective cusp with a degenerate pullback	1478
A.7.2	A logarithmic endpoint for integrable data	1481
A.8	Nonclosed equations on cuspidal products	1483

	Index	1497

Conventions

Unless otherwise stated, X denotes a connected compact complex manifold of dimension $n \geq 1$. A Hermitian form is a smooth real strictly positive $(1, 1)$ -form. The letter ω is reserved for such a form, while θ denotes an arbitrary smooth real $(1, 1)$ -form. Whenever θ or ω is assumed to be closed, this is stated explicitly.

We follow the normalizations of [Xia]:

$$d^c = \frac{i}{4\pi}(\bar{\partial} - \partial), \quad dd^c = \frac{i}{2\pi}\partial\bar{\partial}.$$

Thus, on a disk in $\mathbb{C}$ with coordinate z , $dd^c \log |z|^2$ is the unit Dirac measure at the origin. Multiplier ideals of a quasi-plurisubharmonic function u are defined with the weight $\exp(-u)$, and Monge–Ampère masses carry no factor $1/n!$.

Frequently used notation

The following symbols are used throughout the book; the last column gives the place where each is defined. Notation that is used in only one chapter is introduced in that chapter.

Symbol	Meaning	Defined in
$\text{PSH}(X, \theta), \theta_u$	θ -plurisubharmonic functions; $\theta_u = \theta + \text{dd}^c u$	Definition 1.1.1
$u \preceq v, u \sim v$	comparison and equality of ordinary singularity types	Definition 1.12.1
$\mathcal{I}(u)$	multiplier ideal sheaf of u	Definition 1.12.2
$u \preceq_I v, u \sim_I v$	comparison and equality of multiplier ideals at all weights	Section 1.12
$\nu(u, x)$	Lelong number of u at x	Section 1.13
$P_\theta(f), V_\theta$	envelope below an obstacle f ; $V_\theta = P_\theta(0)$	Section 1.19
$P_\theta[u]$	envelope of the ordinary singularity type; its fixed points are the ordinary models	Definition 1.19.1
$P_\theta[u]_I$	multiplier-ideal envelope	Definition 15.2.1
$\text{MA}_\theta(u)$	Monge–Ampère measure of a bounded potential; where a chapter says so, also the extended measure	Proposition 1.7.1
$\text{MA}_\theta^{\text{ext}}(u)$	extended non-pluripolar measure, also written $\langle \theta_u^n \rangle$	Theorem 6.1.1
Cap_ω	Hermitian capacity	Section 1.8
$\nu_-(\omega), \nu_+(\omega)$	lower and upper mass of a Hermitian form; bounded mass property	Definition 6.5.1
Gauduchon, balanced and pluriclosed metrics	Hermitian forms γ with $\text{dd}^c(\gamma^{n-1}) = 0$, $\text{d}(\gamma^{n-1}) = 0$ and $\text{dd}^c \gamma = 0$, respectively	Definition 4.1.1
$\mathcal{T}_\gamma, d_{\gamma, d}$	Gauduchon trace map and trace metric	Section 5.1
$\underline{\text{vol}}_\theta, \overline{\text{vol}}_\theta$	lower and upper volumes of a singularity type	Definition 12.3.1
$\mathcal{E}_{\text{env}}(X, \theta, \varphi)$	relative envelope class of a reference φ	Definition 12.4.1
d_θ	volume comparison of ordinary models	Definition 29.6.1
$b_h(f)$	subsolution threshold of a density f	Theorem 13.25.1
$\mathcal{D}_h, \rho_h$	space of density roots and root functional	Proposition 13.28.2
$\mathcal{V}_\mu(\theta), \lambda_\mu(\theta)$	Gauduchon variational volume and root volume	Definition 25.1.1

Part I
The Hermitian foundations

Chapter 1

Plurisubharmonic functions and singularities

A function whose complex Hessian is bounded below by a smooth form becomes plurisubharmonic after a local smooth correction. This brings the local theory of plurisubharmonic functions to a compact complex manifold, provided the smooth remainder left by the correction is kept when potentials are glued, when their Hessians are multiplied and when one integrates by parts. Normalization by the supremum then controls the resulting families globally, giving compactness, uniform exponential integrability and capacity estimates on the whole manifold. Products of Hessians require more care than the potentials themselves: without a common bound, convergence of potentials in L^1 , or even in capacity, does not prevent their Monge–Ampère measures from concentrating.

To keep track of singularities under these operations, we compare potentials in two ways: by domination up to an additive constant, which leads to ordinary singularity types and their envelopes, and by the local integrability of holomorphic functions against exponential weights, which leads to multiplier ideals. Lelong numbers, analytic approximation and modifications are the main tools for computing the latter.

1.1 Plurisubharmonic potentials

Throughout the chapter, X is a connected compact complex manifold of dimension $n \geq 1$, θ is a smooth real $(1, 1)$ -form and ω is a Hermitian form on X , unless a statement specifies another setting. There are two distinct extensions of the Kähler setting: one can study a closed background on a non-Kähler manifold, or allow the background itself to be nonclosed. In both cases positivity is expressed through quasi-plurisubharmonic functions.

On an open set U in a complex manifold, a *plurisubharmonic function* is a locally integrable upper semicontinuous function satisfying the submean inequality on every complex line in local coordinates. We write $\text{PSH}(U)$ for the set of these functions. A function is *quasi-plurisubharmonic* if it is locally the sum of a plurisubharmonic

function and a smooth real function; the set of such functions is denoted by $\text{QPSH}(U)$. The following relative positivity condition makes sense on any such open set as well.

Definition 1.1.1 A quasi-plurisubharmonic function u on X is θ -plurisubharmonic if

$$\theta + \text{dd}^c u \geq 0$$

as a current. We denote the set of these functions by $\text{PSH}(X, \theta)$.

Since $\omega > 0$, every constant function belongs to $\text{PSH}(X, \omega)$.

Proposition 1.1.1 *Every real distribution u on X with $\theta + \text{dd}^c u \geq 0$ has a unique θ -plurisubharmonic representative. On each relatively compact coordinate ball with coordinates $z = (z_1, \dots, z_n)$, there is a constant $A > 0$ such that $u + A|z|^2$ is plurisubharmonic. Conversely, every quasi-plurisubharmonic function u on X belongs to $\text{PSH}(X, C\omega)$ for some constant $C > 0$.*

Proof On a coordinate ball with compact closure in a larger chart, smoothness of θ gives

$$\theta \leq \text{Add}^c |z|^2$$

for a sufficiently large A . Consequently,

$$\text{dd}^c(u + A|z|^2) \geq \text{Add}^c |z|^2 - \theta \geq 0.$$

The local distributional characterization of plurisubharmonic functions, [Dem12, Chapter I, Theorem 5.8], gives a unique plurisubharmonic representative of $u + A|z|^2$. Subtracting the smooth correction gives a quasi-plurisubharmonic representative of u on the ball. These representatives agree on overlaps: after a common local smooth correction, two of them become plurisubharmonic functions that are equal almost everywhere, hence everywhere. They therefore glue to a unique θ -plurisubharmonic representative.

For the converse, cover X by finitely many open sets $V_j \Subset U_j$, where each U_j is a chart on which $u = p_j + f_j$, with p_j plurisubharmonic and f_j smooth. On the compact set $\overline{V_j}$, the smooth form $\text{dd}^c f_j$ is bounded below by $-C_j\omega$ for some constant C_j , so $\text{dd}^c u \geq \text{dd}^c f_j \geq -C_j\omega$ on V_j . Any constant $C > 0$ larger than all the C_j gives $\text{dd}^c u \geq -C\omega$ on X . $\square$

For $u \in \text{PSH}(X, \theta)$, choose coordinates z and a constant $A > 0$ as in **Proposition 1.1.1**, and put $p = u + A|z|^2$. Then

$$\theta + \text{dd}^c u = \text{dd}^c p + (\theta - \text{Add}^c |z|^2).$$

Thus local plurisubharmonic theory applies to p , while the smooth remainder $\theta - \text{Add}^c |z|^2$ records the original background; this remainder must be kept when forming products or integrating by parts.

Proposition 1.1.2 *If $\theta = \text{dd}^c \rho$ on an open set for a smooth function ρ , then $\text{d}\theta = 0$ on that set. In particular, at a point where $\text{d}\theta \neq 0$, no neighborhood admits such a representation.*

Proof Apply d and use $\text{ddd}^c = 0$. $\square$

Conversely, a closed real $(1, 1)$ -form has smooth local dd^c -potentials on sufficiently small coordinate balls, by the local $\partial\bar{\partial}$ -lemma; this local fact does not require X to admit a Kähler metric.

The exterior derivative also constrains the regularity of a potential whose current is pointwise proportional to a Hermitian form. In dimension at least two, differentiating such an identity expresses the derivative of the proportionality factor through smooth coefficients.

Lemma 1.1.1 *Let X be a complex manifold of dimension $n \geq 2$, let θ be a smooth real $(1, 1)$ -form and let γ be a Hermitian form on X . Suppose that real-valued $u, a \in L^1_{\text{loc}}(X)$ satisfy*

$$\theta + \text{dd}^c u = a\gamma$$

as currents. Then a and u are smooth.

Proof Taking the exterior derivative and multiplying by γ^{n-2} gives

$$\text{d}a \wedge \gamma^{n-1} = \text{d}\theta \wedge \gamma^{n-2} - a \text{d}\gamma \wedge \gamma^{n-2}.$$

At each point, $\xi \mapsto \xi \wedge \gamma^{n-1}$ is an isomorphism from real one-forms to real $(2n-1)$ -forms, as one sees in a unitary frame. Its inverse depends smoothly on the point. Let B and C be the images of $\text{d}\theta \wedge \gamma^{n-2}$ and $\text{d}\gamma \wedge \gamma^{n-2}$ under this inverse. They are smooth real one-forms, and

$$\text{d}a = B - aC$$

in the sense of distributions. Since $a \in L^1_{\text{loc}}$, the right-hand side is locally integrable, so $a \in W^{1,1}_{\text{loc}}$. Differentiating the equation and using the smoothness of its coefficients, we obtain inductively $a \in W^{k,1}_{\text{loc}}$ for every integer k , and the local Sobolev embedding shows that a is smooth. Consequently $\text{dd}^c u = a\gamma - \theta$ is smooth; taking its trace in local coordinates and applying elliptic regularity shows that u is smooth as well. $\square$

1.2 Changes of background

A positive current can be written as a smooth form plus a complex Hessian in more than one way. Changing the decomposition by a smooth dd^c -exact form changes the potential by a bounded function, and positive linear combinations allow us to compare potentials belonging to different backgrounds. In this section, η denotes a second smooth real $(1, 1)$ -form on X .

Proposition 1.2.1 *Let f be a smooth real function on X , and set $\theta' = \theta + \text{dd}^c f$. Then*

$$\text{PSH}(X, \theta) \longrightarrow \text{PSH}(X, \theta'), \quad u \longmapsto u - f$$

is a bijection. It preserves the positive current and changes each potential by a bounded function. Moreover, $\text{d}\theta' = \text{d}\theta$.

Proof For every $u \in \text{PSH}(X, \theta)$,

$$\theta' + \text{dd}^c(u - f) = \theta + \text{dd}^c u.$$

The inverse map is $v \mapsto v + f$, and f is bounded because X is compact. The last assertion follows from $\text{dd}^c f = 0$. $\square$

Thus the natural object is the class of θ modulo smooth dd^c -exact forms. This quotient of all smooth real $(1, 1)$ -forms contains nonclosed classes; the usual Bott–Chern cohomology group is the corresponding quotient of closed forms.

Proposition 1.2.2 *If $u \in \text{PSH}(X, \theta)$ and $v \in \text{PSH}(X, \eta)$, then, for $a, b \geq 0$ with $a + b > 0$,*

$$au + bv \in \text{PSH}(X, a\theta + b\eta).$$

In particular, $\text{PSH}(X, \theta)$ is convex. If $\eta \geq \theta$, then $\text{PSH}(X, \theta) \subseteq \text{PSH}(X, \eta)$.

Proof Omitting a term whose coefficient is zero, we see that $au + bv$ is quasi-plurisubharmonic. Moreover,

$$a\theta + b\eta + \text{dd}^c(au + bv) = a(\theta + \text{dd}^c u) + b(\eta + \text{dd}^c v) \geq 0.$$

For the inclusion, add the semipositive smooth form $\eta - \theta$ to $\theta + \text{dd}^c u$. $\square$

By [Proposition 1.1.1](#), any two quasi-plurisubharmonic functions on X belong to $\text{PSH}(X, C\omega)$ for a common sufficiently large constant C . This allows us to compare their singularities within one positive background.

1.3 Maxima and the maximum principle

Maxima allow us to truncate potentials and to modify them on an open set without losing the lower curvature bound. For a smooth background, the local maximum and gluing principles for plurisubharmonic functions keep this bound: one freezes the coefficients of the background on small balls and then lets the resulting curvature error tend to zero.

Lemma 1.3.1 *If $u, v \in \text{PSH}(X, \theta)$, then $\max(u, v) \in \text{PSH}(X, \theta)$. Consequently, if $\theta \geq 0$ and $u \in \text{PSH}(X, \theta)$, then $\max(u, -t)$ is θ -plurisubharmonic for every real t .*

Proof Adding a common local smooth correction to u and v shows that $\max(u, v)$ is quasi-plurisubharmonic. To obtain the sharp lower bound for its Hessian, fix a positive constant $(1, 1)$ -form κ on a coordinate ball. For each $\varepsilon > 0$, every point of the ball has a neighborhood on which θ is close to a constant form θ' , in the sense that $-\varepsilon\kappa \leq \theta - \theta' \leq \varepsilon\kappa$. Write $\theta' + \varepsilon\kappa = \text{dd}^c r$ with a quadratic polynomial r . Then $\text{dd}^c(u + r) \geq \theta + \text{dd}^c u \geq 0$, so $u + r$ and, likewise, $v + r$ are plurisubharmonic; hence so is their maximum. It follows that

$$\theta + 2\varepsilon\kappa + \text{dd}^c \max(u, v) \geq 0$$

on each such neighborhood, and letting $\varepsilon \rightarrow 0$ gives $\theta + \text{dd}^c \max(u, v) \geq 0$. The last assertion follows because constants belong to $\text{PSH}(X, \theta)$ when $\theta \geq 0$. $\square$

Lemma 1.3.2 *Let Y be a complex manifold, let β be a smooth real $(1, 1)$ -form on Y , and let $D \subset Y$ be open. Suppose that u is β -plurisubharmonic on Y , that v is β -plurisubharmonic on D , and that*

$$\limsup_{D \ni y \rightarrow x} v(y) \leq u(x) \quad (x \in \partial D).$$

Then the function equal to $\max(u, v)$ on D and to u on $Y \setminus D$ is β -plurisubharmonic.

Proof Denote the glued function by w ; it is upper semicontinuous by the boundary inequality. Freeze β on a small coordinate ball as in the proof of Lemma 1.3.1, and choose a quadratic correction r such that $u + r$ and $v + r$ are plurisubharmonic on their respective domains. Off ∂D , the function $w + r$ is plurisubharmonic, being locally either $u + r$ or the maximum of two plurisubharmonic functions. At a point of ∂D , it equals $u + r$ and dominates $u + r$ on the ball, so it satisfies the submean inequality on every complex line through that point. Thus $w + r$ is plurisubharmonic on the whole ball. Letting the error of the frozen coefficients tend to zero gives $\beta + \text{dd}^c w \geq 0$. $\square$

For quasi-plurisubharmonic functions, an inequality that holds almost everywhere holds everywhere. This allows comparisons proved for Sobolev or Lebesgue classes to be applied to the potentials themselves.

Lemma 1.3.3 *Let a, b be quasi-plurisubharmonic functions on a complex manifold. If $a \leq b$ almost everywhere, then $a \leq b$ everywhere. In particular, equality almost everywhere implies equality everywhere.*

Proof On a coordinate ball, add the same smooth function q to both functions so that $a + q$ and $b + q$ are plurisubharmonic. By the submean inequality and upper semicontinuity, a plurisubharmonic function is, at each point, the limit of its averages over balls centered there as the radius tends to zero. The almost-everywhere inequality orders these averages, so passing to the limit gives $a + q \leq b + q$. Subtracting q proves the claim. $\square$

Lemma 1.3.4 *Let a, b be quasi-plurisubharmonic functions on a complex manifold. If $a(x) < b(x)$ at a point x where both values are finite, then $\{a < b\}$ has positive volume with respect to any smooth positive volume form.*

Proof Choose a number c with $a(x) < c < b(x)$. By upper semicontinuity, $a < c$ on a neighborhood V of x . If $\{b > c\} \cap V$ had zero volume, then $b \leq c$ almost everywhere on V , and **Lemma 1.3.3** would give $b(x) \leq c$, a contradiction. Thus $\{b > c\} \cap V$, which is contained in $\{a < b\}$, has positive volume. $\square$

Lemma 1.3.5 *A plurisubharmonic function on $\mathbb{C}^m$, $m \geq 1$, that is bounded above is constant.*

Proof First let f be a smooth subharmonic function on $\mathbb{C}$ with $f \leq M$. Write $\sigma = (\Delta f) dA$ for its nonnegative Laplacian measure, where Δ and dA are Euclidean. Green's formula for circular means gives, for $R > 0$,

$$\frac{1}{2\pi} \int_0^{2\pi} f(Re^{it}) dt - f(0) = \frac{1}{2\pi} \int_0^R \frac{\sigma(B(0, r))}{r} dr.$$

For fixed $r_0 > 0$ and $R > r_0$, the right-hand side is at least $\sigma(B(0, r_0)) \log(R/r_0)/(2\pi)$, while the left-hand side is at most $M - f(0)$. Letting $R \rightarrow \infty$ gives $\sigma(B(0, r_0)) = 0$. Thus f is harmonic, and the Liouville theorem for the positive harmonic function $M + 1 - f$ shows that f is constant.

Now let p be plurisubharmonic on $\mathbb{C}^m$ and bounded above. Its convolutions with a smooth nonnegative radial probability kernel are smooth plurisubharmonic functions with the same upper bound. By the planar case, their restrictions to every affine complex line are constant, so each convolution is constant on $\mathbb{C}^m$. Since the convolutions converge to p in L^1_{loc} , the function p is almost everywhere equal to a constant, and hence constant by **Lemma 1.3.3**. $\square$

For a function f , we write $f^*(x) = \limsup_{y \rightarrow x} f(y)$ for its upper semicontinuous regularization. A subset of a complex manifold is *pluripolar* if each of its points has a neighborhood U such that the part of the subset in U is contained in $\{p = -\infty\}$ for some $p \in \text{PSH}(U)$. The local upper-envelope theorem recalled in [Xia] states that if a nonempty family of plurisubharmonic functions is locally uniformly bounded above, then the regularization of its supremum is plurisubharmonic and differs from the supremum only on a pluripolar set.

Periodicity also forces rigidity when an entire subharmonic function has only logarithmic upper growth.

Lemma 1.3.6 *Let h be subharmonic on $\mathbb{C}$, with $h(\zeta + 1) = h(\zeta)$. If there are real constants $A \geq 0$ and B such that*

$$h(\zeta) \leq A \log(1 + |\zeta|) + B \quad (\zeta \in \mathbb{C}),$$

then h is constant.

Proof By the growth bound, the real translates $h(\cdot + s)$, $s \in [0, 1]$, form a family of subharmonic functions that is locally uniformly bounded above. The local upper-envelope theorem therefore shows that

$$H(\zeta) = \left(\sup_{s \in [0, 1]} h(\zeta + s) \right)^*$$

is subharmonic. By periodicity, H is invariant under every real translation, so it depends only on $\text{Im } \zeta$, and its subharmonicity means that it is a convex function of $\text{Im } \zeta$. On the imaginary axis it satisfies $H(iy) \leq A \log(2 + |y|) + B$. Since a nonconstant convex function on $\mathbb{R}$ grows at least linearly at one end, this bound shows that H is constant. Thus $h \leq H$ is bounded above, and [Lemma 1.3.5](#) shows that h is constant. $\square$

Lemma 1.3.7 *Let U be a complex manifold, let θ be a smooth real $(1, 1)$ -form on U , and let $Z \subset U$ be closed and locally pluripolar. Let u be θ -plurisubharmonic on $U \setminus Z$ and locally bounded above near Z . Then its upper-limit extension, defined at $x \in Z$ by $u(x) = \limsup_{U \setminus Z \ni y \rightarrow x} u(y)$, is θ -plurisubharmonic on U . In particular, this applies when Z is a proper analytic subset of U .*

Proof First suppose that u is plurisubharmonic. Near a point of Z , choose a plurisubharmonic function $\psi \leq 0$ with $\psi = -\infty$ on Z . For $t > 0$, extend $u + t\psi$ by $-\infty$ on Z . The local upper bound for u makes this extension upper semicontinuous. It is plurisubharmonic off Z , and its submean inequality on complex lines is automatic at points of Z , where its value is $-\infty$. It is therefore plurisubharmonic on the whole neighborhood. As $t \downarrow 0$, these functions increase, with a common local upper bound. By the local upper-envelope theorem, the regularization of their limit is a plurisubharmonic function that agrees with u almost everywhere off Z , hence everywhere off Z by [Lemma 1.3.3](#). By upper semicontinuity and the submean inequality, its value at a point of Z is the upper limit of u off Z , so it is the upper-limit extension of u .

For a smooth background, fix a positive constant form κ on a coordinate chart and let $\epsilon > 0$. On a sufficiently small ball, freeze θ to a constant form θ' with $-\epsilon\kappa \leq \theta - \theta' \leq \epsilon\kappa$, and choose a quadratic potential q for $\theta' + \epsilon\kappa$. Applying the preceding argument to the plurisubharmonic function $u + q$ shows that the upper-limit extension satisfies $\theta + \text{dd}^c u \geq -2\epsilon\kappa$ on the ball. Since the extension is defined by upper limits, it does not depend on the ball, and letting $\epsilon \downarrow 0$ gives $\theta + \text{dd}^c u \geq 0$. Finally, analytic subsets are locally pluripolar: locally, a proper analytic subset is contained in the $-\infty$ locus of the logarithm of the sum of the squared moduli of local defining functions. $\square$

Lemma 1.3.8 *Let X be a complex manifold of dimension $n \geq 2$, let θ be a smooth real $(1, 1)$ -form on X , and let $p \in X$. Every θ -plurisubharmonic function on $X \setminus \{p\}$ is locally bounded above near p and extends uniquely to a member of $\text{PSH}(X, \theta)$. If X is compact, it is bounded above on $X \setminus \{p\}$.*

Proof Choose coordinates centered at p and write $\Delta_R = \{z \in \mathbb{C} : |z| < R\}$. On the coordinate polydisk Δ_R^n , add a smooth quadratic function to the given function to obtain a plurisubharmonic function h on $\Delta_R^n \setminus \{0\}$. Write the coordinates as (z_1, z_2, z') , with z' absent when $n = 2$, and choose $0 < r < R$. The compact set

$$K = \{|z_1| \leq r, |z_2| = r, |z'_j| \leq r\}$$

avoids the puncture, so $h \leq M$ on K for some finite M . Consider a point of the punctured closed polydisk of radius r . If $z_1 \neq 0$, the disk in the z_2 -direction through the point avoids the puncture and has its boundary in K , so the maximum principle gives $h \leq M$ at the point. If $z_1 = 0$ and $(z_2, z') \neq 0$, the disk in the z_1 -direction through the point avoids the puncture, and its boundary consists of points with $z_1 \neq 0$, where the bound has already been proved; the maximum principle again gives $h \leq M$. Subtracting the smooth correction proves the local upper bound.

By Lemma 1.3.7, applied with $Z = \{p\}$, the upper-limit extension belongs to $\text{PSH}(X, \theta)$. It is unique by Lemma 1.3.3. If X is compact, the extension is an upper semicontinuous function on a compact space and is therefore bounded above. $\square$

Lemma 1.3.9 *Let u be θ -plurisubharmonic near a point x . If a C^2 function a touches u from above at x , that is, $a \geq u$ near x and $a(x) = u(x)$, then $\theta(x) + \text{dd}^c a(x) \geq 0$.*

Proof In coordinates centered at x , let q be a quadratic polynomial with $\text{dd}^c q = \theta(x)$, and let $\varepsilon > 0$. On a sufficiently small ball about x , we have $\theta \leq \theta(x) + \varepsilon \text{dd}^c |z|^2$, so $u + q + \varepsilon |z|^2$ is plurisubharmonic, and $a + q + \varepsilon |z|^2$ touches it from above at x . By the submean inequality on complex lines through x , a C^2 function touching a plurisubharmonic function from above at x has nonnegative complex Hessian at x . Hence $\theta(x) + \text{dd}^c a(x) + \varepsilon \text{dd}^c |z|^2 \geq 0$, and letting $\varepsilon \rightarrow 0$ proves the lemma. $\square$

1.4 Normalized compactness

Fix a smooth positive probability volume form dV on X , used for L^1 norms. Consider a sequence of plurisubharmonic functions on a connected domain that is locally uniformly bounded above. By the local compactness theorem recalled in [Xia], it has a subsequence that either converges in L^1_{loc} or converges locally uniformly to $-\infty$. For normalized θ -plurisubharmonic functions on X , a point at which the maximum is attained excludes the second alternative, and connectedness of X propagates the first one across X .

The submean inequality also controls upper limits at moving points.

Lemma 1.4.1 *Let u_j, u be quasi-plurisubharmonic functions on an open set U in a complex manifold. Suppose that $u_j \rightarrow u$ in $L^1_{\text{loc}}(U)$ and that $\text{dd}^c u_j \geq -\beta$ for a fixed smooth real $(1, 1)$ -form β on U . If $x_j \rightarrow x$ in U , then*

$$\limsup_{j \rightarrow \infty} u_j(x_j) \leq u(x).$$

Moreover, the tail envelopes $h_j = (\sup_{k \geq j} u_k)^*$ decrease to u .

Proof On a coordinate ball about x , add a common smooth correction q so that $u_j + q$ and $u + q$ are plurisubharmonic. For a fixed small radius, the submean inequality bounds $(u_j + q)(x_j)$ by the average of $u_j + q$ over the ball of that radius centered at x_j . As $j \rightarrow \infty$, these averages converge to the average of $u + q$ over the ball of the same radius centered at x : the contribution of $u_j - u$ tends to zero in L^1 , and the integral of the fixed locally integrable function $u + q$ over a ball depends continuously on its center. Letting the radius decrease to zero proves the inequality.

The same estimate gives local uniform upper bounds for the u_j with j large. By coefficient freezing and the local upper-envelope theorem, the tail envelopes are therefore quasi-plurisubharmonic, with the same lower Hessian bound. They decrease with j . If their limit exceeded $u(x)$ at some point x , the definition of the regularization would give indices $k_j \geq j$ and points $x_j \rightarrow x$ contradicting the first assertion for the subsequence (u_{k_j}) . On the other hand, an almost everywhere convergent subsequence of (u_j) shows that $h_j \geq u$ almost everywhere, hence everywhere by Lemma 1.3.3. Thus $h_j \downarrow u$. $\square$

Theorem 1.4.1 *For every smooth real $(1, 1)$ -form θ on X , the family*

$$\mathcal{K}_\theta = \{u \in \text{PSH}(X, \theta) : \sup_X u = 0\}$$

is compact in $L^1(X, dV)$. In particular, there is a constant C_θ such that

$$\int_X |u| dV \leq C_\theta \quad (u \in \mathcal{K}_\theta).$$

Proof Let (u_j) be a sequence in $\mathcal{K}_\theta$. By upper semicontinuity, there are points x_j with $u_j(x_j) = 0$; passing to a subsequence, we may assume that $x_j \rightarrow x$. Cover X by finitely many connected coordinate balls, and on a slightly larger ball around each of them choose a fixed smooth function r_i such that every $u_j + r_i$ is plurisubharmonic; such corrections exist because θ is smooth. Since $u_j \leq 0$, these local functions are uniformly bounded above.

On a ball containing x in its interior, locally uniform convergence to $-\infty$ is impossible, because the values $(u_j + r_i)(x_j) = r_i(x_j)$ stay bounded below. Local compactness therefore gives a subsequence converging in L^1 on this ball. If a second ball meets the first, local compactness on the second ball cannot yield convergence to $-\infty$ on compact subsets of the intersection, since the first limit is finite almost everywhere there. Thus a further subsequence converges in L^1 on the second ball. Since X is connected, the intersection graph of the finite cover by connected balls is

connected. Proceeding along this graph and passing to subsequences finitely many times, we obtain local L^1 convergence on every ball, and a partition of unity then gives convergence in $L^1(X)$ to a function u .

The inequalities $\theta + dd^c u_j \geq 0$ pass to the limit in the sense of distributions. By [Proposition 1.1.1](#), u has a θ -plurisubharmonic representative, still denoted by u . Since $u_j \leq 0$, we have $u \leq 0$ almost everywhere, hence everywhere by [Lemma 1.3.3](#).

By [Lemma 1.4.1](#), $0 = \lim_j u_j(x_j) \leq u(x)$. Thus $u(x) = 0$, and the limit belongs to $\mathcal{K}_\theta$. This proves sequential compactness, which is compactness in the metric space $L^1(X)$. The norm bound follows, since a compact subset of $L^1(X)$ is bounded. $\square$

Corollary 1.4.1 *Let (u_j) be a decreasing sequence in $\text{PSH}(X, \theta)$ with uniformly bounded L^1 norms. Then its pointwise limit u belongs to $\text{PSH}(X, \theta)$; in particular, u is not identically $-\infty$. Moreover, $u_j \rightarrow u$ in L^1 .*

Proof On each connected coordinate ball, after a common smooth correction, the limit of a decreasing sequence of plurisubharmonic functions is either plurisubharmonic or identically $-\infty$. Fatou's lemma, applied to the negative parts, excludes the second alternative because of the L^1 bound. Hence u is quasi-plurisubharmonic, and the inequality $\theta + dd^c u \geq 0$ passes to the decreasing limit. Finally, the nonnegative functions $u_1 - u_j$ increase to $u_1 - u$, so monotone convergence gives $u_j \rightarrow u$ in L^1 . $\square$

1.5 Uniform exponential integrability

For a single quasi-plurisubharmonic function v on X , Skoda's local integrability theorem, recalled in [\[Xia\]](#), applies after local smooth corrections. Taking the smallest exponent over a finite cover gives $e^{-a(v)v} \in L^1(X)$ for some $a(v) > 0$. Normalized compactness makes the exponent and the bound for the integral uniform: otherwise, a convergent weighted sum of counterexamples would violate this qualitative statement.

Let K_ω be the constant of [Theorem 1.4.1](#) for the background ω , so that every $v \in \text{PSH}(X, \omega)$ with $\sup_X v = 0$ satisfies

$$\int_X |v| dV \leq K_\omega. \quad (1.1)$$

Lemma 1.5.1 *There are constants $\alpha > 0$ and $C < +\infty$, depending only on (X, ω, dV) , such that*

$$\int_X e^{-\alpha v} dV \leq C \quad \text{for all } v \in \text{PSH}(X, \omega) \text{ with } \sup_X v = 0.$$

Proof Suppose that no such pair exists. Set $a_j = 2^{-j}$ and choose normalized potentials $v_j \in \text{PSH}(X, \omega)$ with

$$\int_X \exp\left(-\frac{a_j}{j} v_j\right) dV \geq 2^j.$$

The partial sums $V_N = \sum_{j \leq N} a_j v_j$ decrease, since every $v_j \leq 0$. They belong to $\text{PSH}(X, \omega)$ by [Proposition 1.2.2](#), because $\sum_j a_j \leq 1$, and their L^1 norms are uniformly bounded by (1.1). By [Corollary 1.4.1](#), their limit V is therefore ω -plurisubharmonic. Since all summands are nonpositive, $V \leq a_j v_j$ for every j .

Fix $p > 0$. For every $j \geq 1/p$,

$$\int_X e^{-pV} dV \geq \int_X e^{-pa_j v_j} dV \geq \int_X e^{-(a_j/j)v_j} dV \geq 2^j.$$

Thus e^{-pV} is not integrable for any $p > 0$, which contradicts the integrability of $e^{-a(V)V}$ obtained above from Skoda's theorem. $\square$

1.6 Local products and capacity

Bedford–Taylor products of bounded plurisubharmonic functions, and the capacity defined through them, measure the exceptional sets of plurisubharmonic functions and control bounded approximation. We recall these classical facts of local pluripotential theory from [\[Xia, GZ17\]](#). The *plurifine topology* is the coarsest topology that makes all local plurisubharmonic functions continuous. It is finer than the ordinary topology; in particular, strict superlevel sets of quasi-plurisubharmonic functions are plurifine open.

Theorem 1.6.1 (Bedford–Taylor) *Let $1 \leq k \leq n$. If $p_1, \dots, p_k$ are locally bounded plurisubharmonic functions on a domain in $\mathbb{C}^n$, their mixed product $\text{dd}^c p_1 \wedge \dots \wedge \text{dd}^c p_k$ is a positive closed current of order zero. It is symmetric, multilinear in its current factors, and continuous under simultaneous locally bounded decreasing approximation. It does not charge pluripolar sets and is local in the plurifine topology.*

Here plurifine locality means that if two families of such functions agree on a plurifine open Borel set, then their products have the same restriction to that set.

Products multiplied by a bounded potential need more than the weak convergence of the unweighted products in [Theorem 1.6.1](#). An auxiliary complex variable recovers the weight from an ordinary mixed product in one more dimension, including at top degree.

Lemma 1.6.1 *Let $a_j \downarrow a$ and $b_{i,j} \downarrow b_i$, $1 \leq i \leq r \leq n$, be locally uniformly bounded plurisubharmonic functions on a domain in $\mathbb{C}^n$. Then*

$$a_j \text{dd}^c b_{1,j} \wedge \dots \wedge \text{dd}^c b_{r,j} \longrightarrow a \text{dd}^c b_1 \wedge \dots \wedge \text{dd}^c b_r$$

weakly as currents. The same holds for quasi-plurisubharmonic functions that become plurisubharmonic after fixed smooth corrections, and after wedging with smooth forms that converge locally in C^∞ .

Proof First let $r = n$, and write $\mu_j = \bigwedge_i \text{dd}^c b_{i,j}$ and $\mu = \bigwedge_i \text{dd}^c b_i$. Work over a relatively compact ball on which $-M \leq a_j, a \leq M$. On the product of this ball with a disk of radius R in an auxiliary variable w , where $\log R^2 > M + 1$, set

$$v_j(z, w) = \max\{a_j(z), \log |w|^2\}, \quad v(z, w) = \max\{a(z), \log |w|^2\}.$$

These are locally bounded plurisubharmonic functions, also at $w = 0$, and $v_j \downarrow v$. Pulling back the functions $b_{i,j}$ and b_i to the product and applying [Theorem 1.6.1](#) in dimension $n + 1$, we obtain

$$T_j = \mu_j \wedge \text{dd}^c v_j \longrightarrow T = \mu \wedge \text{dd}^c v.$$

Since μ is closed, $T = \text{dd}^c(v\mu)$. As μ has top degree in the base variables, only derivatives in w contribute. Testing against product test functions and applying Fubini's theorem therefore identifies T with $\mu(dz)$ times the circle measure

$$\text{dd}_w^c \max\{a(z), \log |w|^2\} = \sigma_{\exp(a(z)/2)}.$$

Here σ_t is the uniform probability measure on the circle $|w| = t$: the radial derivative jumps from zero to $2/t$ there, so the Euclidean Laplacian has total mass 4π , and our normalization of dd^c divides that mass by 4π . This distributional computation is valid for every bounded Borel function a ; no continuity in z is needed. The same description holds for T_j .

Choose a smooth radial compactly supported function $\vartheta(w)$, supported away from zero and from the circle $|w| = R$, that equals $\log |w|^2$ on all circles with $-M \leq \log |w|^2 \leq M$. For every smooth compactly supported test function ξ on the base,

$$\langle T_j, \xi \vartheta \rangle = \int \xi a_j d\mu_j, \quad \langle T, \xi \vartheta \rangle = \int \xi a d\mu.$$

The convergence $T_j \rightarrow T$ therefore proves the top-degree assertion.

For $r < n$, wedge with $n - r$ constant positive $(1, 1)$ -forms, each the Hessian of a positive quadratic function, and apply the top-degree case. By polarization, the products of positive constant $(1, 1)$ -forms span the real constant forms of bidegree $(n - r, n - r)$, and multiplying them by smooth test functions recovers every coefficient of the currents. For quasi-plurisubharmonic functions, add the fixed smooth corrections to the decreasing sequences, apply the result to the corrected functions, and expand; the term involving the correction to a_j converges by the ordinary decreasing continuity of the products. Finally, the local Chern–Levine–Nirenberg bounds show that these finitely many products have uniformly bounded variation on compact sets. This allows smooth forms converging locally in C^∞ to replace fixed forms in the tests. $\square$

For concentric coordinate balls $B' \Subset B$ and a Borel set $E \subset B'$, the *relative Bedford–Taylor capacity* is

$$\text{cap}(E, B) = \sup \left\{ \int_E (\text{dd}^c v)^n : v \in \text{PSH}(B), 0 \leq v \leq 1 \right\}.$$

If v is bounded, nonconstant and plurisubharmonic on B , applying the definition to $(v - \inf_B v) / (\sup_B v - \inf_B v)$ gives

$$(\text{dd}^c v)^n(E) \leq (\sup_B v - \inf_B v)^n \text{cap}(E, B);$$

for constant v both sides vanish. Write $\text{Vol}(E) = \int_E dV$, where dV is a fixed smooth positive volume form. We use two standard local estimates on these balls, with constants $C, a > 0$ depending only on the nested balls and on dV :

- (1) If $w \leq 0$ is plurisubharmonic on B and v is bounded and plurisubharmonic on B , then

$$\int_{B'} |w| (\text{dd}^c v)^n \leq C \|w\|_{L^1(B)} \|v\|_{L^\infty(B)}^n.$$

Since adding a constant to v does not change $(\text{dd}^c v)^n$, one may first normalize v by such a constant. This is the weighted Chern–Levine–Nirenberg inequality.

- (2) For every Borel set $E \subset B'$,

$$\text{Vol}(E) \leq C \exp(-a \text{cap}(E, B)^{-1/n}),$$

where the right-hand side is zero when the capacity is zero. This is the classical local volume–capacity estimate.

Both are classical results of local pluripotential theory [GZ17, Chapters 3 and 4]; the conventions for bounded products and capacity in [Xia, Chapter 2] agree with these up to fixed constants.

The dependence on the range of the potential can be read off from the usual cutoff argument. Let $M > 0$ and let p be plurisubharmonic on B with $0 \leq p \leq M$. Let $\kappa = \text{dd}^c |z|^2$ be the Euclidean form, and choose a cutoff function χ supported in B , with $0 \leq \chi \leq 1$, equal to one on a smaller ball and satisfying $-C\kappa \leq \text{dd}^c \chi \leq C\kappa$. Integration by parts gives, for $1 \leq j \leq n$,

$$\begin{aligned} \int \chi (\text{dd}^c p)^j \wedge \kappa^{n-j} &= \int p \text{dd}^c \chi \wedge (\text{dd}^c p)^{j-1} \wedge \kappa^{n-j} \\ &\leq CM \int_{\text{supp } \chi} (\text{dd}^c p)^{j-1} \wedge \kappa^{n-j+1}. \end{aligned}$$

Iterating this estimate with nested cutoffs between B' and B , and stopping at degree one or at degree zero, we obtain respectively

$$\begin{aligned} \int_{B'} (\mathrm{dd}^c p)^j \wedge \kappa^{n-j} &\leq C_j M^{j-1} \int_B \mathrm{dd}^c p \wedge \kappa^{n-1}, \\ \int_{B'} (\mathrm{dd}^c p)^j \wedge \kappa^{n-j} &\leq C_j M^j. \end{aligned} \quad (1.2)$$

The constants depend only on the nested balls and on j . For bounded p , the integrations by parts are justified by local decreasing regularization.

Definition 1.6.1 For a compact set E in an open Euclidean ball $B \subset \mathbb{C}^n$, the *relative extremal function* is

$$h_{E,B} = \sup\{u \in \mathrm{PSH}(B) : -1 \leq u \leq 0, u|_E \leq -1\}.$$

The constant -1 is a competitor, and the family is bounded above by zero. The local upper-envelope theorem therefore gives $h_{E,B}^* \in \mathrm{PSH}(B)$ with $-1 \leq h_{E,B}^* \leq 0$. Allowing all competitors $u \leq 0$ with $u|_E \leq -1$ gives the same supremum, because the truncation $\max(u, -1)$ of such a competitor is a competitor in the original family.

A sequence of functions f_j converges to f in *local capacity* if $\mathrm{cap}(K \cap \{|f_j - f| > \epsilon\}, B) \rightarrow 0$ for every $\epsilon > 0$, every coordinate ball B and every compact set $K \subset B$. An assertion holds *quasi-everywhere*, abbreviated q.e., if it holds outside a pluripolar set; in particular, differences of functions that may both be $-\infty$ are considered only off such a set. A positive measure is *non-pluripolar* if it gives zero mass to every pluripolar set.

A function is *quasi-continuous* if, for every $\epsilon > 0$, it is continuous outside an open set of capacity less than ϵ . Plurisubharmonic functions have this property for the local Bedford–Taylor capacity, and a Borel set has zero capacity if and only if it is pluripolar. A locally uniformly bounded monotone sequence of plurisubharmonic functions converges in capacity: to its limit if it decreases, and to the upper semicontinuous regularization of its limit if it increases. If uniformly bounded plurisubharmonic functions converge in capacity, their local products converge weakly, and this remains true after the products are multiplied by uniformly bounded quasi-continuous coefficients converging in capacity. These local results, recalled in [Xia, GZ17], also apply to quasi-plurisubharmonic functions after a common smooth correction.

Theorem 1.6.2 (Mixed Monge–Ampère inequality) *Let $U \subset \mathbb{C}^n$ be a domain, and let β be its Euclidean Hermitian form. Let a, b be locally bounded plurisubharmonic functions on U , and let f, g be nonnegative measurable functions on U with*

$$(\mathrm{dd}^c a)^n \geq f\beta^n, \quad (\mathrm{dd}^c b)^n \geq g\beta^n.$$

Then, for $0 \leq k \leq n$,

$$(\mathrm{dd}^c a)^k \wedge (\mathrm{dd}^c b)^{n-k} \geq f^{k/n} g^{(n-k)/n} \beta^n.$$

The comparison principle of Bedford and Taylor also has mixed forms, recalled in [Xia]. Let a, b be locally bounded plurisubharmonic functions on U such that $E = \{a < b\} \Subset U$, and let S be a positive closed $(n-1, n-1)$ -current that is

a product of Hessians of bounded plurisubharmonic functions and smooth closed positive forms. Then

$$\int_E \mathrm{dd}^c b \wedge S \leq \int_E \mathrm{dd}^c a \wedge S. \quad (1.3)$$

Indeed, apply the Bedford–Taylor integration by parts formula to $b_\epsilon = \max\{a, b - \epsilon\}$, and let $\epsilon \downarrow 0$, using monotone continuity to pass to the limit. Replacing one factor at a time, we obtain, with $P = \mathrm{dd}^c a$ and $Q = \mathrm{dd}^c b$,

$$\int_E P^{n-j} \wedge Q^j \leq \int_E P^n, \quad 0 \leq j \leq n. \quad (1.4)$$

The local envelope theorem for bounded obstacles, recalled in [Xia, GZ17], shows where an envelope can carry Monge–Ampère mass. Let B be a ball with a smooth strictly plurisubharmonic defining function $h < 0$, and let f be a bounded quasi-continuous obstacle with $Ah \leq f \leq 0$ for some $A > 0$. Then the envelope

$$q = (\sup\{v \in \mathrm{PSH}(B) : v \leq f \text{ q.e.}\})^*$$

satisfies $Ah \leq q \leq 0$, tends to zero at the boundary, and

$$\mathbf{1}_{\{q < f\}} (\mathrm{dd}^c q)^n = 0. \quad (1.5)$$

For a locally bounded quasi-plurisubharmonic function v and a smooth convex increasing function F on a neighborhood of the range of v , the bounded Bedford–Taylor chain rule reads

$$\mathrm{dd}^c F(v) = F'(v) \mathrm{dd}^c v + F''(v) \mathrm{d}v \wedge \mathrm{d}^c v. \quad (1.6)$$

The gradient term, and its products with positive Bedford–Taylor factors of bounded potentials, are nonnegative. These identities belong to the bounded local calculus recalled in [Xia, GZ17]; they follow by decreasing regularization, and bounded potentials have the local Sobolev regularity needed to define the gradient term. In particular, inequalities derived from this formula survive local smoothing with a lower curvature error tending to zero.

Lemma 1.6.2 *Let B be a coordinate ball and let τ be a finite non-pluripolar measure with compact support in B . Then there is a bounded plurisubharmonic function v on B such that $\tau \ll (\mathrm{dd}^c v)^n$.*

Proof For $n \geq 2$, we use Cegrell’s decomposition theorem. On a bounded hyperconvex domain in $\mathbb{C}^n$, $n \geq 2$, let $\mathcal{E}_0$ consist of the bounded negative plurisubharmonic functions with zero boundary values and finite total Monge–Ampère mass. The theorem states that every positive compactly supported measure τ has a decomposition

$$\tau = g(\mathrm{dd}^c v)^n + \tau_s, \quad v \in \mathcal{E}_0, \quad 0 \leq g \in L^1((\mathrm{dd}^c v)^n),$$

where τ_s is a positive measure carried by a pluripolar set. If τ is non-pluripolar, then $\tau_s = 0$, so $\tau \ll (\mathrm{dd}^c v)^n$.

In dimension one, the assertion follows directly from the Green potential. Let $a \leq 0$ be the Green potential of τ on the disk, normalized by $\text{dd}^c a = \tau$. Then $v = e^a$ is bounded and subharmonic, and

$$\text{dd}^c v \geq e^a \tau.$$

To justify this inequality, set $a_M = \max(a, -M)$. The chain rule (1.6) in dimension one gives $\text{dd}^c e^{a_M} \geq e^{a_M} \text{dd}^c a_M$, and the right-hand side is at least $e^a \tau$ on $\{a > -M\}$. Let $M \rightarrow \infty$, using the decreasing convergence of the bounded subharmonic functions e^{a_M} on the left and monotone convergence on the right. Since $\{a = -\infty\}$ is polar and τ charges no polar set, $e^a > 0$ almost everywhere for τ . Thus $\tau \ll \text{dd}^c v$. $\square$

For a signed measure ν , write $|\nu|$ for its total variation measure and $\|\nu\|_{\text{TV}(B)} = |\nu|(B)$. On a curve, the Green representation controls capacity by the total variation of the Laplacian, together with an L^1 term for the harmonic remainder.

Lemma 1.6.3 *Let $B' \Subset B$ be concentric disks in $\mathbb{C}$. There is a constant C , depending only on these disks, such that for all quasi-subharmonic functions u, v on a neighborhood of $\overline{B}$ and all $t > 0$,*

$$\text{cap}(B' \cap \{|u - v| > t\}, B) \leq \frac{C}{t} \left(\|u - v\|_{L^1(B)} + \|\text{dd}^c(u - v)\|_{\text{TV}(B)} \right). \quad (1.7)$$

Here the difference $u - v$ is formed off the pole sets of u and v .

Proof Put $f = u - v$ and write the Jordan decomposition on B as $\text{dd}^c f = \alpha^+ - \alpha^-$. Let $g^\pm \leq 0$ be the Green potentials of $\alpha^\pm$ on B with zero boundary values. The $L^1(B)$ norm of the Green kernel of the disk is bounded uniformly in its pole, so

$$\|g^+\|_{L^1(B)} + \|g^-\|_{L^1(B)} \leq C \|\text{dd}^c f\|_{\text{TV}(B)}.$$

Indeed, on the unit disk the kernel is $\log |(z - \zeta)/(1 - \bar{\zeta}z)|^2$; its logarithmic singularity is uniformly integrable, and $|1 - \bar{\zeta}z| \leq 2$. Scaling gives the bound on B .

The distribution $h = f - g^+ + g^-$ is harmonic, and the interior mean-value estimate gives

$$\|h\|_{L^\infty(B')} \leq C \left(\|f\|_{L^1(B)} + \|\text{dd}^c f\|_{\text{TV}(B)} \right).$$

The identity $u + g^- = v + g^+ + h$ holds almost everywhere, hence everywhere by Lemma 1.3.3. Thus $|u - v| \leq -g^+ - g^- + |h|$ off the polar sets of u and v . Let $0 \leq a \leq 1$ be a subharmonic test function on B . Since the measure $\text{dd}^c a$ charges no polar set, this pointwise bound, the weighted Chern–Levine–Nirenberg estimate and (1.2) yield

$$\int_{B'} |u - v| \text{dd}^c a \leq C \left(\|f\|_{L^1(B)} + \|\text{dd}^c f\|_{\text{TV}(B)} \right).$$

Restricting the integral to $B' \cap \{|u - v| > t\}$, dividing by t and taking the supremum over a proves (1.7). $\square$

1.6.1 Polar parts on curves

Every locally finite signed measure ν on a Riemann surface splits uniquely as the sum of its *polar part* ν^{pol} , which is carried by a polar Borel set, and a measure that charges no polar set. To construct the splitting locally, choose countably many polar Borel sets whose $|\nu|$ -masses approach the supremum over all polar Borel sets, and restrict ν to their union, which is again polar. Uniqueness allows these local decompositions to be patched together and shows that $\nu \mapsto \nu^{\text{pol}}$ is linear.

For a locally quasi-subharmonic function u , the *polar curvature* of u is the positive measure $\mu_u = (\text{dd}^c u)^{\text{pol}} = \mathbf{1}_{\{u=-\infty\}} \text{dd}^c u$. The second equality holds because smooth corrections do not change polar parts, while bounded truncations and plurifine locality show that $\mathbf{1}_{\{u > -j\}} \text{dd}^c u$ charges no polar set. The following inverse maximum principle shows that an upper bound for the difference of two potentials orders their polar curvatures.

Lemma 1.6.4 *Let $B \subset \mathbb{C}$ be a disk and let $f \in L^1_{\text{loc}}(B)$ have a distributional Laplacian that is a signed Radon measure. If $f \leq 0$ almost everywhere, then $(\Delta f)^{\text{pol}} \geq 0$.*

Proof It suffices to prove $\Delta f(K) \geq 0$ for every compact polar set $K \subset B$; restriction to smaller disks and inner regularity then give the assertion. Choose open neighborhoods O_j of K with smooth boundaries such that $\overline{O_{j+1}} \subset O_j \Subset B$ and $\bigcap_j \overline{O_j} = K$. Let h_j be the function that equals one on $\overline{O_j}$, is harmonic on $B \setminus \overline{O_j}$, and vanishes on ∂B . The Dirichlet problem on this smooth domain shows that h_j is continuous with $0 \leq h_j \leq 1$. Its outward normal derivative on ∂O_j is nonpositive, so the jump of the derivative across ∂O_j gives $\Delta h_j \leq 0$ on B in the sense of distributions. The maximum principle gives $h_{j+1} \leq h_j$.

Let h be the superharmonic representative of the decreasing limit of the h_j . It is harmonic off K , so its Laplacian is supported on the polar set K . On the other hand, $-h$ is bounded and subharmonic, so its Laplacian charges no polar set, by [Theorem 1.6.1](#). Hence h is harmonic on B . Since $0 \leq h \leq h_1$ and h_1 tends to zero at ∂B , the maximum principle gives $h = 0$. It follows that $h_j \rightarrow 0$ smoothly on compact subsets of $B \setminus K$, while $h_j = 1$ on K .

Choose $0 \leq \chi \in C_c^\infty(B)$ equal to one near K . For large j , regularize h_j by convolution on a neighborhood of $\text{supp } \chi$, obtaining smooth functions $h_{j,\epsilon}$ with $\Delta h_{j,\epsilon} \leq 0$. Since $f \leq 0$,

$$\begin{aligned} \int_B \chi h_{j,\epsilon} \, d(\Delta f) &= \int_B f \, \Delta(\chi h_{j,\epsilon}) \, dx \, dy \\ &\geq \int_B f (2\nabla \chi \cdot \nabla h_{j,\epsilon} + h_{j,\epsilon} \Delta \chi) \, dx \, dy. \end{aligned}$$

For fixed j , the convolutions converge uniformly to h_j on $\text{supp } \chi$, because h_j is continuous. On the support of the derivatives of χ , the function h_j is harmonic for all large j . We may therefore first let $\epsilon \downarrow 0$ and then let $j \rightarrow \infty$. The smooth convergence away from K makes the right-hand side tend to zero, and dominated convergence

for the signed measure Δf makes the left-hand side tend to $\Delta f(K)$. This proves $\Delta f(K) \geq 0$. $\square$

Corollary 1.6.1 *Let u, v be locally quasi-subharmonic functions on a Riemann surface. If $u \leq v + C$ on an open set for some constant C , then $\mu_u \geq \mu_v$ there. Moreover,*

$$\mu_{\max(u,v)} = \mu_u \wedge \mu_v, \quad (1.8)$$

where the right-hand side is the greatest measure dominated by both μ_u and μ_v .

Proof Apply Lemma 1.6.4 to $u - v - C$ in local coordinates. Since smooth functions have zero polar part, linearity of the polar part gives the first assertion. Applying it to $u - \max(u, v)$ and to $v - \max(u, v)$ gives the inequality $\leq$ in (1.8).

For the reverse inequality, add a common smooth correction to make u and v subharmonic on a coordinate disk. On a smaller disk, let g be the Green potential of the restriction of $\lambda = \mu_u \wedge \mu_v$ to that disk, so that $dd^c g = \lambda$. The distributions $u - g$ and $v - g$ have positive Hessians and hence subharmonic representatives a and b . Since $\max(u, v) = g + \max(a, b)$ almost everywhere, the Hessian of $\max(u, v)$ dominates λ . Restricting this inequality to a polar Borel set carrying λ proves the reverse inequality on the smaller disk, and these local statements give it on the whole surface. $\square$

1.6.2 Products at small pole sets

A top-degree product can carry mass on a pole set, and the non-pluripolar product discards this mass. When the unbounded locus is sufficiently small, the full local current product is well defined. Singularity order then compares its residual measures on the pole set, and bounded perturbations leave these measures unchanged.

Theorem 1.6.3 *Let $\Omega \subset \mathbb{C}^n$ be a domain and $S \subset \Omega$ a closed set of Hausdorff dimension zero. Suppose that $u_1, \dots, u_q$, $1 \leq q \leq n$, are plurisubharmonic on Ω and locally bounded on $\Omega \setminus S$. Then their inductively defined full current product*

$$(dd^c u_1 \wedge \dots \wedge dd^c u_q)_{\text{full}}$$

is a closed positive current of order zero. It is symmetric, multilinear, local in the ordinary topology, and continuous under simultaneous decreasing approximation by plurisubharmonic functions. The weighted current $u_1 (dd^c u_2 \wedge \dots \wedge dd^c u_q)_{\text{full}}$ has coefficients of locally finite variation. These full products may charge S .

Proof Apply the classical theorem on products with unbounded potentials, together with its monotone continuity statement, in [Dem12, Chapter III, Theorem 4.5 and Proposition 4.9, pp. 152–156], with the underlying current $T = 1$. For every choice of m of the functions, that theorem requires the intersection of their unbounded loci to have zero Hausdorff measure of dimension $2n - 2m + 1$. This intersection lies in

S , and $2n - 2m + 1 \geq 1$, so the measure is zero. The same hypothesis gives local integrability of the weighted current. Symmetry, multilinearity and locality on open sets follow from the local construction of the currents and decreasing regularization. $\square$

The subscript distinguishes this product from the non-pluripolar product used later; the two coincide for locally bounded functions.

Lemma 1.6.5 *Let $\Omega \subset \mathbb{C}^n$ be a domain and $S \subset \Omega$ a closed set of Hausdorff dimension zero. Let a, b be plurisubharmonic on Ω and locally bounded off S , with $\{a = -\infty\} = S$. If $a \leq b + C$ near S for some finite constant C , then, as positive Radon measures,*

$$\mathbf{1}_S(\mathrm{dd}^c b)_{\mathrm{full}}^n \leq \mathbf{1}_S(\mathrm{dd}^c a)_{\mathrm{full}}^n.$$

If $a - b$ is bounded near S , equality holds.

Proof Fix a compact set $E \subset S$ and $\varepsilon > 0$, and put $w_c = \max\{b - c, (1 + \varepsilon)a\}$ for $c > 0$. Since $a = -\infty$ on the compact set E , upper semicontinuity gives a neighborhood of E on which $a < -(C + c)/\varepsilon$ and $a \leq b + C$. Off S , on this neighborhood, $b - c - (1 + \varepsilon)a \geq -C - c - \varepsilon a > 0$, while on S the second branch of the maximum equals $-\infty$. Thus $w_c = b - c$ near E , and locality on open sets gives $(\mathrm{dd}^c w_c)_{\mathrm{full}}^n(E) = (\mathrm{dd}^c b)_{\mathrm{full}}^n(E)$.

As $c \rightarrow \infty$, the functions w_c decrease to $(1 + \varepsilon)a$. **Theorem 1.6.3** applies to every w_c with the same set S , so their full measures converge weakly to $(1 + \varepsilon)^n (\mathrm{dd}^c a)_{\mathrm{full}}^n$. Since the mass of a compact set is upper semicontinuous under weak convergence of positive measures, we obtain

$$(\mathrm{dd}^c b)_{\mathrm{full}}^n(E) \leq (1 + \varepsilon)^n (\mathrm{dd}^c a)_{\mathrm{full}}^n(E).$$

Here we apply the semicontinuity after multiplying the measures by a fixed nonnegative cutoff function with compact support, equal to one near E ; both masses on E are finite by the theorem. Letting $\varepsilon \downarrow 0$ and applying inner regularity to all compact sets $E \subset S$ gives the asserted inequality of measures. If $a - b$ is bounded near S , then also $\{b = -\infty\} = S$, so the roles of a and b can be interchanged, and equality follows. $\square$

1.6.3 Sobolev regularity at divisorial poles

For a potential that is a convex function of $\log |f|$, with f holomorphic, the growth of the convex function at $-\infty$ determines which derivatives are integrable near the divisor of f . The gradient and the classical Laplacian have different thresholds. Moreover, the distributional Laplacian keeps a measure on the divisor unless the slope of the convex function tends to zero.

Let $U \subset \mathbb{C}^n$ be a sufficiently small neighborhood of 0, and let $f \not\equiv 0$ be a holomorphic function on U with $f(0) = 0$. Write

$$f = g \prod_{j=1}^N h_j^{m_j}, \quad m_0 = \min_j m_j,$$

where g is a holomorphic unit and the h_j are distinct irreducible germs represented on U . Fix a convex nondecreasing function $\chi \in C^2((-\infty, A])$ and shrink U so that $\log |f| < A - 1$. Set $v = \chi(\log |f|)$ off $Z = \{f = 0\}$; this function is plurisubharmonic and bounded above, and we extend it across Z by [Lemma 1.3.7](#). In this subsection, gradients, Laplacians, Sobolev spaces and the volume form dV are the real Euclidean ones. Write $|\partial f|^2 = \sum_j |\partial f / \partial z_j|^2$, so that $|\nabla |f|| = |\partial f|$ off Z .

Lemma 1.6.6 *After shrinking U , there is a constant $C > 0$ such that*

$$|\partial f| \leq C |f|^{1-1/m_0} \quad \text{on } U \setminus Z.$$

For each compact set $K \subset U$, there are $C_K, r_K > 0$ with

$$\int_{K \cap \{|f|=r\}} |\partial f| dS \leq C_K r \quad (0 < r < r_K),$$

where dS is the Euclidean surface measure on the real hypersurface $\{|f| = r\}$. In particular, for every nonnegative measurable function Ψ ,

$$\int_{K \cap \{0 < |f| < r_K\}} \Psi(|f|) |\partial f|^2 dV \leq C_K \int_0^{r_K} \Psi(r) r dr.$$

Proof Shrink U so that $|h_j| \leq 1$ and the unit g , its inverse and the first derivatives of g and of all h_j are bounded. For each j , $|f|^{1/m_0} \leq C |h_j|^{m_j/m_0} \leq C |h_j|$. Logarithmic differentiation of the factorization therefore gives

$$\frac{|\partial f|}{|f|} \leq C \left(1 + \sum_j |h_j|^{-1} \right) \leq C |f|^{-1/m_0},$$

which proves the first bound.

For small $\zeta \in \mathbb{C}$, let μ_ζ be the Euclidean volume measure of the fiber divisor $\{f = \zeta\}$, counted with multiplicity. As $\zeta \rightarrow 0$, we have $\log |f - \zeta| \rightarrow \log |f|$ in L^1_{loc} : by the local compactness theorem recalled at the beginning of [Section 1.4](#), it suffices to identify subsequential limits, and the convergence is locally uniform off Z , which identifies every such limit and excludes convergence to $-\infty$. The Poincaré–Lelong formula therefore gives weak convergence of the fiber currents, and hence of their Euclidean trace measures. Pairing with a fixed nonnegative cutoff function equal to one near K shows that $\sup_{|\zeta| < r_K} \mu_\zeta(K) < \infty$ for some $r_K > 0$.

The critical locus of f has finitely many local components, and f is constant on each of them. After shrinking U , every remaining critical component passes through 0, where f vanishes. Thus the small nonzero fibers are smooth. On $\{|f| = r\}$, the coarea formula for the map f to the circle of radius r gives

$$\int_{K \cap \{|f|=r\}} |\partial f| \, dS = \int_{|\zeta|=r} \mu_\zeta(K) \, dS(\zeta) \leq C_K r.$$

The coarea formula for the function $|f|$, together with $|\nabla|f|| = |\partial f|$, proves the last inequality. The same formulas hold in dimension one, where the fiber volume is the counting measure. $\square$

Proposition 1.6.1 *For each $2 \leq p < \infty$,*

$$v \in W_{\text{loc}}^{1,p}(U) \iff \int_{-\infty}^A |\chi'(s)|^p e^{(2-p)s/m_0} \, ds < \infty.$$

In this case, the weak gradient of v is the zero extension of $\chi'(\log|f|)\nabla \log|f|$ from $U \setminus Z$.

Proof At a smooth point of a component of multiplicity m_0 , outside the other components, multiplying the defining function of the component by a holomorphic m_0 -th root of the remaining unit gives a normal coordinate w_1 with $f = w_1^{m_0}$. Coordinate changes with bounded derivatives and Jacobians preserve local first-order Sobolev integrability. With $r = |w_1|$ and $s = m_0 \log r$, polar integration of the classical gradient gives, up to fixed positive factors,

$$\int_0^{r_0} |\chi'(m_0 \log r)|^p r^{1-p} \, dr = \frac{1}{m_0} \int_{-\infty}^{m_0 \log r_0} |\chi'(s)|^p e^{(2-p)s/m_0} \, ds.$$

Such smooth points occur in every neighborhood of 0. This proves necessity, since changing the finite upper endpoint does not affect convergence.

For sufficiency, put

$$s_\varepsilon = \frac{1}{2} \log(|f|^2 + \varepsilon^2), \quad v_\varepsilon = \chi(s_\varepsilon).$$

For small $\varepsilon > 0$, these are C^2 plurisubharmonic functions decreasing to v . By convexity, $|\chi(s)| \leq C(1 + |s|)$ for $s \leq A$, so the local exponential integrability of $\log|f|$, recalled in [Xia], gives convergence in every local L^p space with $p < \infty$. By the chain rule,

$$|\nabla v_\varepsilon| = \chi'(s_\varepsilon) \frac{|f|}{|f|^2 + \varepsilon^2} |\partial f|.$$

Apply Lemma 1.6.6 with the coarea formula, keeping two powers of $|\partial f|$ for the level estimate and bounding the other $p - 2$ powers by the first inequality of the lemma. The local integral of $|\nabla v_\varepsilon|^p$ over $K \cap \{0 < |f| < r_K\}$ is then bounded by

$$C \int_0^{r_K} |\chi'(\frac{1}{2} \log(r^2 + \varepsilon^2))|^p \frac{r^{p+(p-2)(1-1/m_0)+1}}{(r^2 + \varepsilon^2)^p} \, dr.$$

With $s = \frac{1}{2} \log(r^2 + \varepsilon^2)$, we have $ds = r \, dr / (r^2 + \varepsilon^2)$ and $r \leq (r^2 + \varepsilon^2)^{1/2}$, so this is at most

$$C \int_{-\infty}^A |\chi'(s)|^p e^{(2-p)s/m_0} ds.$$

The integral over the part where $|f| \geq r_K$ is uniformly bounded as well. Weak compactness in Sobolev spaces and the local L^p convergence therefore show that $v \in W_{\text{loc}}^{1,p}$. Its weak gradient agrees with the classical one off Z , and Z has Lebesgue measure zero, which proves the final assertion. $\square$

Proposition 1.6.2 *Let G be the zero extension of $\chi''(\log |f|)|\nabla \log |f||^2$ from $U \setminus Z$, and put $\ell = \lim_{s \rightarrow -\infty} \chi'(s)$. For each $1 \leq p < \infty$,*

$$G \in L_{\text{loc}}^p(U) \iff \int_{-\infty}^A |\chi''(s)|^p e^{2(1-p)s/m_0} ds < \infty.$$

In the sense of distributions,

$$\Delta v = G + \ell \Delta \log |f|,$$

where $\Delta \log |f|$ is a positive measure carried by the divisor of f . In particular, Δv is represented by a locally L^p function exactly when $\ell = 0$ and the integral above is finite.

Proof The limit $\ell \geq 0$ exists because χ' is nonnegative and nondecreasing. Near a smooth point of a component of multiplicity m_0 , outside the other components, the coordinate reduction to $f = w_1^{m_0}$ makes the positive complex Hessian of v off Z a single factor in the normal direction. Its Euclidean traces in the two coordinate systems are uniformly comparable, so polar integration gives necessity. In general, $G = \chi''(\log |f|)|\partial f|^2/|f|^2$ off Z . The coarea formula and [Lemma 1.6.6](#), now bounding the remaining $2p - 2$ powers of $|\partial f|$ by the first inequality of the lemma, give

$$\int_{K \cap \{0 < |f| < r_K\}} G^p dV \leq C \int_0^{r_K} |\chi''(\log r)|^p r^{-1-2(p-1)/m_0} dr.$$

The substitution $s = \log r$ proves sufficiency. For $p = 1$ the integral is always finite, since $\int_{-\infty}^A \chi'' = \chi'(A) - \ell$.

For the distributional identity, use s_ε and v_ε from the preceding proof. Direct differentiation gives

$$\begin{aligned} \Delta v_\varepsilon &= \chi''(s_\varepsilon) \frac{|f|^2 |\partial f|^2}{(|f|^2 + \varepsilon^2)^2} + \chi'(s_\varepsilon) \Delta s_\varepsilon, \\ \Delta s_\varepsilon &= \frac{2\varepsilon^2 |\partial f|^2}{(|f|^2 + \varepsilon^2)^2}. \end{aligned}$$

Off Z , the first term tends locally uniformly to G . By the level estimate of [Lemma 1.6.6](#) and the same substitution, its integral over $K \cap \{|f| < r_0\}$ is at most

$$C \int_{-\infty}^{\frac{1}{2} \log(r_0^2 + \varepsilon^2)} \chi''(s) \, ds.$$

This bound tends to zero if we first let $\varepsilon \rightarrow 0$ and then $r_0 \rightarrow 0$, so the first term converges to G in L_{loc}^1 .

The positive measures Δs_ε converge weakly to $\Delta \log |f|$, with locally bounded masses, and the Poincaré–Lelong formula shows that this limit is a measure supported on Z . On $\{|f| < r_0\}$,

$$0 \leq \chi'(s_\varepsilon) - \ell \leq \chi'(\tfrac{1}{2} \log(r_0^2 + \varepsilon^2)) - \ell,$$

while $\Delta s_\varepsilon \rightarrow 0$ uniformly on compact subsets of $\{|f| \geq r_0\}$. Taking the same successive limits shows that $(\chi'(s_\varepsilon) - \ell) \Delta s_\varepsilon \rightarrow 0$ weakly. Since $v_\varepsilon \rightarrow v$ in L_{loc}^1 , passing to the limit in the formula for Δv_ε gives the identity. If $\ell > 0$, the measure $\ell \Delta \log |f|$ is nonzero and singular with respect to Lebesgue measure; uniqueness of the Lebesgue decomposition therefore proves the final criterion. $\square$

Example 1.6.1 Shrink U so that $\log |f| < -2$, and let $0 < a < 1$. Then the plurisubharmonic function

$$v_a = -(-\log |f|)^a$$

has $\Delta v_a \in L_{\text{loc}}^1$, while

$$v_a \in W_{\text{loc}}^{1,2} \iff a < \tfrac{1}{2}.$$

It belongs to no $W_{\text{loc}}^{1,p}$ with $p > 2$ and to no $W_{\text{loc}}^{2,1}$.

Proof Here $\chi(s) = -(-s)^a$ is of class C^2 on $(-\infty, -1]$, so the preceding propositions apply with $A = -1$. Moreover, $\chi'(s) = a(-s)^{a-1}$ and $\chi''(s) = a(1-a)(-s)^{a-2}$, so $\ell = 0$. The two propositions give the assertion about the Laplacian and the first-order thresholds. At $a = 1/2$, the first-order integral diverges logarithmically; for $p > 2$, its exponential factor forces divergence.

For second derivatives, take a smooth point of a component of multiplicity m , outside the other components, with a normal coordinate w_1 such that $f = w_1^m$. Write $F(r) = \chi(m \log r)$ with $r = |w_1|$. The real second derivative of v_a in the unit direction tangent to the circles $|w_1| = r$ equals $F'(r)/r = m\chi'(m \log r)/r^2$. Thus the integral of its absolute value over the normal disk is bounded below, up to a fixed positive factor, by

$$\int_0^{r_0} \chi'(m \log r) \frac{dr}{r} = \frac{1}{m} \int_{-\infty}^{m \log r_0} \chi'(s) \, ds = +\infty.$$

Hence the classical Hessian of v_a off the divisor is not locally integrable, whereas local integrability is necessary for $W_{\text{loc}}^{2,1}$. Since smooth coordinate changes preserve this Sobolev class, the argument is complete. $\square$

1.6.4 Measure concentration under integrable convergence

Decreasing approximation controls Bedford–Taylor products, but convergence of the potentials in L^1 alone does not. If plurisubharmonic functions tend to zero in L^1_{loc} and are locally uniformly bounded, the range estimate (1.2) shows that their Monge–Ampère measures tend to zero. Without a common bound, smooth bounded potentials that tend to zero, even in capacity, can have Monge–Ampère measures converging to a point mass.

Lemma 1.6.7 *Let $\Omega \subset \mathbb{C}^n$ be a domain. Suppose that $u_j \in \text{PSH}(\Omega) \cap L^\infty_{\text{loc}}(\Omega)$ tend to zero in $L^1_{\text{loc}}(\Omega)$ and satisfy $\sup_j \|u_j\|_{L^\infty(K)} < \infty$ for every compact set $K \subset \Omega$. Then $(\text{dd}^c u_j)^n(K) \rightarrow 0$ for every such K .*

Proof Fix concentric balls $B' \Subset B \Subset B_1 \Subset \Omega$, and put $\beta = \text{dd}^c |z|^2$. If ψ is a nonnegative smooth cutoff function supported in B_1 and equal to one near $\bar{B}$, integration by parts gives

$$0 \leq \int_B \text{dd}^c u_j \wedge \beta^{n-1} \leq \int_{B_1} u_j \text{dd}^c \psi \wedge \beta^{n-1} \leq C \|u_j\|_{L^1(B_1)} \rightarrow 0.$$

Choose $M > 0$ with $|u_j| \leq M$ on B for all j , and apply the first estimate in (1.2) to $u_j + M$, whose values lie in $[0, 2M]$. It bounds the top-degree mass of B' by $C(2M)^{n-1}$ times the trace integral over B , which tends to zero; for $n = 1$ the trace estimate itself suffices. Covering K by finitely many such balls proves the lemma. $\square$

The construction uses a regularized maximum of a small multiple of a logarithm in one variable and a potential in the remaining variables. Its Monge–Ampère measure can be computed exactly by integration over circles in the first variable, and this will keep its top-degree mass fixed while the logarithmic coefficient tends to zero.

Lemma 1.6.8 *Let $n \geq 2$, let $U \subset \mathbb{C}^{n-1}$ be a domain, and let v be a smooth plurisubharmonic function on U . Fix $\varepsilon, R, \eta > 0$ and $A \in \mathbb{R}$. Let χ_η be the convolution of $t \mapsto \max(t, 0)$ with a smooth even probability density supported in $[-\eta, \eta]$, and put*

$$\begin{aligned} q(\zeta) &= \varepsilon \log(|\zeta|^2/R^2), & T(\zeta, z') &= v(z') - A - q(\zeta), \\ h(\zeta, z') &= q(\zeta) + \chi_\eta(T(\zeta, z')) \end{aligned}$$

for $\zeta \neq 0$. Then h extends to a smooth plurisubharmonic function on $\mathbb{C} \times U$. Set

$$w_\eta(t) = n\chi'_\eta(t)^{n-1}\chi''_\eta(t), \quad r_t(z') = R \exp((v(z') - A - t)/(2\varepsilon)).$$

The function w_η is nonnegative, supported in $[-\eta, \eta]$, and has integral one. For every $f \in C_c(\mathbb{C} \times U)$,

$$\int f(\text{dd}^c h)^n = \varepsilon \int_U \left[\int_{-\eta}^{\eta} w_\eta(t) \int_0^{2\pi} f(r_t(z')e^{i\theta}, z') \frac{d\theta}{2\pi} dt \right] (\text{dd}^c v)^{n-1}. \quad (1.9)$$

Proof By convexity, $0 \leq \chi'_\eta \leq 1$ and $\chi''_\eta \geq 0$. The function χ_η vanishes on $(-\infty, -\eta]$ and equals t on $[\eta, \infty)$. Since $T \rightarrow +\infty$ as $\zeta \rightarrow 0$, we have $h = v - A$ near each point with $\zeta = 0$, which gives the smooth extension. Off the hyperplane $\{\zeta = 0\}$, the function q is pluriharmonic and

$$\mathrm{dd}^c h = \chi'_\eta(T) \mathrm{dd}^c v + \chi''_\eta(T) dT \wedge d^c T \geq 0.$$

The second summand has rank at most one, and the first has rank at most $n - 1$. Hence

$$(\mathrm{dd}^c h)^n = n \chi'_\eta(T)^{n-1} \chi''_\eta(T) dT \wedge d^c T \wedge (\mathrm{dd}^c v)^{n-1}.$$

The last factor has top degree in the variables z' , so the derivatives of v in $dT \wedge d^c T$ contribute nothing. Write $s = \log(|\zeta|^2/R^2)$. In polar coordinates, $dq = \varepsilon ds$ and $d^c q = \varepsilon d\theta/(2\pi)$. At fixed z' , the change of variables from s to $t = v - A - \varepsilon s$ gives (1.9). There is no contribution near $\zeta = 0$, where $h = v - A$ and the form $\mathrm{dd}^c h$ has rank at most $n - 1$. Finally, w_η is the derivative of $(\chi'_\eta)^n$, whose values at $-\eta$ and η are zero and one. $\square$

Proposition 1.6.3 *Let $\Omega \subset \mathbb{C}^n$, $n \geq 2$, be a bounded domain and $a \in \Omega$. For every $c > 0$, there are smooth bounded plurisubharmonic functions $u_j \leq 0$ on Ω such that*

$$\|u_j\|_{L^p(\Omega)} \longrightarrow 0 \quad (1 \leq p < \infty), \quad (\mathrm{dd}^c u_j)^n \longrightarrow c \delta_a \quad \text{vaguely}.$$

The same sequence tends to zero in local capacity. Here the norms are taken with respect to Lebesgue measure, and vague convergence means convergence against every compactly supported continuous test function.

Proof Translate a to the origin and write $z = (\zeta, z') \in \mathbb{C} \times \mathbb{C}^m$, $m = n - 1$. It suffices to construct measures of mass one and then multiply the potentials by $c^{1/n}$. For $\delta > 0$, put $H_\delta(z') = \log(|z'|^2 + \delta^2)$. With $s = |z'|^2$, the complex Hessian of H_δ has the eigenvalue $(s + \delta^2)^{-1}$ with multiplicity $m - 1$ in the directions orthogonal to z' and the eigenvalue $\delta^2(s + \delta^2)^{-2}$ in the radial direction. Taking the determinant and integrating in polar coordinates gives

$$(\mathrm{dd}^c H_\delta)^m = \frac{m!}{\pi^m} \frac{\delta^2}{(|z'|^2 + \delta^2)^{m+1}} d\lambda_{2m}, \quad \int_{|z'| < b} (\mathrm{dd}^c H_\delta)^m = \left(\frac{b^2}{b^2 + \delta^2} \right)^m,$$

where λ_{2m} is Lebesgue measure. These probability measures tend to δ_0 as $\delta \downarrow 0$, since their mass outside each ball about the origin tends to zero.

Choose $R > \max(1, \sup_\Omega |\zeta|)$ and a ball $P \subset \mathbb{C}^m$ containing the projection of Ω to the z' variables. Set

$$\delta_j = \varepsilon_j = j^{-1}, \quad \eta_j = j^{-2}, \quad v_j = \varepsilon_j^{-1/m} H_{\delta_j}, \\ A_j = \sup_P v_j + 2\varepsilon_j \log(Rj).$$

Apply Lemma 1.6.8 on $\mathbb{C} \times \mathbb{C}^m$ to these data, and let $u_j = h_j - \eta_j$, where h_j is the resulting function. The convolution satisfies $0 \leq \chi_{\eta_j}(t) - \max(t, 0) \leq \eta_j$, and

$q + \max(T, 0) = \max(q, v_j - A_j)$. Both branches of this maximum are negative on Ω , so

$$\varepsilon_j \log(|\zeta|^2/R^2) - \eta_j \leq u_j \leq 0.$$

Each u_j is smooth and bounded on Ω , since the second branch $v_j - A_j$ is bounded below on the bounded set P . The logarithm has finite $L^p(\Omega)$ norm for every finite p , by polar integration on a fixed polydisk containing Ω . Hence $u_j \rightarrow 0$ in all these norms.

Let $B' \Subset B \Subset \Omega$ be concentric balls, and let $w \in \text{PSH}(B)$ with $0 \leq w \leq 1$. Since $|u_j| \leq \varepsilon_j |\log(|\zeta|^2/R^2)| + \eta_j$, the weighted Chern–Levine–Nirenberg estimate applied to $\log(|\zeta|^2/R^2)$, together with the range estimate (1.2) for the constant term, gives

$$\int_{B'} |u_j| (\text{dd}^c w)^n \leq C_B (\varepsilon_j + \eta_j),$$

where C_B depends on the fixed balls and the logarithm but not on j or w . Restricting the integral to $B' \cap \{|u_j| > t\}$, dividing by $t > 0$ and taking the supremum over w shows that the capacity of $B' \cap \{|u_j| > t\}$ relative to B tends to zero.

In (1.9), the factor $\varepsilon_j (\text{dd}^c v_j)^m$ equals $(\text{dd}^c H_{\delta_j})^m$. For $z' \in P$ and $|t| \leq \eta_j$, the radii satisfy

$$r_t(z') \leq j^{-1} \exp(\eta_j/(2\varepsilon_j)) \leq e^{1/2}/j.$$

Extend $f \in C_c(\Omega)$ by zero to $\mathbb{C}^n$. Outside the projection of $\text{supp } f$ to the z' variables, both $f(r_t e^{i\theta}, z')$ and $f(0, z')$ vanish. On this projection, the uniform continuity of f and the bound on the radii make their difference tend to zero uniformly. Since the weights $w_{\eta_j}(t) dt$ and $d\theta/(2\pi)$ and the measures $(\text{dd}^c H_{\delta_j})^m$ all have total mass one, it follows that

$$\int_{\Omega} f(\text{dd}^c u_j)^n - \int_{\mathbb{C}^m} f(0, z') (\text{dd}^c H_{\delta_j})^m \rightarrow 0.$$

The second integral tends to $f(0)$, which proves the asserted vague limit. $\square$

Each approximating measure has a smooth density and charges no pluripolar set, whereas the limit is a point mass. By Lemma 1.6.7, the potentials therefore have no common lower bound on some compact set. Thus convergence in capacity is compatible with concentration of the Monge–Ampère measures once common local bounds are lost.

1.6.5 Adding a prescribed local measure

The concentration in Proposition 1.6.3 can be produced on top of a given bounded potential b and repeated, so as to add an arbitrary prescribed measure to $(\text{dd}^c b)^n$. Adding a perturbation h to b creates the mixed terms $(\text{dd}^c b)^{n-r} \wedge (\text{dd}^c h)^r$. A mixed Chern–Levine–Nirenberg estimate controls them, provided that the lower-degree currents of h are kept small.

Lemma 1.6.9 Fix the data $n, U, v, \varepsilon, R, \eta, \chi_\eta$ of Lemma 1.6.8, and write h_A for the smooth plurisubharmonic function h of that lemma, regarded as a function of A . Put $D = \{0\} \times U$, and write $[D]$ for the current of integration over this hypersurface. Then, for every $1 \leq r \leq n$,

$$(\mathrm{dd}^c h_A)^r \longrightarrow \varepsilon [D] \wedge (\mathrm{dd}^c v)^{r-1} \quad \text{as currents on } \mathbb{C} \times U, \quad A \rightarrow \infty.$$

The product on the right is integration of the restriction of the smooth form $(\mathrm{dd}^c v)^{r-1}$ over D .

Proof Write $S = \mathrm{dd}^c v$, $q = \varepsilon \log(|\zeta|^2/R^2)$ and $T_A = v - A - q$. The rank-one calculation in the proof of Lemma 1.6.8 gives

$$(\mathrm{dd}^c h_A)^r = \chi'_\eta(T_A)^r S^r + r \chi'_\eta(T_A)^{r-1} \chi''_\eta(T_A) dT_A \wedge \mathrm{d}^c T_A \wedge S^{r-1}$$

off D ; since h_A is smooth and D has measure zero, this formula determines the current. Fix a smooth compactly supported test form. On the projection of its support to U , the function v and its derivatives are bounded. Hence the support of $\chi'_\eta(T_A)$ lies in $\{|\zeta| \leq s_A\}$, where $s_A = C \exp(-A/(2\varepsilon))$ and C depends only on this compact set and the fixed data. The coefficients involving v and χ_η are bounded at the fixed parameters, so the first summand has pairing $O(s_A^2)$. In the second summand, the term with two derivatives of v also has pairing $O(s_A^2)$, and the two cross terms have pairing $O(s_A)$: the derivative of q in the ζ direction has size $O(|\zeta|^{-1})$, and its area integral over the disk $\{|\zeta| \leq s_A\}$ is $O(s_A)$.

It remains to integrate the term containing $dq \wedge \mathrm{d}^c q$. The logarithmic change of the radial variable used for (1.9) leaves the factor ε and the probability weight

$$r \chi'_\eta(t)^{r-1} \chi''_\eta(t) dt, \quad -\eta \leq t \leq \eta.$$

Only the component of the test form in the z' directions enters this term, and on the shrinking circles its coefficients tend uniformly to their values at $\zeta = 0$. Integration in the angle therefore gives, in the limit, exactly the pairing with $\varepsilon [D] \wedge S^{r-1}$. This proves the convergence in every degree. $\square$

Lemma 1.6.10 Let $\Omega \subset \mathbb{C}^n$ be a domain, let K and L be compact subsets of Ω with K contained in the interior L° of L , and put $\beta = \mathrm{dd}^c |z|^2$. Let b be a locally bounded plurisubharmonic function on Ω , and let T be a smooth positive closed (r, r) -form, $1 \leq r < n$. Then

$$\int_K (\mathrm{dd}^c b)^{n-r} \wedge T \leq C_{K,L,n} (1 + \|b\|_{L^\infty(L)})^{n-r} \int_L T \wedge \beta^{n-r}.$$

Proof Put $M = 1 + \|b\|_{L^\infty(L)}$. Cover K by finitely many balls whose larger concentric balls have closures in L° . Replacing b by $b + M$, which has the same Hessian and takes values in $[0, 2M]$ on L , we may assume $0 \leq b \leq 2M$ there. For nested cutoff functions ψ , integration by parts against closed forms gives

$$\int \psi \operatorname{dd}^c b \wedge W = \int b \operatorname{dd}^c \psi \wedge W \leq CM \int_{\operatorname{supp} \psi} \beta \wedge W,$$

where W is T multiplied by the remaining positive closed factors. Apply this successively to the $n - r$ Hessians of b . For bounded b , the integrations by parts are justified by local decreasing regularization and [Theorem 1.6.1](#), with one common bound on the range. Summing over the finite cover gives the asserted constant. $\square$

Proposition 1.6.4 *Let $\Omega \subset \mathbb{C}^n$, $n \geq 2$, be a bounded domain, let $b \in \operatorname{PSH}(\Omega) \cap L^\infty(\Omega)$, $a \in \Omega$ and $c > 0$. Given finitely many $f_i \in C_c(\Omega)$ and numbers $\tau, t > 0$, there is a smooth bounded plurisubharmonic function $h \leq 0$ on Ω such that*

$$\|h\|_{L^p(\Omega)} \leq C_{\Omega,p} t \quad (1 \leq p < \infty),$$

$$\left| \int_{\Omega} f_i ((\operatorname{dd}^c(b+h))^n - (\operatorname{dd}^c b)^n) - c f_i(a) \right| < \tau \quad \text{for every } i.$$

For concentric balls $B' \Subset B \Subset \Omega$ and every $w \in \operatorname{PSH}(B)$ with $0 \leq w \leq 1$, it also satisfies

$$\int_{B'} |h| (\operatorname{dd}^c w)^n \leq C_{B',B,\Omega} t.$$

These constants are independent of b, a, c , the test functions and the tolerances.

Proof We take for h a function from [Lemma 1.6.8](#) whose top-degree measure approximates $c\delta_a$ and whose lower-degree currents are small; [Lemma 1.6.10](#) then controls the mixed terms.

Write $a = (a_1, a')$ and $m = n - 1$, and fix $R = 2 \sup_{\Omega} |z_1| + 2$. For $\delta > 0$, put $H_\delta(z') = \log(|z' - a'|^2 + \delta^2)$. By the radial calculation in the proof of [Proposition 1.6.3](#), $(\operatorname{dd}^c H_\delta)^m$ is a probability measure tending to $\delta_{a'}$ as $\delta \downarrow 0$. Extend every f_i by zero outside Ω , and choose δ such that

$$\left| c \int_{\mathbb{C}^m} f_i(a_1, z') (\operatorname{dd}^c H_\delta)^m - c f_i(a) \right| < \tau/3 \quad \text{for all } i.$$

Choose compact sets $K, L \subset \Omega$ with $K \subset L^\circ$ and K containing the supports of all f_i , and a nonnegative smooth cutoff function ψ with compact support in Ω , equal to one near L . Put $\beta = \operatorname{dd}^c |z|^2$. Expanding the top power of $\operatorname{dd}^c(b+h)$, summing the bounds of [Lemma 1.6.10](#) with their binomial coefficients and the norms $\|f_i\|_\infty$, we find $\gamma > 0$ such that the mixed terms contribute less than $\tau/3$ to every test integral whenever h is smooth and plurisubharmonic and

$$\int_L (\operatorname{dd}^c h)^r \wedge \beta^{n-r} < \gamma, \quad 1 \leq r < n.$$

Fix $0 < \eta \leq t/2$. Apply [Lemma 1.6.8](#) on $\mathbb{C} \times \mathbb{C}^m$ with transverse variable $\zeta = z_1 - a_1$ and $v = c^{1/m} \varepsilon^{-1/m} H_\delta$. For $r < n$, [Lemma 1.6.9](#) gives

$$(\operatorname{dd}^c h_A)^r \longrightarrow \varepsilon^{(n-r)/(n-1)} c^{(r-1)/(n-1)} [\{z_1 = a_1\}] \wedge (\operatorname{dd}^c H_\delta)^{r-1}$$

as $A \rightarrow \infty$. For the fixed δ , the integrals of these limits against $\psi\beta^{n-r}$ are finite, and their exponents of ε are positive. Choose $0 < \varepsilon \leq t/2$ so that each of them is less than $\gamma/2$. With these parameters fixed, choose A so large that the integrals $\int_L (\text{dd}^c h_A)^r \wedge \beta^{n-r}$ are less than γ , that $v - A \leq 0$ on the projection of Ω to the z' variables, and that

$$\left| \int_{\Omega} f_i (\text{dd}^c h_A)^n - c \int_{\mathbb{C}^m} f_i(a_1, z') (\text{dd}^c H_{\delta})^m \right| < \tau/3 \quad \text{for all } i.$$

The last choice follows directly from (1.9), because the circles there shrink uniformly over the projected supports of the tests and $\varepsilon(\text{dd}^c v)^m = c(\text{dd}^c H_{\delta})^m$.

Set $h = h_A - \eta$. As in the proof of Proposition 1.6.3, h is smooth, bounded and nonpositive on Ω , with

$$\varepsilon \log(|z_1 - a_1|^2/R^2) - \eta \leq h \leq 0.$$

The logarithm has $L^p(\Omega)$ norm bounded uniformly for a_1 in the projection of Ω to the first coordinate: after translation, its one-variable integral is bounded by polar integration on one fixed disk. This uniform bound, the weighted Chern–Levine–Nirenberg estimate and the range estimate (1.2) give the asserted bound for the integrals over B' . Since $\varepsilon + \eta \leq t$, both estimates hold with constants depending only on Ω , p , B' and B .

Finally, multilinearity of bounded products gives

$$(\text{dd}^c(b+h))^n = (\text{dd}^c b)^n + (\text{dd}^c h)^n + \sum_{r=1}^{n-1} \binom{n}{r} (\text{dd}^c b)^{n-r} \wedge (\text{dd}^c h)^r.$$

The choice of δ , the choice of A for the top-degree term and the estimate of the mixed terms each contribute less than $\tau/3$ to every test integral. This proves the required inequalities, with one choice of h for all finite p . $\square$

Theorem 1.6.4 *Let $\Omega \subset \mathbb{C}^n$, $n \geq 2$, be a bounded domain, let $b \in \text{PSH}(\Omega) \cap L^\infty(\Omega)$, and let v be a positive Radon measure on Ω . There are bounded plurisubharmonic functions $u_j \leq b$ on Ω such that*

$$\begin{aligned} \|u_j - b\|_{L^p(\Omega)} &\longrightarrow 0 \quad (1 \leq p < \infty), \\ (\text{dd}^c u_j)^n &\longrightarrow (\text{dd}^c b)^n + v \quad \text{vaguely}. \end{aligned}$$

The same sequence converges to b in local capacity. If b is smooth, every u_j can be chosen smooth. The measure v may have infinite total mass.

Proof Choose relatively compact open sets exhausting Ω , each with closure contained in the next one. On each of these sets, take a countable family of smooth compactly supported functions that is uniformly dense in the space of continuous functions vanishing at its boundary, and add a nonnegative smooth compactly supported cutoff function equal to one on its closure. Enumerate the union of these families as (f_i) . If positive measures converge against every f_i to a fixed positive Radon measure, they

converge vaguely: the cutoff functions give common local mass bounds, and uniform approximation then handles every continuous compactly supported test function.

For each j , approximate ν against $f_1, \dots, f_j$ by a finite positive atomic measure

$$\nu_j = \sum_{s=1}^{N_j} c_{j,s} \delta_{a_{j,s}}, \quad \left| \int_{\Omega} f_i (\nu_j - \nu) \right| < j^{-1} \quad (i \leq j).$$

Such an approximation uses only the finite mass of ν on a compact neighborhood of the supports of these tests: a finite partition on which all the tests have small oscillation provides the atoms and their positive weights. Atoms of weight zero are omitted. If $N_j = 0$, set $u_j = b$. Otherwise start with $b_{j,0} = b$ and apply **Proposition 1.6.4** successively to $b_{j,s-1}$, $a_{j,s}$ and $c_{j,s}$, with the tests $f_1, \dots, f_j$ and $\tau = t = (jN_j)^{-1}$. This gives perturbations $h_{j,s}$, and we define

$$b_{j,s} = b_{j,s-1} + h_{j,s}, \quad u_j = b_{j,N_j}.$$

Every intermediate potential is bounded and plurisubharmonic, so the proposition applies at each step; the choice at the next step may depend on the bound of the current potential, and each perturbation serves all finite p at once. Summing the norm estimates yields $\|u_j - b\|_{L^p(\Omega)} \leq C_{\Omega,p}/j$, and since every $h_{j,s} \leq 0$, we have $u_j \leq b$. Summing the measure errors gives

$$\left| \int_{\Omega} f_i ((dd^c u_j)^n - (dd^c b)^n - \nu) \right| < 2/j \quad (i \leq j).$$

By the choice of the family (f_i) , this proves the asserted vague limit, also when $\nu(\Omega) = \infty$.

For fixed concentric balls $B' \Subset B \Subset \Omega$, the perturbations are nonpositive, so $|u_j - b| = \sum_s |h_{j,s}|$. The last estimate of **Proposition 1.6.4** bounds the integral of this function against $(dd^c w)^n$ over B' by $C_{B',B,\Omega}/j$, for every $w \in \text{PSH}(B)$ with $0 \leq w \leq 1$. Restricting to the set where $|u_j - b|$ exceeds a fixed threshold, dividing by the threshold and taking the supremum over w proves convergence in local capacity. If b is smooth, the finite sums defining u_j are smooth as well. $\square$

The construction takes place in a bounded Euclidean domain, without prescribed boundary values and without a common bound on the approximating potentials. These freedoms allow concentration even under convergence in local capacity; a fixed global Hermitian background imposes further constraints.

1.6.6 Full cluster sets at the zero potential

Theorem 1.6.4 prescribes one limit of the Monge–Ampère measures, but a single sequence of potentials can have many subsequential limits. In fact, every vaguely closed set of measures is the set of all subsequential limits for a suitable sequence of

potentials tending to zero. For a domain $\Omega \subset \mathbb{C}^n$, write $\mathcal{M}_+(\Omega)$ for the set of positive Radon measures on Ω , including zero and measures of infinite total mass, with the vague topology defined by integration against $C_c(\Omega)$.

Lemma 1.6.11 *There are real functions $f_i \in C_c^\infty(\Omega)$ such that*

$$d_v(\alpha, \beta) = \sum_{i \geq 1} 2^{-i} \frac{|\int_{\Omega} f_i(\alpha - \beta)|}{1 + |\int_{\Omega} f_i(\alpha - \beta)|}$$

is a metric inducing the vague topology on $\mathcal{M}_+(\Omega)$. This metric space is separable.

Proof Choose relatively compact open sets U_ℓ exhausting Ω , with $\overline{U}_\ell \subset U_{\ell+1}$. For each ℓ , choose a countable uniformly dense subset of $C_0(U_{\ell+1}; \mathbb{R})$ consisting of smooth compactly supported functions, extended by zero to Ω ; such families exist because $C_0(U_{\ell+1}; \mathbb{R})$ is separable and its elements can be approximated uniformly by smooth functions. Add a nonnegative smooth compactly supported cutoff function equal to one near $\overline{U}_{\ell+1}$, and enumerate the union of all these functions as (f_i) .

Call the maps $\alpha \mapsto \int_{\Omega} f_i d\alpha$ the coordinates. If positive measures converge to a fixed measure in every coordinate, the cutoff coordinates give common mass bounds on each $\overline{U}_{\ell+1}$, and uniform approximation then gives convergence against every $g \in C_c(\Omega)$. The same argument, applied near a fixed measure, shows that $\alpha \mapsto \int_{\Omega} g d\alpha$ is continuous for the topology generated by the coordinates: bound the relevant cutoff coordinate on a neighborhood, choose one smooth test that is uniformly close to g , and shrink the neighborhood using the coordinate of that test. Thus the coordinates generate exactly the vague topology, and they separate measures.

The function $s \mapsto s/(1+s)$ is increasing and subadditive on $[0, \infty)$. Applying it to the triangle inequalities for the coordinates gives the triangle inequality for d_v , and d_v is positive on distinct measures because the coordinates separate them. Each coordinate is continuous for this metric, and the tails of the series are uniformly small, so the metric induces exactly the topology generated by the coordinates.

Finally, the finite atomic measures with nonnegative rational weights at points of a fixed countable dense subset of Ω form a countable dense family. To approximate a measure in finitely many coordinates, partition a compact neighborhood of the supports of the corresponding tests into sets on which all these tests have small oscillation, place an atom in each set of nonzero mass, and then perturb its location and weight. Only the finite mass of that compact neighborhood is used, and the remaining tail of the metric is arbitrarily small. $\square$

The metric controls limits along corresponding subsequences: if $d_v(\alpha_j, \beta_j) \rightarrow 0$ and one of the sequences converges vaguely to a fixed measure along a subsequence, then, by the triangle inequality, so does the other. Without common local mass bounds, however, $d_v(\alpha_j, \beta_j) \rightarrow 0$ need not imply that $\int g(\alpha_j - \beta_j) \rightarrow 0$ for every $g \in C_c(\Omega)$. For example, fix $a \in \Omega$, a unit vector e , and numbers $r_j \downarrow 0$ with $a + r_j e \in \Omega$, and put

$$\alpha_j = r_j^{-1/2} \delta_{a+r_j e}, \quad \beta_j = r_j^{-1/2} \delta_a.$$

For every smooth compactly supported test, the difference of the two integrals is $O(r_j^{1/2})$, so $d_v(\alpha_j, \beta_j) \rightarrow 0$ because the tails of the series are small. On the other hand, if $\chi \in C_c^\infty(\Omega)$ equals one near a , the continuous test function $g(z) = \chi(z)|z - a|^{1/2}$ gives $\int g(\alpha_j - \beta_j) = 1$ for all large j .

Theorem 1.6.5 *Let $\Omega \subset \mathbb{C}^n$, $n \geq 2$, be a bounded domain. A set $F \subset \mathcal{M}_+(\Omega)$ is vaguely closed if and only if there are smooth bounded plurisubharmonic functions $u_j \leq 0$ on Ω , tending to zero in $L^p(\Omega)$ for every $1 \leq p < \infty$ and in local capacity, whose full vague cluster set is F :*

$$F = \left\{ \mu \in \mathcal{M}_+(\Omega) : (\text{dd}^c u_{j_k})^n \longrightarrow \mu \text{ vaguely for some } j_1 < j_2 < \dots \right\}.$$

The empty set is allowed.

Proof In a metric space, the full cluster set of a sequence is the intersection of the closures of its tails: a point of this intersection can be approximated within $1/k$ at an index larger than the preceding one, successively for $k = 1, 2, \dots$. The full cluster set is therefore closed, and [Lemma 1.6.11](#) proves necessity.

For sufficiency, suppose first that F is nonempty and closed. A subset of a separable metric space is separable, so we may choose a dense sequence $\mu_1, \mu_2, \dots$ in F , repetitions allowed. Concatenating the finite lists (μ_1) , (μ_1, μ_2) , (μ_1, μ_2, μ_3) , and so on, we obtain a sequence (ν_j) in which every μ_k appears arbitrarily late. Hence every point of F is the limit of a subsequence, and since F is closed, no other subsequential limit occurs. If F is empty, take $\nu_j = j\delta_a$ for a fixed $a \in \Omega$. A nonnegative compactly supported test function equal to one at a has integral j against ν_j , so this sequence has no vaguely convergent subsequence.

In either case, let (f_i) and d_v be as in [Lemma 1.6.11](#), and perform the finite atomic construction from the proof of [Theorem 1.6.4](#) separately for each j , with background zero, target ν_j and tests $f_1, \dots, f_j$. Thus we approximate ν_j in these coordinates by a finite atomic measure with error less than $1/j$. If this measure has $N_j > 0$ atoms, apply [Proposition 1.6.4](#) successively with $t = \tau = (jN_j)^{-1}$; if it has none, take $u_j = 0$. The resulting smooth bounded plurisubharmonic functions $u_j \leq 0$ satisfy

$$\|u_j\|_{L^p(\Omega)} \leq C_{\Omega,p}/j, \quad \left| \int_{\Omega} f_i ((\text{dd}^c u_j)^n - \nu_j) \right| < 2/j \quad (i \leq j).$$

On every fixed pair of concentric balls $B' \Subset B \Subset \Omega$, the bounds of that proposition for test measures $(\text{dd}^c w)^n$, with $w \in \text{PSH}(B)$ and $0 \leq w \leq 1$, also sum to $C_{B',B,\Omega}/j$. Dividing by a positive threshold and taking the supremum over w gives convergence in local capacity. These estimates require neither convergence of the targets ν_j nor a common local mass bound for them.

Splitting the series defining the metric after its first j terms gives

$$d_v((\text{dd}^c u_j)^n, \nu_j) \leq 2/j + 2^{-j} \longrightarrow 0.$$

Consequently, the two sequences of measures have the same limits along corresponding subsequences, and hence the same full cluster set F . $\square$

For subharmonic functions on a planar domain, by contrast, L^1_{loc} convergence to zero forces $\text{dd}^c u_j \rightarrow 0$ in the sense of distributions, and positivity, tested against compactly supported cutoff functions, then gives vague convergence to zero. The freedom in the theorem therefore begins in dimension two.

1.6.7 Cluster sets at a bounded background

Let $\Omega \subset \mathbb{C}^n$ be a domain, $n \geq 1$, and let b be a locally bounded plurisubharmonic function on Ω . If potentials approach b from below in local capacity, every limit of their Monge–Ampère measures must dominate $(\text{dd}^c b)^n$. Truncation at a fixed distance below b provides a common bound, and plurifine locality keeps the measure outside the small set where the truncation changes the potential.

Lemma 1.6.12 *Let b, u_j be locally bounded plurisubharmonic functions on Ω with $u_j \leq b$ and $u_j \rightarrow b$ in local capacity. Then, for every nonnegative $f \in C_c(\Omega)$,*

$$\liminf_{j \rightarrow \infty} \int_{\Omega} f(\text{dd}^c u_j)^n \geq \int_{\Omega} f(\text{dd}^c b)^n.$$

In particular, every vague subsequential limit of $(\text{dd}^c u_j)^n$ dominates $(\text{dd}^c b)^n$.

Proof First suppose that f is supported in B' , where $B' \Subset B \Subset \Omega$ are concentric balls. Put $v_j = \max(u_j, b - 1)$ and $E_j = \{u_j \leq b - 1\}$. The functions v_j lie between $b - 1$ and b and tend to b in local capacity. Because of their common bounds, the continuity of bounded products recalled in [Section 1.6](#) gives $(\text{dd}^c v_j)^n \rightarrow (\text{dd}^c b)^n$ vaguely on B . With $R = \sup_B b - \inf_B b + 1$, the capacity bound for bounded potentials gives

$$(\text{dd}^c v_j)^n(E_j \cap \text{supp } f) \leq R^n \text{cap}(E_j \cap \text{supp } f, B) \rightarrow 0,$$

where the limit holds because $E_j \subset \{|u_j - b| > 1/2\}$. On the plurifine open Borel set $\{u_j > b - 1\}$ we have $v_j = u_j$, so [Theorem 1.6.1](#) shows that the two measures agree there. By positivity,

$$\int f(\text{dd}^c u_j)^n \geq \int f(\text{dd}^c v_j)^n - \|f\|_{\infty} (\text{dd}^c v_j)^n(E_j \cap \text{supp } f).$$

Taking the lower limit proves the assertion for such f . For a general f , use a finite nonnegative partition of unity subordinate to a cover of its support by such balls. Applying the inequality along a vaguely convergent subsequence proves the final assertion. $\square$

Theorem 1.6.6 Assume that Ω is bounded, $n \geq 2$, and $b \in \text{PSH}(\Omega) \cap L^\infty(\Omega)$. For a set $F \subset \mathcal{M}_+(\Omega)$, the following are equivalent:

- (1) F is vaguely closed and every $\mu \in F$ satisfies $\mu \geq (\text{dd}^c b)^n$;
- (2) there are bounded plurisubharmonic functions $u_j \leq b$ on Ω , converging to b in $L^p(\Omega)$ for every $1 \leq p < \infty$ and in local capacity, whose full vague cluster set is F .

The empty set is allowed. If b is smooth, every u_j in the second condition can be chosen smooth.

Proof If the second condition holds, [Lemma 1.6.12](#) gives the measure inequality, and the full cluster set is closed in the metrizable vague topology by the argument at the beginning of the proof of [Theorem 1.6.5](#).

Conversely, assume the first condition. If F is nonempty, the concatenation of a dense sequence used in the proof of [Theorem 1.6.5](#) gives measures $\nu_j \in F$ whose full vague cluster set is F . If F is empty, take $\nu_j = (\text{dd}^c b)^n + j\delta_a$ for a fixed $a \in \Omega$. A nonnegative compactly supported test function equal to one at a has integral at least j against ν_j , so this sequence has no vaguely convergent subsequence. In either case, $\nu_j - (\text{dd}^c b)^n$ is a positive Radon measure.

Let (f_i) and d_ν be as in [Lemma 1.6.11](#). For each j , approximate the excess $\nu_j - (\text{dd}^c b)^n$ against $f_1, \dots, f_j$ by a positive finite atomic measure, with each error less than $1/j$. If this measure has $N_j > 0$ atoms, perform the construction from the proof of [Theorem 1.6.4](#), starting at b and using $\tau = t = (jN_j)^{-1}$ for each atom; if it has none, take $u_j = b$. Summing the estimates of [Proposition 1.6.4](#) gives

$$\|u_j - b\|_{L^p(\Omega)} \leq C_{\Omega,p}/j, \quad \left| \int_{\Omega} f_i ((\text{dd}^c u_j)^n - \nu_j) \right| < 2/j \quad (i \leq j).$$

For every fixed pair of concentric balls $B' \Subset B \Subset \Omega$, the same construction bounds the integral of $|u_j - b|$ over B' against $(\text{dd}^c w)^n$ by $C_{B',B,\Omega}/j$, for every $w \in \text{PSH}(B)$ with $0 \leq w \leq 1$. Dividing by a fixed positive threshold and taking the supremum over w gives convergence in local capacity. Each u_j is bounded and lies below b , and it is smooth when b is smooth. One sequence serves all finite p , and no common local mass bound on the ν_j is needed.

The error in the first j coordinates and the tail of the series yield

$$d_\nu((\text{dd}^c u_j)^n, \nu_j) \leq 2/j + 2^{-j} \longrightarrow 0.$$

By the remark following [Lemma 1.6.11](#), the two sequences of measures have the same limits along corresponding subsequences. Hence their full vague cluster sets coincide. $\square$

For example, on the unit ball the function $b = |z|^2 - 1$ has nonzero Monge–Ampère measure. For every point a of the ball, the theorem allows the cluster sets $\{(\text{dd}^c b)^n\}$, $\{(\text{dd}^c b)^n + \delta_a\}$ and the empty set, but it excludes $\{0\}$; this exclusion relies on the convergence in local capacity. In dimension one, L^1 convergence alone forces $\text{dd}^c u_j \rightarrow \text{dd}^c b$ vaguely, so the full cluster set is always $\{\text{dd}^c b\}$.

1.7 Products with smooth backgrounds

The Bedford–Taylor construction also defines products of currents of the form $\theta + \text{dd}^c u$ with u locally bounded: one expands them into Hessians of plurisubharmonic functions and smooth forms. Since the result does not depend on the local correction, these products are defined globally. Their positivity is not visible term by term; it follows from the lower curvature bound by freezing the coefficients of the background. For a smooth real $(1, 1)$ -form θ and a function v , we write $\theta_v = \theta + \text{dd}^c v$, and similarly $\omega_v = \omega + \text{dd}^c v$ for other backgrounds. Fix $1 \leq k \leq n$.

Let u be locally bounded and θ -plurisubharmonic. On a relatively compact coordinate ball with coordinates z , choose $A > 0$ such that $p = u + q$ is plurisubharmonic, where $q = A|z|^2$. Set $\beta = \theta - \text{dd}^c q$ and define

$$(\theta + \text{dd}^c u)^k := \sum_{j=0}^k \binom{k}{j} (\text{dd}^c p)^j \wedge \beta^{k-j}. \quad (1.10)$$

Each summand is a product from [Theorem 1.6.1](#) multiplied by a smooth form. The individual terms of this expansion need not be positive.

Proposition 1.7.1 *The construction (1.10) and its mixed version are independent of the local correction q and of the decomposition of each current into a smooth form and the Hessian of a potential. They define global products of currents with locally bounded quasi-plurisubharmonic potentials. These products are symmetric, multilinear and plurifinely local, and they do not charge pluripolar sets. If every factor is positive, their mixed product is positive.*

Proof On the intersection of two coordinate balls, the two corrected potentials differ by a smooth function. The rule $\text{dd}^c(p + f) = \text{dd}^c p + \text{dd}^c f$, for bounded p and smooth f in bounded local products, follows by smooth approximation; together with the binomial formula, it shows that the two expansions agree. The same argument handles a smooth change in the decomposition of a current. Moreover, any two decompositions of the same $(1, 1)$ -current differ by a smooth function: the difference of the potentials has a smooth Hessian, and taking its local Euclidean trace and applying elliptic regularity shows that it is smooth. Symmetry, multilinearity and locality then follow term by term. Bounded Bedford–Taylor products wedged with smooth forms have locally finite variation and do not charge pluripolar sets, so these properties pass to the finite expansion as well.

It remains to prove positivity, which does not follow from the signs of the summands. Write the factors as $T_i = \theta_i + \text{dd}^c u_i$, $1 \leq i \leq k$, where each θ_i is a smooth real $(1, 1)$ -form and each u_i is locally bounded and quasi-plurisubharmonic, and assume $T_i \geq 0$. Fix $\varepsilon > 0$, a point of the coordinate ball and a positive constant form κ . On a sufficiently small neighborhood of the point, each θ_i is close to a constant, hence closed, form θ'_i :

$$-\varepsilon\kappa \leq \theta_i - \theta'_i \leq \varepsilon\kappa.$$

Then $S_i = \theta'_i + \varepsilon\kappa + \text{dd}^c u_i \geq T_i$ is a positive closed current there, with a bounded local plurisubharmonic potential, and

$$T_i + 2\varepsilon\kappa = S_i + (\theta_i - \theta'_i + \varepsilon\kappa),$$

where the last term is a smooth semipositive form. Expanding the product of the currents $T_i + 2\varepsilon\kappa$ therefore gives a sum of positive currents, so this product is positive near the chosen point. Such neighborhoods, although they depend on ε , cover the coordinate ball, so the product of the $T_i + 2\varepsilon\kappa$ is positive on the whole ball. By multilinearity, it converges weakly to the product of the T_i as $\varepsilon \rightarrow 0$, which proves positivity. $\square$

The local expansion also gives continuity along decreasing sequences of uniformly locally bounded potentials: apply [Theorem 1.6.1](#) to the corrected potentials and sum the finitely many terms. Since X is compact, every bounded top-degree product has finite total mass. For bounded $u \in \text{PSH}(X, \theta)$ we write $\text{MA}_\theta(u) = (\theta + \text{dd}^c u)^n$.

Decreasing maxima compare the products of two ordered potentials on the set where they are equal. The comparison also holds in the presence of fixed positive factors, which will be useful in integration by parts.

Lemma 1.7.1 *Let $a \leq b$ be locally bounded quasi-plurisubharmonic functions on an n -dimensional complex manifold, and let θ be a smooth real $(1, 1)$ -form such that $\theta_a, \theta_b \geq 0$. For $1 \leq k \leq n$, let W be a product of $n - k$ positive currents with smooth backgrounds and locally bounded potentials, with $W = 1$ when $k = n$. Then*

$$\mathbf{1}_{\{a=b\}} \theta_a^k \wedge W \leq \mathbf{1}_{\{a=b\}} \theta_b^k \wedge W.$$

Proof The functions $m_\delta = \max(a + \delta, b)$ satisfy $b \leq m_\delta \leq b + \delta$ and decrease to b as $\delta \downarrow 0$. By [Lemma 1.3.1](#) and [Proposition 1.7.1](#), the products $\theta_{m_\delta}^k \wedge W$ are positive, and by bounded decreasing continuity they converge weakly to $\theta_b^k \wedge W$. On the plurifine open set $\{a + \delta > b\}$, which contains $\{a = b\}$, we have $m_\delta = a + \delta$, so plurifine locality identifies the restriction of $\theta_{m_\delta}^k \wedge W$ to this set with that of $\theta_a^k \wedge W$. Hence, for every compact set $K \subset \{a = b\}$ in a coordinate chart, the upper semicontinuity of the mass of compact sets under weak convergence gives

$$\int_K \theta_a^k \wedge W = \lim_{\delta \downarrow 0} \int_K \theta_{m_\delta}^k \wedge W \leq \int_K \theta_b^k \wedge W.$$

Since the measures are locally finite, inner regularity extends this inequality to all Borel subsets of the contact set, and a countable cover by charts proves the assertion. $\square$

The products commute with pullback by holomorphic submersions. Here the pullback of a current is defined in local product coordinates by pulling back its distributional coefficients.

Lemma 1.7.2 *Let $\pi : Z \rightarrow Y$ be a holomorphic submersion of complex manifolds. For $1 \leq r \leq \dim Z$, let $u_1, \dots, u_r$ be locally bounded quasi-plurisubharmonic functions on Y , and let $\theta_1, \dots, \theta_r$ be smooth real $(1, 1)$ -forms on Y . Then*

$$\bigwedge_{i=1}^r (\pi^* \theta_i + \text{dd}^c(u_i \circ \pi)) = \pi^* \left(\bigwedge_{i=1}^r (\theta_i + \text{dd}^c u_i) \right).$$

For $r > \dim Y$, the product on the left vanishes, and the right-hand side is interpreted as zero.

Proof Work in product coordinates in which π is a coordinate projection. On a smaller chart of Y , choose smooth quadratic functions q_i such that $p_i = u_i + q_i$ is plurisubharmonic, and approximate each p_i by a decreasing sequence of smooth plurisubharmonic functions. Their pullbacks have the same properties on the product chart, and for smooth forms pullback commutes with wedge products. Applying bounded decreasing continuity to the local expansions (1.10) on both charts gives the asserted identity, because pullback of currents by the projection is weakly continuous: pairing the pullback with a compactly supported test form amounts to pairing the original current with the integral of the test form over the fiber variables. If $r > \dim Y$, every smooth approximating product vanishes for degree reasons, and so does its limit. $\square$

For $C^{1,1}$ potentials, these products of currents agree with the products of their measurable Hessian coefficients.

Proposition 1.7.2 *Let $u_1, \dots, u_k$ be locally $C^{1,1}$ quasi-plurisubharmonic functions, and let $\theta_1, \dots, \theta_k$ be smooth real $(1, 1)$ -forms. Then the bounded product*

$$(\theta_1 + \text{dd}^c u_1) \wedge \dots \wedge (\theta_k + \text{dd}^c u_k)$$

is the form with locally bounded measurable coefficients obtained by taking the wedge product of the factors pointwise almost everywhere.

Proof On a smaller coordinate ball, add a common smooth quadratic function q such that each $u_i + q$ is plurisubharmonic, and convolve with a smooth radial probability kernel. The Hessians of the convolutions are uniformly locally bounded and converge to the weak Hessians in every L^s space with $s < \infty$, so their finite products converge in L^1 on smaller balls. Since the potentials converge uniformly, the continuity of bounded Bedford–Taylor products identifies this limit with the pluripotential product. Expanding with respect to the smooth correction, as in (1.10), proves the assertion for the original factors. $\square$

When the Hessian coefficients are bounded, a positive lower bound for the top-degree product gives a lower bound for the current itself.

Proposition 1.7.3 *Let θ be a smooth real $(1, 1)$ -form, let h be a Hermitian form on X , and let $u \in \text{PSH}(X, \theta) \cap C^{1,1}(X)$. If*

$$(\theta + \text{dd}^c u)^n \geq ah^n$$

for a constant $a > 0$, then $\theta + \text{dd}^c u \geq \delta h$ as a current for some $\delta > 0$.

Proof Put $T = \theta + \text{dd}^c u$. Its measurable coefficients are bounded on the compact manifold X , so there is $K > 0$ such that, almost everywhere, the eigenvalues of T relative to h lie in $[0, K]$. By Proposition 1.7.2, their product is the density of T^n with respect to h^n , and hence it is at least a . Each eigenvalue is therefore at least a/K^{n-1} almost everywhere. This inequality of matrices almost everywhere gives the asserted inequality of currents with $\delta = a/K^{n-1}$. $\square$

The mixed Monge–Ampère inequality of Theorem 1.6.2 also holds after a smooth background is added. In the following three lemmas, $U \subset \mathbb{C}^n$ is an open set and $\beta = \text{dd}^c |z|^2$.

Lemma 1.7.3 *Let $T_i = \vartheta_i + \text{dd}^c u_i \geq 0$, $i = 1, 2$, where the ϑ_i are smooth real $(1, 1)$ -forms on U and the u_i are locally bounded quasi-plurisubharmonic functions on U . If*

$$T_i^n \geq F_i \beta^n, \quad F_i \geq 0 \text{ measurable},$$

then, for every integer $0 \leq k \leq n$,

$$T_1^k \wedge T_2^{n-k} \geq F_1^{k/n} F_2^{(n-k)/n} \beta^n. \quad (1.11)$$

Consequently, for $a, b \geq 0$,

$$(aT_1 + bT_2)^n \geq (aF_1^{1/n} + bF_2^{1/n})^n \beta^n. \quad (1.12)$$

Proof Fix $W \Subset U$. Since the forms ϑ_i are smooth, there is a constant C such that, for every $x \in W$ and every small ball $B_r(x)$, the constant forms

$$A_i = \vartheta_i(x) + Cr\beta$$

satisfy $0 \leq S_i \leq 2Cr\beta$ on $B_r(x)$, where $S_i = A_i - \vartheta_i$. If q_i is a quadratic potential for A_i , then $u_i + q_i$ is plurisubharmonic on $B_r(x)$ and

$$(\text{dd}^c(u_i + q_i))^n = (T_i + S_i)^n \geq F_i \beta^n.$$

Apply [Theorem 1.6.2](#) to these two closed Hessians. After expansion, every term other than $T_1^k \wedge T_2^{n-k}$ contains some S_i and is therefore bounded by $C'r\mu$, where

$$\mu = \sum_{\ell+m \leq n-1} T_1^\ell \wedge T_2^m \wedge \beta^{n-\ell-m}$$

is a locally finite measure.

A finite cover and a partition of unity give, on W ,

$$T_1^k \wedge T_2^{n-k} \geq F_1^{k/n} F_2^{(n-k)/n} \beta^n - C'r\mu.$$

Letting $r \downarrow 0$ proves [\(1.11\)](#), and the binomial expansion then gives [\(1.12\)](#). $\square$

Lemma 1.7.4 *Let ϑ be a smooth real $(1, 1)$ -form on U . Suppose that u is continuous, $T = \vartheta + \text{dd}^c u \geq 0$, and $T^n \geq g^n \beta^n$ with $g \geq 0$ continuous. For a nonnegative convolution kernel χ_δ of mass one,*

$$(T * \chi_\delta)^n \geq (g * \chi_\delta)^n \beta^n \tag{1.13}$$

on every smaller domain on which the convolution is defined.

Proof Approximate the convolution by finite convex combinations of translates, and apply [\(1.12\)](#), extended by induction to finitely many terms. Along these approximations, the background forms converge smoothly and the potentials converge uniformly on compact sets. To pass to the limit, add a common quadratic function and write the difference of two n -th powers as a telescoping sum. After pairing with a test form, integration by parts bounds each term by the uniform distance between the potentials times the mass of a mixed current, and successive integration against nested cutoff functions bounds these masses uniformly. Thus the products of the bounded potentials converge, and [\(1.13\)](#) follows. $\square$

For a positive $(1, 1)$ -current T on U , write T_{ac} for the measurable $(1, 1)$ -form whose coefficients are the absolutely continuous parts of the coefficients of T , and define $\det_\beta T_{\text{ac}}$ by $(T_{\text{ac}})^n = (\det_\beta T_{\text{ac}}) \beta^n$. When the top-degree product has a continuous density, the convolution estimate identifies this determinant.

Lemma 1.7.5 *Let u be continuous and $T = \vartheta + \text{dd}^c u \geq 0$, with ϑ a smooth real $(1, 1)$ -form on U . If $T^n = F \beta^n$ for a continuous function $F \geq 0$, then*

$$\det_\beta T_{\text{ac}} = F \quad \text{almost everywhere.}$$

Proof Take a nonnegative smooth radial mollifier χ_δ supported in the ball of radius δ . Then $T * \chi_\delta \rightarrow T_{\text{ac}}$ almost everywhere. Indeed, the convolutions of the absolutely continuous parts converge at Lebesgue points of their densities, while the convolution of the singular part λ_s of a coefficient measure is bounded by $C\delta^{-2n}|\lambda_s|(B_\delta)$, which tends to zero almost everywhere by the differentiation theorem for measures. Applying [Lemma 1.7.4](#) with $g = F^{1/n}$ and letting $\delta \downarrow 0$ gives $\det_\beta T_{\text{ac}} \geq F$.

For the reverse inequality, write the convolved current as the Hessian of a decreasing regularization of a locally bounded plurisubharmonic function plus a convergent smooth correction. The continuity of bounded products gives $(T * \chi_\delta)^n \rightarrow T^n$. Fatou's lemma, applied against a nonnegative compactly supported test function, then gives $\det_\beta T_{ac} \beta^n \leq T^n = F\beta^n$. $\square$

Lemma 1.7.6 *Let $h \leq a$ be locally bounded θ -plurisubharmonic functions, and let χ be a smooth function on a neighborhood of $(-\infty, 0]$ with $0 \leq \chi' \leq 1$ and $\chi'' \geq 0$. Then $w = a + \chi(h - a)$ is θ -plurisubharmonic and*

$$\theta_w = (1 - \chi'(h - a))\theta_a + \chi'(h - a)\theta_h + \chi''(h - a) d(h - a) \wedge d^c(h - a).$$

In particular, $\theta_w^n \geq \chi'(h - a)^n \theta_h^n$. The positivity of θ_w and this inequality also hold for convex functions χ of class $C^{1,1}$ on compact intervals with $0 \leq \chi' \leq 1$.

Proof The function $G(x, y) = x + \chi(y - x)$, for $y \leq x$, is convex and nondecreasing in each variable: its first derivatives are $1 - \chi'$ and χ' , and its Hessian is

$$\chi'' \begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix} \geq 0.$$

For smooth potentials, the chain rule gives the identity. For bounded potentials, add a common quadratic correction and convolve. Convolution preserves the order of the potentials, and since $G(x + r, y + r) = r + G(x, y)$, adding the same correction to both arguments adds it to G . The bounded chain rule (1.6) and its products with the gradient term give the identity in the limit. Freezing the smooth background as in the proof of Proposition 1.7.1 preserves the exact lower bound. Every term on the right is positive, and the positivity of bounded mixed products gives the last assertion.

For a convex weight of class $C^{1,1}$, extend it convexly across zero with derivative in $[0, 1]$, and smooth it in one variable. The smooth convex weights and their first derivatives converge uniformly on compact intervals, and the derivatives stay in $[0, 1]$. On each smaller coordinate ball, the corresponding potentials converge uniformly to w . The continuity of bounded products gives convergence of their top powers, while the weights on the right-hand side converge uniformly against the fixed measure θ_h^n . Passing to the limit proves the positivity and the product inequality with the original smooth background. $\square$

1.8 Hermitian capacity

After a fixed rescaling, a local capacity test can be glued to a constant function and so becomes a global potential on X . This compares the local Bedford–Taylor capacity with a capacity defined by global potentials, and it transfers to X both the volume–capacity estimate and an estimate for the sublevel sets of normalized potentials.

For a Borel set $E \subset X$, the *Hermitian capacity* of E is

$$\text{Cap}_\omega(E) = \sup_{v \in \text{PSH}(X, \omega), 0 \leq v \leq 1} \int_E (\omega + \text{dd}^c v)^n,$$

where the products are those of [Proposition 1.7.1](#). Their local expansion and [\(1.2\)](#) show that $\text{Cap}_\omega(X) < +\infty$. On relatively compact coordinate balls, a fixed smooth correction bounds the measures of global tests by a constant times the corresponding local capacity. Conversely, the gluing construction in the proof of [Lemma 1.8.1](#) below bounds local capacity by global capacity. Consequently, the quasi-continuity of quasi-plurisubharmonic functions and the characterization of sets of capacity zero recalled in [Section 1.6](#) hold for Cap_ω . A sequence u_j converges to u in capacity if

$$\text{Cap}_\omega(\{|u_j - u| > \delta\}) \longrightarrow 0 \quad \text{for every } \delta > 0,$$

where pole sets may be omitted. To compare with another Hermitian form ω' , choose $C \geq 1$ with $\omega' \leq C\omega$. Every test $0 \leq v \leq 1$ for $\text{Cap}_{\omega'}$ gives a test v/C for Cap_ω , and the positivity of mixed products gives

$$(\omega' + \text{dd}^c v)^n \leq C^n (\omega + \text{dd}^c (v/C))^n.$$

Thus $\text{Cap}_{\omega'} \leq C^n \text{Cap}_\omega$. Interchanging the two forms shows that the capacities are equivalent up to fixed multiplicative constants, so convergence in capacity does not depend on the choice of ω . Finally, the continuity statements for bounded products in [Section 1.6](#) pass to the products with smooth backgrounds, by their local expansion and a finite cover.

1.8.1 Capacity estimates

In this subsection we abbreviate $\text{Cap} = \text{Cap}_\omega$, and, as before, $\omega_v = \omega + \text{dd}^c v$.

Lemma 1.8.1 *There are constants $a, C > 0$ such that*

$$\text{Vol}(E) \leq C \exp(-a \text{Cap}(E)^{-1/n}) \quad (1.14)$$

for every Borel set $E \subset X$. Moreover, for every $u \in \text{PSH}(X, \omega)$ with $\sup_X u = 0$ and every $t > 1$,

$$\text{Cap}(\{u < -t\}) \leq C/t. \quad (1.15)$$

Proof Cover X by finitely many coordinate balls B'_j , with larger concentric balls B_j , $B'_j \Subset B_j$. A local capacity test $0 \leq v \leq 1$ on B_j can be turned into a global test as follows. Choose a smooth function χ_j with $-2 \leq \chi_j \leq 0$, equal to zero near $\overline{B'_j}$ and to -2 near ∂B_j . Choose $\delta > 0$ so small that

$$\omega + \delta \text{dd}^c \chi_j \geq 0, \quad 3\delta/2 \leq 1.$$

The function

$$V = \max\{\delta(v + \chi_j), -\delta/2\} + \delta/2 \quad \text{on } B_j, \quad V = 0 \quad \text{outside } B_j,$$

is ω -plurisubharmonic on X , because near ∂B_j the constant branch is the larger one, and it takes values between zero and one. On B'_j we have $\omega_V \geq \delta \text{dd}^c v$. By the positivity of bounded products,

$$\text{cap}(E \cap B'_j, B_j) \leq \delta^{-n} \text{Cap}(E).$$

The local volume–capacity estimate, summed over the finite cover, proves (1.14).

For the second estimate, choose on each B_j a smooth negative quadratic function r_j with $\text{dd}^c r_j \geq \omega$. For every global test $0 \leq v \leq 1$, the functions $u + r_j \leq 0$ and $v + r_j$ are plurisubharmonic on B_j . Thus

$$\begin{aligned} \int_{\{u < -t\}} \omega_v^n &\leq t^{-1} \int_X (-u) \omega_v^n \\ &\leq t^{-1} \sum_j \int_{B'_j} (-u - r_j) (\text{dd}^c(v + r_j))^n \\ &\leq \frac{C}{t} \left(1 + \int_X |u| \, dV \right). \end{aligned}$$

Here the second inequality uses $\omega_v \leq \text{dd}^c(v + r_j)$, and the third is the weighted Chern–Levine–Nirenberg inequality, applied to local test functions with a common bound. The L^1 bound for normalized potentials in Theorem 1.4.1 completes the proof after taking the supremum over v . $\square$

Corollary 1.8.1 *Fix $p > 1$. There is a constant C_p such that every nonnegative $F \in L^p(X, dV)$ satisfies*

$$\int_E F \, dV \leq C_p \|F\|_p \text{Cap}(E)^2$$

for every Borel set $E \subset X$.

Proof By Hölder’s inequality and (1.14), the integral is at most

$$C \|F\|_p \exp(-a \text{Cap}(E)^{-1/n}/p'), \quad p' = p/(p-1).$$

The function $x \mapsto x^{-2} \exp(-ax^{-1/n}/p')$ is bounded on $0 < x \leq \text{Cap}(X) < \infty$, and sets of capacity zero have zero volume. $\square$

The same proof bounds the integral of an L^p density by any fixed positive power of the capacity. The exponent two will be convenient for the iteration over sublevel sets in Lemma 10.3.2.

1.8.2 Convergence of potentials and measures

For quasi-continuous obstacles, a decreasing lower semicontinuous approximation keeps the original bounds and confines the error to sets of vanishing capacity.

Lemma 1.8.2 *Every bounded quasi-continuous function f on X admits bounded lower semicontinuous functions f_j with common bounds such that $f_j \downarrow f$ quasi-everywhere and $f_j \rightarrow f$ in capacity.*

Proof Choose open sets O_j of capacity at most 2^{-j} such that the restriction of f to $X \setminus O_j$ is continuous, and set $G_j = \bigcup_{k \geq j} O_k$. Then the sets G_j decrease, their capacities tend to zero, and f is continuous on the closed complement of each G_j . Choose $M \geq \sup_X f$ and define

$$f_j = f \text{ on } X \setminus G_j, \quad f_j = M \text{ on } G_j.$$

At a boundary point of G_j , the values of f_j on the closed complement tend to the value of f there, while the values inside G_j are at least that value. Thus f_j is lower semicontinuous. The functions f_j decrease to f outside $\bigcap_j G_j$, a set of capacity zero. Since $f_j - f$ is supported in G_j , they also converge to f in capacity. $\square$

Uniform bounds on potentials give a common capacity bound for their mixed measures.

Lemma 1.8.3 *Let $A \geq 0$ and let $0 \leq k \leq n$ be an integer. There is a constant C_A such that all the positive mixed measures*

$$\omega_{v_1} \wedge \cdots \wedge \omega_{v_k} \wedge \omega^{n-k}, \quad v_i \in \text{PSH}(X, \omega), \quad \|v_i\|_\infty \leq A,$$

are bounded above on Borel sets by $C_A \text{Cap}_\omega$. In particular, their total masses are uniformly bounded. If uniformly bounded functions tend to zero in capacity, then their integrals against these measures tend to zero uniformly in the v_i .

Proof Translate the v_i so that $0 \leq v_i \leq 2A$, and put $q = (v_1 + \cdots + v_k)/B$, where $B \geq \max\{2k, 2kA, 1\}$. Then $0 \leq q \leq 1$ and

$$\omega_q = B^{-1} \sum_{i=1}^k \omega_{v_i} + (1 - k/B)\omega,$$

where all coefficients are positive. Expanding ω_q^n shows that the given mixed product is bounded by a constant multiple of ω_q^n , and the definition of capacity proves the first claim. The case $k = 0$ follows by testing with $v = 0$. For a bounded function z , split its integral into the parts over $\{|z| > t\}$ and over its complement; first use convergence in capacity for fixed $t > 0$, and then let $t \downarrow 0$. $\square$

The same control applies to the total variation of a product formed with a different smooth background.

Lemma 1.8.4 *Let Ω be a Hermitian form and θ a smooth real $(1, 1)$ -form on X . Suppose that Ω -plurisubharmonic functions v_j have common finite upper and lower bounds and decrease to v . Then the signed measures*

$$v_j = (\theta + \text{dd}^c v_j)^n$$

converge to $(\theta + \text{dd}^c v)^n$ against every fixed bounded quasi-continuous function. Their total variations are bounded, uniformly in j , by a constant multiple of the local capacity on the balls of a fixed finite cover.

Proof On a relatively compact coordinate ball, choose a fixed quadratic function q such that the functions $v_j + q$ are plurisubharmonic; they still have common bounds. Expand

$$(\theta + \text{dd}^c v_j)^n = \sum_{\ell=0}^n \binom{n}{\ell} (\text{dd}^c(v_j + q))^\ell \wedge (\theta - \text{dd}^c q)^{n-\ell}.$$

The absolute value of the ℓ -th summand is bounded by a fixed constant times

$$(\text{dd}^c(v_j + q))^\ell \wedge \kappa_0^{n-\ell},$$

where κ_0 is a fixed positive Euclidean form. This positive mixed measure is bounded, uniformly in j , by a constant times the local capacity: add a fixed strictly plurisubharmonic quadratic function to $v_j + q$, expand the top power of its Hessian, and rescale its uniformly bounded range into $[0, 1]$ to apply the definition of capacity. This also covers $\ell = 0$. Summing over a finite cover gives the asserted control of the total variations. The ordinary decreasing continuity of Bedford–Taylor products gives weak convergence term by term. For a bounded quasi-continuous coefficient, remove an open set of small capacity and extend the restriction of the coefficient to the compact complement to a continuous function on X . The variation bound controls the resulting error uniformly for the sequence and its limit, and letting the capacity of the removed set tend to zero proves the assertion. $\square$

A finite non-pluripolar measure is uniformly absolutely continuous with respect to capacity, although it need not be bounded by a power of the capacity.

Lemma 1.8.5 *Let μ be a finite non-pluripolar Borel measure on X . Then*

$$\lim_{\delta \downarrow 0} \sup \{ \mu(E) : E \text{ Borel}, \text{Cap}_\omega(E) \leq \delta \} = 0.$$

Consequently, convergence in capacity implies convergence in μ -measure.

Proof If the first assertion failed, there would be $\epsilon > 0$ and Borel sets E_j of capacity at most 2^{-j} with $\mu(E_j) \geq \epsilon$. By countable subadditivity of capacity,

$$\text{Cap}_\omega \left(\limsup_j E_j \right) = 0.$$

Hence $\limsup_j E_j$ is pluripolar and has μ -measure zero. On the other hand, since μ is finite, continuity from above applied to the sets $\bigcup_{k \geq j} E_k$ shows that $\limsup_j E_j$ has measure at least ϵ , a contradiction. If $u_j \rightarrow u$ in capacity, applying the first assertion to the sets $\{|u_j - u| > \delta\}$ gives the consequence. $\square$

Lemma 1.8.6 *Let $u_j \in \text{PSH}(X, \theta)$. Suppose either that u_j decreases to a function $u \not\equiv -\infty$, or that u_j increases, the sequence is uniformly bounded above, and $u = (\lim_j u_j)^*$. Then $u_j \rightarrow u$ in capacity.*

Proof In the decreasing case u is a common lower bound for the sequence and its limit; in the increasing case u_1 is one. Choose a Hermitian form $\Omega \geq \theta$ and truncate all functions at $-T$. The truncations are bounded, monotone and Ω -plurisubharmonic, so the convergence in capacity of locally bounded monotone sequences, recalled in [Section 1.6](#), applies to them on the balls of a finite cover. By quasi-continuity of the common lower bound, there is an open set of arbitrarily small capacity containing its pole set such that the restriction of the lower bound to the compact complement is continuous. There it is finite and hence bounded below, so the capacity of the sublevel set of the lower bound at height $-T$ tends to zero as $T \rightarrow \infty$. Since the functions agree with their truncations outside this sublevel set, letting $T \rightarrow \infty$ proves the lemma. $\square$

A fixed bounded reference potential also controls a mixed trace in which one normalized potential varies.

Lemma 1.8.7 *Let $\theta \geq 0$, and fix a bounded $\psi \in \text{PSH}(X, \theta)$. There is a constant C_ψ such that*

$$\int_X \theta_v \wedge \theta_\psi^{n-1} \leq C_\psi$$

for every bounded $v \in \text{PSH}(X, \theta)$ with $\sup_X v = 0$.

Proof For $n = 1$, Stokes' theorem gives $\int_X \theta_v = \int_X \theta$, so assume $n \geq 2$. Choose a fixed Hermitian form $\Omega \geq \theta$. All currents on the left-hand side are positive, and $\Omega_\psi \geq \theta_\psi$. Hence Stokes' theorem for bounded potentials gives

$$\int_X \theta_v \wedge \theta_\psi^{n-1} \leq \int_X \theta \wedge \Omega_\psi^{n-1} + \int_X v \, \text{dd}^c(\Omega_\psi^{n-1}).$$

The first term on the right is bounded independently of v . To estimate the second, differentiate:

$$\mathrm{dd}^c(\Omega_\psi^{n-1}) = (n-1)\mathrm{dd}^c\Omega \wedge \Omega_\psi^{n-2} + (n-1)(n-2)\mathrm{d}\Omega \wedge \mathrm{d}^c\Omega \wedge \Omega_\psi^{n-3},$$

where the second term is absent for $n = 2$. Since $\mathrm{dd}^c\Omega$ and $\mathrm{d}\Omega \wedge \mathrm{d}^c\Omega$ are smooth forms, the absolute values of these terms are bounded by fixed multiples of the positive measures $\Omega^2 \wedge \Omega_\psi^{n-2}$ and $\Omega^3 \wedge \Omega_\psi^{n-3}$. The weighted local Chern–Levine–Nirenberg inequality of [Section 1.6](#) bounds the integrals of $|v|$ against these measures. Indeed, on each larger coordinate ball, add fixed smooth corrections to v and ψ , shift the corrected v so that it becomes negative, expand in the corrected positive Hessian of ψ , and apply that inequality on a smaller ball. The resulting bound is

$$C(1 + \|\psi\|_\infty)^n(1 + \|v\|_{L^1(X)}).$$

By [Theorem 1.4.1](#), normalized θ -plurisubharmonic functions have uniformly bounded L^1 norms, and summing the local bounds proves the assertion. $\square$

1.8.3 Vanishing area on curves

On a compact curve, the integral of the background is the total mass of every curvature current. When this integral vanishes, positivity forces the current to vanish. Normalized compactness and the local estimate of capacity by total variation make this uniqueness stable as the area tends to zero.

Throughout this subsection, Y is a compact connected Riemann surface and η is a smooth positive $(1, 1)$ -form on Y with $\int_Y \eta = 1$, which we use for L^1 norms and for the capacity Cap_η on Y .

Lemma 1.8.8 *For a smooth real $(1, 1)$ -form σ on Y , put $A = \int_Y \sigma$. There is a smooth real function h with $\sigma = A\eta + \mathrm{dd}^c h$. The class $\mathrm{PSH}(Y, \sigma)$ is nonempty if and only if $A \geq 0$. If $A = 0$, it consists of the functions $-h + c$, $c \in \mathbb{R}$, and its unique member with supremum zero is $u_\sigma = -h + \min_Y h$.*

Proof The smooth form $\sigma - A\eta$ has integral zero, so the Poisson equation on the compact connected surface Y has a smooth solution h , unique up to an additive constant. If $u \in \mathrm{PSH}(Y, \sigma)$, positivity and Stokes' theorem give

$$0 \leq (\sigma + \mathrm{dd}^c u)(Y) = A.$$

Conversely, $\sigma + \mathrm{dd}^c(-h) = A\eta$, so $-h \in \mathrm{PSH}(Y, \sigma)$ when $A \geq 0$. If $A = 0$, every positive curvature measure has total mass zero and therefore vanishes. Thus $\mathrm{dd}^c(u + h) = 0$ for every $u \in \mathrm{PSH}(Y, \sigma)$, and elliptic regularity and the uniqueness of harmonic functions on Y show that $u + h$ is constant. Normalizing the supremum gives the stated formula. $\square$

Theorem 1.8.1 *Let σ_j be smooth real $(1, 1)$ -forms on Y that converge uniformly to a smooth form σ_0 , and suppose that*

$$A_j = \int_Y \sigma_j \geq 0, \quad \int_Y \sigma_0 = 0.$$

Let u_0 be the normalized σ_0 -plurisubharmonic potential of [Lemma 1.8.8](#). Then, for every $t > 0$,

$$\begin{aligned} \sup_{u \in \text{PSH}(Y, \sigma_j), \sup_Y u = 0} \|u - u_0\|_{L^1(Y)} &\longrightarrow 0, \\ \sup_{u \in \text{PSH}(Y, \sigma_j), \sup_Y u = 0} \text{Cap}_\eta(\{|u - u_0| > t\}) &\longrightarrow 0. \end{aligned}$$

Moreover, the curvature measures $\sigma_j + \text{dd}^c u$ of these potentials tend to zero in total variation, uniformly in u , since each has total variation A_j .

Proof Choose $C > 0$ with $\sigma_j \leq C\eta$ for every j . Every sequence of normalized σ_j -plurisubharmonic functions then lies in the compact family of normalized $C\eta$ -plurisubharmonic functions of [Theorem 1.4.1](#). Every L^1 limit u of a subsequence is normalized and, by passing to the limit in the sense of distributions, satisfies $\sigma_0 + \text{dd}^c u \geq 0$. The preceding lemma gives $u = u_0$. If the first uniform limit failed, a sequence violating it would have a subsequence converging to this same limit, a contradiction.

For a potential u in the j -th normalized family, put $T = \sigma_j + \text{dd}^c u$. Positivity and Stokes' theorem give $\|T\|_{\text{TV}} = A_j$, and $A_j \rightarrow \int_Y \sigma_0 = 0$. Since $\sigma_0 + \text{dd}^c u_0 = 0$,

$$\|\text{dd}^c(u - u_0)\|_{\text{TV}} \leq A_j + \|\sigma_j - \sigma_0\|_{\text{TV}} \longrightarrow 0$$

uniformly over that family. Apply [Lemma 1.6.3](#) on a fixed finite cover of Y by concentric coordinate disks. The first limit and the bound above make each local capacity tend to zero uniformly, and the comparison between local and global capacity at the beginning of this section proves the second limit. The identity $\|T\|_{\text{TV}} = A_j$ proves the final assertion. $\square$

1.9 Comparing local regularizations

To glue local convolutions, we need them to agree on overlaps up to an error tending uniformly to zero. A bounded plurisubharmonic function need not be continuous, so this comparison cannot come from uniform convergence to the original function. Instead, the logarithmic convexity of its suprema over balls controls both the change of scale and the change of coordinates.

Let $U \subset \mathbb{C}^n$ be a domain and u a bounded plurisubharmonic function on U . For z in a fixed relatively compact subset of U and small $\delta > 0$, put

$$S_\delta u(z) = \sup_{|\zeta - z| \leq \delta} u(\zeta), \quad A_\delta u(z) = \int_{|\zeta - z| = \delta} u(\zeta) d\sigma(\zeta), \quad u_\delta = u * \rho_\delta,$$

where $d\sigma$ is the Euclidean surface measure and ρ is a smooth nonnegative radial mollifier of integral one, supported in the unit ball, with $\rho_\delta(\zeta) = \delta^{-2n} \rho(\zeta/\delta)$. All balls below lie in a fixed larger relatively compact subset of U , and B denotes a bound for the oscillation of u on that subset.

Lemma 1.9.1 *For each fixed $A > 1$,*

$$S_{A\delta} u - S_\delta u \longrightarrow 0, \quad S_\delta u - u_\delta \longrightarrow 0$$

uniformly on compact subsets as $\delta \downarrow 0$.

Proof The maximum of a plurisubharmonic function over concentric balls is a convex function of the logarithm of the radius. This follows by restricting to each complex line through the center and comparing, on an annulus, with the harmonic function that is affine in $\log |\zeta|$. Fix a radius $r > A\delta$ for which all the balls of radius r about points of the given compact set lie in the larger subset. Comparing secant slopes of this convex function between $\log \delta$, $\log(A\delta)$ and $\log r$ gives

$$0 \leq S_{A\delta} u - S_\delta u \leq \frac{B \log A}{\log(r/\delta)}, \quad (1.16)$$

which proves the first assertion.

To compare the maximum with the spherical mean, we use the Poisson kernel in real dimension $2n$. For a point at distance at most $\delta/2$ from the center, the normalized Poisson kernel of the ball of radius δ is bounded below by a positive dimensional constant c_n . Since u is bounded above by $S_\delta u$ and by its harmonic extension from the sphere of radius δ , we obtain

$$S_\delta u - S_{\delta/2} u \geq c_n (S_\delta u - A_\delta u).$$

These inequalities hold for bounded plurisubharmonic functions by local smoothing followed by a decreasing limit. By (1.16), $S_\delta u - A_\delta u$ therefore tends uniformly to zero.

For $0 < t \leq 1$, the spherical mean is increasing in the radius, and

$$0 \leq A_\delta u - A_{t\delta} u \leq (S_\delta u - S_{t\delta} u) + (S_{t\delta} u - A_{t\delta} u).$$

By logarithmic convexity, the first term is at most $B \log(1/t)/\log(r/(t\delta))$, and by the preceding estimate the second is at most $C_n B / \log(r/(t\delta))$. Write the radial convolution as an average of the spherical means $A_{t\delta} u$ with respect to the probability density $\widehat{\rho}(t) = |\mathbb{S}^{2n-1}| t^{2n-1} \rho(t)$ on $[0, 1]$, where $\rho(t)$ denotes the value of ρ at radius t . Since $\int_0^1 (1 + \log(1/t)) \widehat{\rho}(t) dt < \infty$, integration gives

$$0 \leq A_\delta u - u_\delta \leq \frac{C_{n,\rho} B}{\log(r/\delta)}.$$

Combining the two comparisons proves the second assertion. $\square$

Corollary 1.9.1 *Let $U, V \subset \mathbb{C}^n$ be domains, let $F : U \rightarrow V$ be biholomorphic, and let u be bounded and plurisubharmonic on U . Then*

$$u_\delta - ((u \circ F^{-1}) * \rho_\delta) \circ F$$

tends locally uniformly to zero as $\delta \downarrow 0$.

Proof On a compact subset, F and its inverse have uniformly bounded first derivatives. Thus, for a fixed $A > 1$, the inverse image under F of the ball of radius δ about $F(z)$ lies between the balls about z of radii δ/A and $A\delta$. Consequently, $S_\delta(u \circ F^{-1})(F(z))$ and $S_\delta u(z)$ both lie between $S_{\delta/A} u(z)$ and $S_{A\delta} u(z)$, and the first assertion of [Lemma 1.9.1](#) shows that their difference tends to zero uniformly. The second assertion of the lemma, applied to u and to $u \circ F^{-1}$, compares each of the two convolutions with the corresponding supremum regularization. $\square$

1.10 Gluing with a small curvature error

The overlap estimate allows local regularizations to be glued by a regularized maximum. Small corrections near the boundary of each chart make the corresponding local branch irrelevant there, while convexity of the regularized maximum preserves a common lower curvature bound. The curvature error is measured by the Hermitian form ω .

For an integer $N \geq 1$, choose independent real random variables $Z_1, \dots, Z_N$ with a common smooth even probability density supported in $[-1, 1]$, and define

$$M_\tau(t_1, \dots, t_N) = \mathbb{E} \max_i (t_i + \tau Z_i) \quad (\tau > 0).$$

As a convolution, M_τ is smooth. It is convex and increasing in every argument, and, with $\mathbf{1} = (1, \dots, 1)$, it satisfies

$$\max_i t_i \leq M_\tau(t) \leq \max_i t_i + \tau, \quad M_\tau(t + c\mathbf{1}) = M_\tau(t) + c$$

for $t \in \mathbb{R}^N$ and $c \in \mathbb{R}$. If $t_i < \max_{j \neq i} t_j - 2\tau$, then the i -th argument can be removed without changing the value. Moreover, $M_\tau(t)$ is nondecreasing in τ , because it is a convex even function of τ , the distribution of each Z_i being symmetric.

The second identity expresses invariance under translations. If smooth real functions f_i , $1 \leq i \leq N$, satisfy $\text{dd}^c f_i \geq -\gamma$ for a common smooth real $(1, 1)$ -form γ , then

$$\mathrm{dd}^c M_\tau(f_1, \dots, f_N) \geq -\gamma. \quad (1.17)$$

Indeed, in the chain rule the first partial derivatives of M_τ are nonnegative and, by the translation identity, sum to one, while the real Hessian of the convex function M_τ contributes a semipositive $(1, 1)$ -form.

Proposition 1.10.1 *Let θ be a smooth real $(1, 1)$ -form, let ω be a Hermitian form, and let $u \in \mathrm{PSH}(X, \theta) \cap L^\infty(X)$. There are smooth functions v_j and positive numbers $\varepsilon_j \downarrow 0$ such that*

$$v_j \downarrow u, \quad \theta + \varepsilon_j \omega + \mathrm{dd}^c v_j \geq 0.$$

Proof For fixed $\epsilon > 0$, we first glue the local convolutions of u by a regularized maximum, obtaining smooth functions that decrease to u and have curvature error $2\epsilon\omega$; a diagonal sequence then proves the proposition.

Step 1: local regularizations. Fix $\epsilon > 0$. By continuity of θ , we can choose finitely many nested coordinate neighborhoods $V_i \Subset W_i \Subset U_i$, with the V_i covering X , and smooth quadratic functions r_i such that

$$0 \leq \mathrm{dd}^c r_i - \theta \leq \epsilon\omega \quad \text{on } U_i.$$

To do so, freeze the coefficients of θ at the center of a chart, add a small positive constant form, and shrink the coordinate neighborhood. Then $p_i = u + r_i$ is a bounded plurisubharmonic function on U_i ; let $p_{i,\delta}$ be its convolution in the coordinates of U_i .

On an overlap, express both p_i and p_j in the coordinates of U_j . Their difference is the smooth function $r_i - r_j$, so the difference of their convolutions in these coordinates tends uniformly to $r_i - r_j$. By [Corollary 1.9.1](#), changing the coordinates in which p_i is convolved introduces another uniformly vanishing error. Thus, on the intersections of the closures of the W_i ,

$$(p_{i,\delta} - r_i) - (p_{j,\delta} - r_j) \longrightarrow 0 \quad \text{uniformly.} \quad (1.18)$$

Step 2: gluing. Choose functions $\eta_i \in C^\infty(U_i, [-1, 0])$ that vanish on V_i and equal -1 near the boundary of W_i , and a constant $C \geq 1$ with $\mathrm{dd}^c \eta_i \geq -C\omega$. The cover, the functions r_i, η_i and the constant C may depend on ϵ ; they are fixed while δ tends to zero. Set

$$f_{i,\delta} = p_{i,\delta} - r_i + (\epsilon/C)\eta_i \quad \text{on } W_i.$$

Each of these functions satisfies $\mathrm{dd}^c f_{i,\delta} \geq -\theta - 2\epsilon\omega$. Every boundary point of W_i lies in some V_j , and there $\eta_j = 0$ while $\eta_i = -1$. By [\(1.18\)](#), for all small δ ,

$$f_{i,\delta} < f_{j,\delta} - \epsilon/(2C)$$

on a neighborhood of that boundary point. Since the cover is finite, this separation holds uniformly.

Let $\tau(\delta) \downarrow 0$ as $\delta \downarrow 0$, with $\tau(\delta) < \epsilon/(8C)$, and define the value at each point as the regularized maximum $M_{\tau(\delta)}$ of the functions $f_{i,\delta}$ for those i with the point in W_i . A branch disappears only near the boundary of its W_i , where it lies below

another branch by more than 2τ . By the removal property of M_τ , these local formulas therefore define a global smooth function $\psi_{\epsilon,\delta}$, and (1.17) gives

$$\theta + 2\epsilon\omega + \text{dd}^c\psi_{\epsilon,\delta} \geq 0.$$

At every point there is a branch with $\eta_i = 0$, and $p_{i,\delta} \geq p_i$; hence $\psi_{\epsilon,\delta} \geq u$. For fixed ϵ , the local convolutions decrease with δ , and the regularized maximum decreases when both its arguments and τ decrease. Its pointwise limit is

$$\max_{i: x \in W_i} (u(x) + (\epsilon/C)\eta_i(x)) = u(x).$$

Thus $\psi_{\epsilon,\delta} \downarrow u$ as $\delta \downarrow 0$, and also in L^1 .

Step 3: a diagonal sequence. Take $\epsilon_j \downarrow 0$ and put $v_j = \psi_{\epsilon_j,\delta_j} + 2^{-j}$, where δ_j is chosen so small that

$$\|\psi_{\epsilon_j,\delta_j} - u\|_{L^1} \leq 2^{-j}, \quad v_j < v_{j-1} \quad (j \geq 2).$$

The second requirement can be met because $v_{j-1} \geq u + 2^{-j+1}$. Indeed, as $\delta \downarrow 0$, the continuous functions $\psi_{\epsilon_j,\delta} + 2^{-j} - v_{j-1}$ decrease pointwise to a function bounded above by -2^{-j} . Their sets of nonnegative values are decreasing compact sets with empty intersection, so one of them is empty. The resulting sequence (v_j) decreases, converges to u in L^1 , and stays above u . Its pointwise limit is $(\theta + 2\epsilon_k\omega)$ -plurisubharmonic for every k , hence θ -plurisubharmonic, and it equals u almost everywhere; by Lemma 1.3.3, it equals u everywhere. Taking $\epsilon_j = 2\epsilon_j$ proves the proposition. $\square$

1.11 Regularization in a fixed Hermitian background

For $\theta = \omega$, rescaling the approximants absorbs the curvature error into the positive background. Subtracting a constant first makes the approximants negative, so that this rescaling preserves their decreasing order.

Theorem 1.11.1 *For every $u \in \text{PSH}(X, \omega) \cap L^\infty(X)$, there are smooth functions $u_j \downarrow u$ such that*

$$\omega + \text{dd}^c u_j > 0.$$

The functions u_j are uniformly bounded.

Proof Subtracting a constant, we may assume $u \leq -2$. Apply Proposition 1.10.1 with $\theta = \omega$, obtaining smooth functions $v_j \downarrow u$ and positive numbers $\epsilon_j \downarrow 0$ with $(1 + \epsilon_j)\omega + \text{dd}^c v_j \geq 0$. The compact sets $\{v_j \geq -1\}$ decrease to the empty set, since $u \leq -2$. After discarding finitely many terms, we may therefore assume $v_j < 0$ everywhere. Put

$$u_j = \frac{v_j}{1 + 2\epsilon_j}.$$

Then

$$\omega + dd^c u_j \geq \frac{\varepsilon_j}{1 + 2\varepsilon_j} \omega > 0.$$

Since v_j is negative and decreases, while the positive denominator decreases to one, u_j also decreases, and it converges to u . Moreover, $u \leq v_j \leq u_j \leq u_1$, which gives uniform boundedness. Adding back the subtracted constant proves the theorem. $\square$

This regularization provides the approximation used for products and mass in [Chapter 6](#). For an arbitrary smooth form θ , [Proposition 1.10.1](#) only gives approximants whose curvature error tends to zero.

1.12 Singularity type and multiplier ideals

There are two natural ways to compare the singularities of quasi-plurisubharmonic functions on X . The first asks whether one function is bounded above by the other up to an additive constant; it leads to the ordinary singularity type. The second records only which holomorphic functions are locally square integrable against the weights e^{-ku} , $k > 0$; it leads to multiplier ideals. Domination implies the corresponding inclusion of multiplier ideals. A logarithmic pole on a disk shows that a single weight loses information, which is why the second comparison uses all positive weights.

Definition 1.12.1 Let u, v be quasi-plurisubharmonic functions on X . We write $u \preceq v$ if there is a constant $C \in \mathbb{R}$ such that $u \leq v + C$ on X , and $u \sim v$ if both $u \preceq v$ and $v \preceq u$; in the latter case u and v have the same *singularity type*. When this has to be distinguished from the multiplier-ideal type introduced below, we speak of the *ordinary singularity type*, or simply the *ordinary type*.

Thus $u \preceq v$ means that u is at least as singular as v . For instance, a quasi-plurisubharmonic function with a logarithmic pole lies below every bounded potential in this order, but not conversely.

Proposition 1.12.1 *The relation $\preceq$ is a preorder, and $\sim$ is an equivalence relation. If u is quasi-plurisubharmonic and f is a smooth function on X , then $u + f \sim u$. In particular, all smooth functions on X have the same singularity type.*

Proof Reflexivity follows with $C = 0$. If $u \leq v + C$ and $v \leq w + D$, then $u \leq w + C + D$, which proves transitivity. As for every preorder, comparison in both directions defines an equivalence relation. Since X is compact, a smooth function f satisfies $|f| \leq A$ for some constant A , and then $u - A \leq u + f \leq u + A$. Taking $u = 0$ shows that every smooth function has the singularity type of the constants. $\square$

Some later results require the singularities of a potential to be concentrated on a small closed set. A closed subset $A \subseteq X$ is *complete pluripolar* if every point of X has a neighborhood U with a plurisubharmonic function p on U such that $A \cap U = \{p = -\infty\}$. A quasi-plurisubharmonic function has *small unbounded locus* if it is locally bounded outside a closed complete pluripolar set.

Definition 1.12.2 Let $\mathcal{O}_X$ denote the sheaf of holomorphic functions on X . For a quasi-plurisubharmonic function u on X , the *multiplier ideal* $\mathcal{I}(u) \subseteq \mathcal{O}_X$ is the ideal sheaf whose sections over an open set U are the holomorphic functions g on U for which $|g|^2 e^{-u}$ is locally integrable on U with respect to a smooth positive volume form. Its stalk at x is denoted by $\mathcal{I}(u)_x$.

Changing the volume form does not change local integrability: on relatively compact coordinate neighborhoods, the ratio of two smooth positive volume forms is bounded above and below by positive constants. In particular, the definition does not involve a choice of Hermitian metric, and it applies verbatim to quasi-plurisubharmonic functions on any complex manifold.

Proposition 1.12.2 *If $u \preceq v$, then $\mathcal{I}(ku) \subseteq \mathcal{I}(kv)$ for every real $k > 0$. If $u \sim v$, then these ideals agree for every $k > 0$.*

Proof Let g be a local holomorphic function on X . If $u \leq v + C$, then $e^{-kv} \leq e^{kC} e^{-ku}$. Multiplying by $|g|^2$ shows that local integrability of $|g|^2 e^{-kv}$ implies local integrability of $|g|^2 e^{-ku}$. If $u \sim v$, the same argument applies in both directions. $\square$

Example 1.12.1 On a disk in $\mathbb{C}$ centered at the origin, with coordinate z , let $\lambda \geq 0$ and put $u(z) = \lambda \log |z|^2$ for $\lambda > 0$, while $u = 0$ for $\lambda = 0$. Then

$$\mathcal{I}(u)_0 = (z^{\lfloor \lambda \rfloor}).$$

Indeed, if a nonzero holomorphic germ has order m at the origin, its squared modulus is comparable to $|z|^{2m}$ near the origin. In polar coordinates, its weighted integral over a disk of sufficiently small radius $\epsilon > 0$ is finite precisely when

$$\int_0^\epsilon r^{2m-2\lambda+1} dr < \infty, \quad \text{equivalently} \quad m > \lambda - 1.$$

The smallest nonnegative integer satisfying this strict inequality is $\lfloor \lambda \rfloor$. When λ is an integer, the borderline exponent -1 occurs for $m = \lambda - 1$ and gives a divergent integral; this is where the strictness of the inequality matters.

The example also shows that a single multiplier ideal does not determine the singularity: different coefficients λ can have the same integer part. For a real weight $k > 0$, the same calculation applied to ku gives $\mathcal{I}(ku)_0 = (z^{\lfloor k\lambda \rfloor})$. The ideals at all weights $k > 0$ recover λ : if $0 \leq \lambda < \mu$, the integer parts of $k\lambda$ and $k\mu$ differ as soon as $k(\mu - \lambda) > 1$.

We therefore compare multiplier ideals at all positive weights. For quasi-plurisubharmonic functions u, v , we write $u \preceq_{\mathcal{I}} v$ if $\mathcal{I}(ku) \subseteq \mathcal{I}(kv)$ for every real $k > 0$, and $u \sim_{\mathcal{I}} v$ if $\mathcal{I}(ku) = \mathcal{I}(kv)$ for every real $k > 0$. We call $\preceq_{\mathcal{I}}$ the *ideal order*; if $u \sim_{\mathcal{I}} v$, then u and v have the same *multiplier-ideal type*, or *ideal type*. By **Proposition 1.12.2**, $u \preceq v$ implies $u \preceq_{\mathcal{I}} v$, and $u \sim v$ implies $u \sim_{\mathcal{I}} v$. These relations make sense on any complex manifold. Their relation to envelopes and to global masses requires further arguments; see **Chapter 15**.

1.13 Analytic types and restriction

The simplest singularities of quasi-plurisubharmonic functions are logarithmic poles along the common zeros of finitely many holomorphic functions. The logarithmic growth of a general singularity at a point is measured by its Lelong number. Let u be a quasi-plurisubharmonic function on a complex manifold and let x be a point. Choose holomorphic coordinates centered at x and a smooth function q such that $p = u + q$ is plurisubharmonic near x , and write $B(x, r)$ for the Euclidean coordinate ball of radius r . The *Lelong number* of u at x is

$$\nu(u, x) = \lim_{r \downarrow 0} \frac{\sup_{B(x, r)} p}{\log r^2}.$$

By the local growth theorem recalled in [Xia], the limit exists and does not depend on the coordinates or on the correction q . With this normalization, $\log |z|^2$ has Lelong number one at the origin. For an irreducible analytic subset Z , the *generic Lelong number* of u along Z is

$$\nu(u, Z) = \inf_{x \in Z} \nu(u, x).$$

By Siu's theorem, recalled in Section 1.13.1, $\nu(u, x) = \nu(u, Z)$ for all $x \in Z$ outside a countable union of proper analytic subsets of Z .

For analytic singularities we follow the convention of [Xia]: we say that a quasi-plurisubharmonic function u has *analytic singularities* if near every point there are holomorphic functions $f_1, \dots, f_N$, not all identically zero, and a rational number $c > 0$ such that

$$u = c \log(|f_1|^2 + \dots + |f_N|^2) + O(1), \quad c \in \mathbb{Q}_{>0}.$$

The remainder is only required to be bounded; if it can be chosen smooth, we say that u has analytic singularities *with smooth remainder*. Given a coherent ideal sheaf $\mathfrak{a}$ and a common coefficient c , we say that u has *analytic type* $(c, \mathfrak{a})$ if this holds with local generators $f_1, \dots, f_N$ of $\mathfrak{a}$. The choice of generators does not matter: two finite systems of generators of the same ideal change the logarithm only by a bounded amount on smaller relatively compact open sets.

Proposition 1.13.1 *Analytic singularities are preserved by addition, finite maxima, and multiplication by positive rational numbers. Let u have analytic type $(c, \mathfrak{a})$, and let $Y \subset X$ be a connected complex submanifold on which $\mathfrak{a}$ does not vanish identically. Then the restriction $u|_Y$ is a quasi-plurisubharmonic function on Y , in particular not identically $-\infty$, and it has analytic type*

$$(c, \mathfrak{a}O_Y).$$

Here $\mathfrak{a}O_Y$ is the image ideal, generated by the restrictions to Y of local sections of $\mathfrak{a}$.

Proof For multiplication by a positive rational number, multiply the coefficient. Consider two presentations with coefficients c_1, c_2 and ideals $\mathfrak{a}_1, \mathfrak{a}_2$, and choose

a positive rational number d with $c_1 = kd$ and $c_2 = \ell d$, where k, ℓ are positive integers. Raising a sum of squared moduli of generators of $\mathfrak{a}_1$ to the power k gives, up to bounded factors, the corresponding sum for $\mathfrak{a}_1^k$; similarly for $\mathfrak{a}_2^\ell$. Products of generators of $\mathfrak{a}_1^k$ and $\mathfrak{a}_2^\ell$ therefore present the sum with coefficient d , since a product of sums of squares is a sum of squares of pairwise products.

For the maximum, apply the elementary inequalities

$$\max\{A, B\} \leq A + B \leq 2 \max\{A, B\}, \quad A, B \geq 0,$$

to the two sums of squared moduli of generators of $\mathfrak{a}_1^k$ and $\mathfrak{a}_2^\ell$. Taking logarithms shows that the maximum differs from d times the logarithm of their total by a bounded amount. These are local assertions; on the compact manifold, finitely many charts give the corresponding comparisons of ordinary singularity types.

For the restriction, restrict to Y the two-sided bounds that define the remainder. Since Y is connected and is not contained in the zero set of $\mathfrak{a}$, the common zero set of the restricted generators is a proper analytic subset of Y , so $u|_Y$ is finite on a dense open subset of Y . After a smooth local correction, the restriction theorem for plurisubharmonic functions shows that $u|_Y$ is quasi-plurisubharmonic, and the restricted bounds give the asserted presentation. $\square$

For an arbitrary quasi-plurisubharmonic function, a vanishing generic Lelong number along a submanifold does not prevent the restriction from being identically $-\infty$. For example, on a small polydisk in $\mathbb{C}^n$ with coordinates $z = (z_1, \dots, z_n)$ and $|z_1| < e^{-1}$, the function

$$u(z) = -\sqrt{-\log |z_1|^2}$$

is plurisubharmonic, because $t \mapsto -\sqrt{-t}$ is increasing and convex for $t < 0$. Its Lelong number vanishes at every point of $\{z_1 = 0\}$, but its restriction to this hyperplane is identically $-\infty$. For the analytic approximants constructed below, the analytic hypothesis in [Proposition 1.13.1](#) excludes this behavior.

1.13.1 Lelong level sets

Siu's analyticity theorem states that, for every quasi-plurisubharmonic function u and every $c > 0$, the upper level set $\{x : \nu(u, x) \geq c\}$ is an analytic subset. After a smooth local correction, this is the theorem for closed positive currents, which we use in the form recalled in [\[Xia\]](#); see [Section 33.1](#) for the original source.

For a closed positive current, the Lelong monotonicity formula also bounds the trace mass of small balls. The resulting Hausdorff estimate shows that a closed positive (j, j) -current puts no mass on sets of zero Hausdorff $2(n - j)$ -measure.

Corollary 1.13.1 *Let T be a closed positive (j, j) -current on a complex manifold of dimension n , with $1 \leq j < n$. Its coefficient measures vanish on every Borel set of zero Hausdorff $2(n - j)$ -measure.*

Proof In a coordinate chart put $\kappa = dd^c|z|^2$ and $\mu = T \wedge \kappa^{n-j}$. By the Lelong monotonicity formula in bidimension $(n - j, n - j)$, the function $r \mapsto r^{-2(n-j)}\mu(B(x, r))$ is nondecreasing; see [Dem12, Chapter III, formulas (5.5)–(5.8), pp. 158–159]. Fix a relatively compact inner chart and a radius $r_0 > 0$ such that all balls of radius r_0 centered in it lie in a fixed compact subset of the chart. Their masses are bounded by the mass of that compact set. Hence

$$\mu(B(x, r)) \leq Cr^{2(n-j)}, \quad 0 < r \leq r_0,$$

uniformly for centers in the inner chart. A Borel set in the inner chart with zero Hausdorff $2(n - j)$ -measure can be covered by balls $B(x_i, r_i)$ with $\sum_i r_i^{2(n-j)}$ arbitrarily small, so it has zero μ -mass. Since T is positive, the total variation of each of its coefficient measures is bounded by a constant multiple of μ . A countable cover by charts proves the assertion. $\square$

The non-strict inequality in Siu's theorem cannot be replaced by a strict one, even on a compact Kähler manifold.

Example 1.13.1 Let $X = \mathbb{P}^2$, with homogeneous coordinates $[x : y : z]$, and let σ be the Fubini–Study form normalized by $\int_X \sigma^2 = 1$. Put $\|Z\|^2 = |x|^2 + |y|^2 + |z|^2$, $a_j = 2^{-j}$ and $\lambda_j = 2^{-j-1}$ for $j \geq 1$. The global function

$$u([Z]) = \log \frac{|y|^2}{\|Z\|^2} + \sum_{j \geq 1} \lambda_j \log \frac{|x - a_j z|^2}{(1 + a_j^2)\|Z\|^2}$$

belongs to $\text{PSH}(X, \frac{3}{2}\sigma)$. For the line $D = \{y = 0\}$ and the points $p_j = [a_j : 0 : 1]$, it satisfies

$$\{v(u, \cdot) \geq 1\} = D, \quad \{v(u, \cdot) > 1\} = \{p_j : j \geq 1\}.$$

The second set is not analytic.

Proof For a linear form ℓ with coefficient vector of norm one, the function $v_\ell = \log(|\ell(Z)|^2/\|Z\|^2)$ is nonpositive and satisfies $dd^c v_\ell = [\ell = 0] - \sigma$. Its $L^1(X, \sigma^2)$ norm is finite and independent of ℓ , because the unitary group $U(3)$ acts on homogeneous coordinates, preserves σ , and acts transitively on such forms. Since $\sum_j \lambda_j = 1/2$, the partial sums of the series defining u decrease to an L^1 function. They have the common curvature lower bound $-\frac{3}{2}\sigma$, so their limit is quasi-plurisubharmonic and

$$T := \frac{3}{2}\sigma + dd^c u = [D] + \sum_{j \geq 1} \lambda_j [L_j], \quad L_j = \{x - a_j z = 0\}.$$

The series of positive closed currents converges, since every line has σ -trace mass one and the coefficients are summable.

We compute the Lelong numbers from the local mass formula. In affine coordinates $w = (w_1, w_2)$ centered at a point q , put $\kappa = \text{dd}^c |w|^2$. An affine complex line H at distance d from q satisfies

$$\int_{H \cap B(q, r)} \kappa = (r^2 - d^2)_+.$$

Consequently $r^{-2} \int_{H \cap B(q, r)} \kappa$ is at most one and tends to $\mathbf{1}_H(q)$ as $r \downarrow 0$; a line that does not meet the chart contributes zero. Tonelli's theorem and dominated convergence for the summable coefficients therefore give

$$\nu(u, q) = \nu(T, q) = \mathbf{1}_D(q) + \sum_{j \geq 1} \lambda_j \mathbf{1}_{L_j}(q).$$

Here we used that a smooth local correction does not change the Lelong number. The computation also covers points at which infinitely many lines accumulate.

The lines L_j meet D at the distinct points p_j and meet one another only at $p_\infty = [0 : 1 : 0] \notin D$. Thus $\nu(u, p_j) = 1 + \lambda_j$, whereas $\nu(u, q) = 1$ for $q \in D \setminus \{p_j : j \geq 1\}$. Outside D , the Lelong number is at most $\sum_j \lambda_j = 1/2$. This proves the two level-set identities. Finally, $p_j \rightarrow p_* = [0 : 0 : 1]$ and $\nu(u, p_*) = 1$, so the strict level set is not closed and hence not analytic. $\square$

1.14 The local Bergman estimates

Demailly's approximation of plurisubharmonic functions by functions with analytic singularities is built from Bergman kernels of weighted spaces of holomorphic functions. In this section we recall the local construction and its estimates. Fix a bounded pseudoconvex domain $\Omega \subset \mathbb{C}^n$ and a plurisubharmonic function ψ on Ω . Write $d\lambda$ for Euclidean volume and $B(x, r)$ for the Euclidean ball of radius $r > 0$ about x . For a positive integer m , define the weighted Hilbert space of holomorphic functions

$$\mathcal{H}_m = \left\{ f \in \mathcal{O}(\Omega) : \|f\|_m^2 := \int_{\Omega} |f|^2 e^{-m\psi} d\lambda < \infty \right\}.$$

Choose an orthonormal basis $(g_{m,j})_j$ of $\mathcal{H}_m$ and define $\beta_m = m^{-1} \log \sum_j |g_{m,j}|^2$. The sum is the squared norm of point evaluation,

$$\sum_j |g_{m,j}(x)|^2 = \sup_{\|f\|_m \leq 1} |f(x)|^2,$$

and is therefore independent of the basis. By the local finite generation part of Bergman regularization, β_m has analytic type $(1/m, I(m\psi))$ on relatively compact open subsets of Ω . This follows from the generation of the multiplier ideal by weighted L^2 holomorphic functions and from local L^2 division; see [Dem11, Proposition 5.7

and Section 14.A]. We use this local statement, together with the point-extension estimate in the proof below, as a standard input.

Proposition 1.14.1 *There are constants C_1, C_2 independent of m such that, for $B(x, r) \Subset \Omega$,*

$$\psi(x) - \frac{C_1}{m} \leq \beta_m(x) \leq \sup_{B(x, r)} \psi + \frac{1}{m} \log \frac{C_2}{r^{2n}}. \quad (1.19)$$

Consequently $\beta_m \rightarrow \psi$ pointwise and in L^1_{loc} , and

$$\max\{\nu(\psi, x) - n/m, 0\} \leq \nu(\beta_m, x) \leq \nu(\psi, x). \quad (1.20)$$

Proof For $\|f\|_m \leq 1$, the submean inequality gives

$$|f(x)|^2 \leq C_2 r^{-2n} \int_{B(x, r)} |f|^2 d\lambda \leq C_2 r^{-2n} e^{m \sup_{B(x, r)} \psi}.$$

Taking the supremum over the unit ball of $\mathcal{H}_m$ and then the logarithm proves the upper bound.

For the lower bound, suppose that $\psi(x) > -\infty$. The local Ohsawa–Takegoshi point-extension theorem gives a holomorphic f with $f(x) = 1$ and

$$\int_{\Omega} |f|^2 e^{-m\psi} d\lambda \leq C e^{-m\psi(x)},$$

where the constant is independent of the plurisubharmonic weight and of m . After normalizing f in $\mathcal{H}_m$, we see that the squared norm of point evaluation is at least $C^{-1} e^{m\psi(x)}$, which proves the lower bound. At a pole of ψ the lower bound holds trivially.

Choosing $r = 1/m$ in the upper bound and using upper semicontinuity of ψ proves pointwise convergence. On a fixed relatively compact set, the same estimates bound β_m above by a constant and below by $\psi - C_1/m$. Since ψ is locally integrable, dominated convergence also gives convergence in L^1_{loc} .

For the Lelong estimate, take suprema over $B(x, r)$ in the two inequalities, bounding the right-hand side of the upper one by a supremum over $B(x, 2r)$. Divide by $\log r^2 < 0$ and let $r \downarrow 0$. After the division, the term $-(2n/m) \log r$ contributes $-n/m$, while the constant terms disappear. This proves the two inequalities in (1.20); since Lelong numbers are nonnegative, the lower bound may be replaced by its maximum with zero. $\square$

In [Dem11], the local weight is $e^{-2m\phi}$ and Lelong numbers are normalized by $\log |z|$. With $\psi = 2\phi$, these conventions give exactly the formulas above; in particular, the loss is n/m for the weight $e^{-m\psi}$ and the normalization by $\log |z|^2$.

The same construction and estimates hold for every real $m > 0$. The coefficient $1/m$ of the resulting logarithmic presentation is rational exactly when m is rational, and we speak of an analytic type only in that case. The global sequence constructed below is indexed by integers.

For a quasi-plurisubharmonic function u , the generators of $\mathcal{I}(mu)$ also control the multiplier ideals of u at nearby weights; a small loss in the weight compensates for the finite Bergman index.

Lemma 1.14.1 *Let u be quasi-plurisubharmonic, let $m > 0$, and let a_m be a function which locally satisfies $a_m = m^{-1} \log \sum_k |g_k|^2 + O(1)$, where the g_k generate $\mathcal{I}(mu)$. For $t > 0$ and $s > 1$,*

$$\mathcal{I}(sta_m) \subseteq \mathcal{I}(tu) \quad \text{whenever} \quad m \geq \frac{st}{s-1}.$$

Moreover, $u \preceq a_m$ locally, and hence $\mathcal{I}(tu) \subseteq \mathcal{I}(ta_m)$ for every $t > 0$.

Proof On a sufficiently small coordinate neighborhood, choose generators $g_1, \dots, g_N$ of $\mathcal{I}(mu)$ and put $B = (\sum_k |g_k|^2)e^{-mu}$. After shrinking the neighborhood, B is integrable and $a_m = m^{-1} \log \sum_k |g_k|^2 + O(1)$ with a bounded remainder. If $f \in \mathcal{I}(sta_m)$, shrink once more so that f is bounded and $A = |f|^2 e^{-sta_m}$ is integrable. Then, almost everywhere,

$$|f|^2 e^{-tu} \leq C |f|^{2-2/s} A^{1/s} B^{t/m}.$$

Hölder's inequality with exponents s and $s/(s-1)$ applies because $st/(m(s-1)) \leq 1$, and it shows that the left side is locally integrable, also in the case of equality in the bound for m . Finally, the local Bergman lower estimate of [Proposition 1.14.1](#) gives $u \preceq a_m$ locally; bounded smooth corrections affect neither this comparison nor any of the ideals. $\square$

1.15 The global curvature bound

We return to the compact manifold X with its Hermitian form ω . Demailly's global regularization theorem glues the local Bergman constructions while controlling the curvature error. We use it as a classical input in the following form.

Theorem 1.15.1 (Demailly regularization) *Let u be quasi-plurisubharmonic on X and let γ be a continuous real $(1, 1)$ -form with $\text{dd}^c u \geq \gamma$. There are quasi-plurisubharmonic functions u_m , defined for all sufficiently large positive integers m , and numbers $\epsilon_m \downarrow 0$ such that*

- (1) u_m has analytic type $(1/m, \mathcal{I}(mu))$;
- (2) $u_m \geq u$ and $u_m \rightarrow u$ pointwise and in $L^1(X)$;
- (3) $\text{dd}^c u_m \geq \gamma - \epsilon_m \omega$;
- (4) $\max\{v(u, x) - n/m, 0\} \leq v(u_m, x) \leq v(u, x)$ for all x .

The sequence (u_m) need not be monotone.

This is the form of [Dem11, Theorem 14.12] used in this book. The local generators in the construction are the weighted Bergman generators of $\mathcal{I}(mu)$; smooth local corrections do not change this ideal. On overlaps the local Bergman sums are comparable, so the glued logarithm keeps the analytic type $(1/m, \mathcal{I}(mu))$. The construction freezes the continuous lower bound γ on sufficiently small coordinate balls, and its curvature error combines the modulus of continuity of γ with an overlap term that tends to zero as m increases. It is this global curvature estimate, and not merely the local convergence of Proposition 1.14.1, that we take from the theorem.

Corollary 1.15.1 *Let θ be a smooth real $(1, 1)$ -form on X and $u \in \text{PSH}(X, \theta)$. The approximants u_m of Theorem 1.15.1 for $\gamma = -\theta$ satisfy*

$$\theta + \text{dd}^c u_m \geq -\epsilon_m \omega.$$

In particular, they have analytic type $(1/m, \mathcal{I}(mu))$.

Proof Apply Theorem 1.15.1 to u with the lower bound $\gamma = -\theta$; the theorem does not require γ to be closed. Adding θ to the curvature inequality gives the assertion. In the normalization of [Dem11], the theorem is applied to the potential $u/2$, since $\frac{1}{\pi} \partial \bar{\partial}(u/2) = \text{dd}^c u$. $\square$

Thus the approximants keep the curvature lower bound up to an error that tends to zero. Their multiplier ideals determine the limit of their ordinary envelopes; see Theorem 15.5.1.

1.15.1 Regularization of closed currents

We also use the regularization of closed currents in the form recalled in [Xia]. Let $T = \eta + \text{dd}^c v$ be a closed real $(1, 1)$ -current, where η is a smooth closed form and v is

quasi-plurisubharmonic, and set $v(T, x) = v(v, x)$. Suppose that $T \geq \gamma$ for a smooth real $(1, 1)$ -form γ . Smooth regularization gives smooth representatives $T_j = \eta + \text{dd}^c v_j$ with

$$T_j \geq \gamma - C\lambda_j\omega,$$

where $C > 0$ is a fixed constant and the continuous functions λ_j decrease pointwise to $v(T, \cdot)$. If all Lelong numbers of T vanish, Dini's theorem shows that $\lambda_j \rightarrow 0$ uniformly, so the loss of positivity becomes uniformly small. Analytic regularization instead gives representatives S_j with analytic singularities and

$$S_j \geq \gamma - \varepsilon_j\omega, \quad \varepsilon_j \downarrow 0, \quad v(S_j, x) \leq v(T, x).$$

Thus analytic regularization preserves strict positivity up to a small loss and creates no positive Lelong number at a point where the Lelong number of T vanishes.

1.15.2 Smooth remainders after resolution

For arguments on a modification, the bounded remainder in an analytic presentation is sometimes insufficient. The following version of regularization gives a smooth remainder after resolution.

Theorem 1.15.2 (Demailly regularization) *Let α be a smooth real $(1, 1)$ -form and let $u \in \text{PSH}(X, \alpha)$. There are numbers $\delta_j \downarrow 0$ and functions $\tilde{u}_j \in \text{PSH}(X, \alpha + \delta_j\omega)$ decreasing to u with the following properties. Each $\tilde{u}_j$ is smooth outside an analytic pole set, and there is a modification $\pi_j : Y_j \rightarrow X$, obtained by a finite sequence of blowups with smooth centers, such that locally on Y_j*

$$\pi_j^* \tilde{u}_j = \sum_{\ell} a_{\ell} \log |s_{\ell}|^2 + b, \quad a_{\ell} > 0, \quad b \in C^{\infty}.$$

Here the s_{ℓ} are local holomorphic defining functions of divisors, the $a_{\ell} > 0$ are real numbers, and b is a smooth real function. The divisors may be taken to have simple normal crossings.

This classical theorem is applied to the closed current $\text{dd}^c u$ with the smooth lower bound $-\alpha$; see [Section 33.1](#) for its source. The lower bound need not be closed, and X need not be Kähler. What matters here is the smooth remainder b after resolution; an analytic type, whose remainder is merely bounded, would not suffice. The sequence $(\tilde{u}_j)$ need not be the multiplier-ideal sequence of [Theorem 1.15.1](#), and we do not claim that the conclusions of the two theorems hold for one and the same sequence. If $\theta + \text{dd}^c u \geq \varepsilon\omega$ for some $\varepsilon > 0$, applying the theorem with $\alpha = \theta - \varepsilon\omega$ and discarding the terms with $\delta_j \geq \varepsilon$ gives approximants with $\theta + \text{dd}^c \tilde{u}_j \geq (\varepsilon - \delta_j)\omega > 0$; thus strict positivity is preserved.

1.16 Multiplier ideals and logarithmic poles

For a logarithmic pole along a submanifold, weighted integrability of a holomorphic germ is determined by its vanishing order in the normal directions. For general singularities, the valuative characterization of multiplier ideals and the strong openness theorem, both recalled in [Xia], make the comparison of multiplier ideals compatible with maxima, sums and increasing limits.

In local coordinates $(z, w) \in \mathbb{C}^d \times \mathbb{C}^k$, with $d \geq 0$ and $k \geq 1$, let $Y = \{w = 0\}$ and denote its ideal by $\mathcal{I}_Y$.

Lemma 1.16.1 *If a quasi-plurisubharmonic function has the form $u = c \log |w|^2 + O(1)$ with $c > 0$ and locally bounded remainder, then for every $t > 0$,*

$$\mathcal{I}(tu) = \mathcal{I}_Y^{\max\{\lfloor tc \rfloor - k + 1, 0\}}.$$

The zeroth power is the full structure sheaf.

Proof The bounded remainder changes the weight only by bounded positive factors. Expand a nonzero holomorphic germ $g(z, w)$ in homogeneous polynomials in w , and let a be the smallest degree whose term does not vanish identically. On smaller product neighborhoods, $|g(z, w)| \leq C|w|^a$. Hence $a + k > tc$ suffices for weighted integrability, since the corresponding radial integral in $\rho = |w|$ is

$$\int_0^\varepsilon \rho^{2a-2tc+2k-1} d\rho < +\infty.$$

Conversely, let z be a point near the origin at which the term of degree a does not vanish identically in w . Integration of $|g(z, w)|^2$ over the spheres $|w| = \rho$ gives a positive leading term of order ρ^{2a} , so the radial integral in w diverges when $a + k \leq tc$, logarithmically in the case of equality. Such points z form a nonempty open set in every sufficiently small neighborhood, and Fubini's theorem shows that g is not weighted-integrable near the origin. For $d = 0$ this is the radial calculation at a point. Thus g is weighted-integrable exactly when $a \geq \lfloor tc \rfloor - k + 1$, that is, when g lies in the power of $\mathcal{I}_Y$ given in the statement. $\square$

Cutoff functions allow us to insert small isolated logarithmic poles into any Hermitian background.

Lemma 1.16.2 *Let ω be a Hermitian form on X , and fix distinct points $p_1, \dots, p_N$ of X . There are constants $C_j > 0$ such that, whenever $a_j > 0$ and $\sum_j C_j a_j < 1$, there is $u \in \text{PSH}(X, \omega)$, smooth off these points, with*

$$u = a_j \log |z|^2 + O(1) \quad \text{near } p_j, \quad \omega + \text{dd}^c u \geq \left(1 - \sum_j C_j a_j\right) \omega.$$

Here z denotes local coordinates centered at p_j . The function can be chosen to vanish outside arbitrarily small disjoint coordinate neighborhoods, with the constants depending on those neighborhoods.

Proof Choose disjoint coordinate balls centered at the points p_j and smooth cutoffs χ_j supported in them and equal to one near their centers. The function $\chi_j \log |z|^2$, extended by zero, is plurisubharmonic near its pole and smooth elsewhere, so its complex Hessian is bounded below by $-C_j \omega$. Set $u = \sum_j a_j \chi_j \log |z|^2$. These lower bounds give the asserted current inequality, and the remaining properties follow from the disjointness of the supports. $\square$

Theorem 1.16.1 *Let u, v be plurisubharmonic functions near a point of $\mathbb{C}^n$. By a local modification we mean a modification π , with smooth source, of a neighborhood of this point.*

- (1) *The inclusions $I(ku) \subseteq I(kv)$ for every real $k > 0$ are equivalent to the inequalities $v(u \circ \pi, y) \geq v(v \circ \pi, y)$ at every point y of the source of every local modification π . Likewise, equality of the multiplier ideals at every positive weight is equivalent to equality of all these Lelong numbers.*
- (2) *If p_j is an increasing sequence of plurisubharmonic functions converging almost everywhere to a plurisubharmonic function p , then, for each point x and each $\lambda > 0$,*

$$I(\lambda p_j)_x = I(\lambda p)_x \quad \text{for all sufficiently large } j.$$

In the first item, the neighborhoods may be shrunk as necessary; we never need to extend a local modification to a modification of a compact manifold. The second item is the increasing-limit form of the strong openness theorem used in [Xia]. Since adding a smooth function changes neither multiplier ideals nor Lelong numbers, both items apply to quasi-plurisubharmonic functions after the local correction of [Proposition 1.1.1](#).

Lemma 1.16.3 *Let u, u', v, v' be quasi-plurisubharmonic functions on X . For any quasi-plurisubharmonic h , one has*

$$u + h \sim_I v + h \iff u \sim_I v.$$

If $u \sim_I v$ and $u' \sim_I v'$, then

$$\max(u, u') \sim_I \max(v, v'), \quad u + u' \sim_I v + v', \quad au \sim_I av \quad (a > 0).$$

Proof Fix a coordinate neighborhood $U \subset X$ and a modification $\pi : Y \rightarrow U$ with smooth source. At every $y \in Y$, the elementary rules for the Lelong numbers of maxima, sums and positive multiples give

$$\begin{aligned} v(\max(u, u') \circ \pi, y) &= \min\{v(u \circ \pi, y), v(u' \circ \pi, y)\}, \\ v((u + u') \circ \pi, y) &= v(u \circ \pi, y) + v(u' \circ \pi, y), \\ v(au \circ \pi, y) &= av(u \circ \pi, y). \end{aligned}$$

These rules are unaffected by smooth local corrections. Since $u \sim_I v$ and $u' \sim_I v'$, the first item of [Theorem 1.16.1](#) shows that the right-hand sides do not change when u, u' are replaced by v, v' . The converse direction of the same item, applied on each coordinate neighborhood, gives the three asserted equivalences.

For the cancellation rule, suppose that $u + h \sim_I v + h$. By the first item of [Theorem 1.16.1](#), the pullbacks $(u + h) \circ \pi$ and $(v + h) \circ \pi$ have the same Lelong numbers. The common summand $h \circ \pi$ is quasi-plurisubharmonic, so its Lelong numbers are finite, and subtracting them shows that $u \circ \pi$ and $v \circ \pi$ have the same Lelong numbers. Hence $u \sim_I v$ by the same item. The reverse implication is the addition rule proved above. $\square$

Let v, w be quasi-plurisubharmonic functions on an open set, and let Y be a complex submanifold on which $v|_Y$ is not identically $-\infty$. The restriction and subadditivity theorems give the two inclusions recalled in [\[Xia\]](#) and [\[Dem11, Section 15\]](#):

$$I(v|_Y) \subseteq I(v)O_Y, \quad I(v + w) \subseteq I(v)I(w). \quad (1.21)$$

The first follows from the local Ohsawa–Takegoshi extension theorem. For the second, the weighted Hilbert space of holomorphic functions on a product is the Hilbert tensor product of the two weighted spaces, so the multiplier ideal of $v(x) + w(y)$ on the product is generated by products of generators of $I(v)$ and $I(w)$; the first inclusion, applied to the diagonal, then gives the second. These local results for plurisubharmonic functions extend to quasi-plurisubharmonic functions, in the weight convention of this book, by smooth corrections.

Multiplier ideals commute with pullback by holomorphic submersions. Here the extension IO_Z of an ideal sheaf I on Y is the ideal sheaf on Z generated by the pullbacks of its local sections.

Lemma 1.16.4 *Let $p : Z \rightarrow Y$ be a holomorphic submersion of complex manifolds and let $u \in \text{QPSH}(Y)$. For every $t > 0$,*

$$I(tu \circ p) = I(tu)O_Z.$$

Proof Work in product coordinates (z, ζ) with $p(z, \zeta) = z$. Write α for a multi-index in the fiber variables and $d\lambda_\zeta$ for their Euclidean volume. A germ in the ideal on the right is a finite sum of bounded holomorphic multiples of pullbacks of germs that are square integrable against $e^{-tu(z)}$. Fubini's theorem shows that it is weighted-integrable on a sufficiently small product neighborhood.

Conversely, let $F(z, \zeta)$ be a weighted-integrable holomorphic germ and expand it in the fiber variables,

$$F(z, \zeta) = \sum_{\alpha} f_{\alpha}(z) \zeta^{\alpha}.$$

The coefficient estimate for a holomorphic function on a polydisk gives, on smaller product neighborhoods,

$$|f_{\alpha}(z)|^2 \leq C_{\alpha} \int |F(z, \zeta)|^2 d\lambda_{\zeta}.$$

Multiplying by $e^{-tu(z)}$ and integrating in z shows that each coefficient germ f_{α} belongs to $\mathcal{I}(tu)$. Let J be the extension of this ideal to the local ring R of holomorphic germs on the product. Every finite Taylor sum of F belongs to J , and the remainder of total fiber degree at least N belongs to $(\zeta)^N$. Thus the class of F in R/J lies in $(\zeta)^N(R/J)$ for every N . By the Krull intersection theorem for the finitely generated module R/J over the Noetherian local ring R , the intersection of these submodules is zero. Hence $F \in J$. Smooth corrections and smooth positive volume densities do not change the integrability conditions. $\square$

1.16.1 Weighted distance from a sum of multiplier ideals

Membership in a multiplier ideal is a local integrability condition. On a pseudoconvex domain one can ask, more quantitatively, how small the weighted norm of a holomorphic function can be made by subtracting global sections of such ideals. A sharp L^2 estimate answers this question for one weight. Applied successively, with the remaining weights kept in the auxiliary weight at each step, it gives a product bound for several weights.

Throughout this subsection, $\Omega \subset \mathbb{C}^n$ is a pseudoconvex domain, $n \geq 1$, and dV denotes Euclidean volume. For a plurisubharmonic weight ρ on Ω , put

$$\|f\|_{\rho}^2 = \int_{\Omega} |f|^2 e^{-\rho} dV.$$

For a plurisubharmonic function v on Ω , we write $\Gamma(\Omega, \mathcal{I}(v))$ for the space of holomorphic functions on Ω whose germs belong to $\mathcal{I}(v)$ at every point. Membership requires only local weighted integrability, not a finite global norm.

We first prove a division estimate with two summands. Its sharp constant comes from keeping the full sum of the twisting functions in the $\bar{\partial}$ -estimate.

Lemma 1.16.5 *Let ψ, ϕ_1, ϕ_2 be plurisubharmonic functions on Ω , and suppose that $S = e^{\phi_1} + e^{\phi_2} < 1$. If f is holomorphic and*

$$J = \int_{\Omega} \frac{|f|^2 e^{-\psi}}{S^2} dV < +\infty,$$

then there are holomorphic F_1, F_2 with $F_1 + F_2 = f$ and

$$\int_{\Omega} (|F_1|^2 e^{-\phi_1} + |F_2|^2 e^{-\phi_2}) e^{-\psi} dV \leq J. \quad (1.22)$$

Proof *Step 1: a twisted $\bar{\partial}$ -estimate.* Suppose first that Ω is bounded, that the weights are smooth on a neighborhood of $\bar{\Omega}$ with $S < 1$ there, and that $\Phi = \log S$ is strictly plurisubharmonic. Set $\chi = \phi_1 + \phi_2 + \psi$ and $A = (\Phi_{j\bar{k}})$. For a $(0, 1)$ -form b , write $|b|_A^2$ for its squared norm with respect to the dual of this positive Hermitian matrix. We claim that every $\bar{\partial}$ -closed $(0, 1)$ -form b for which the right-hand side below is finite admits a solution u of

$$\bar{\partial}u = b, \quad \int_{\Omega} |u|^2 e^{\Phi - \chi} dV \leq \int_{\Omega} (1 - e^{\Phi}) |b|_A^2 e^{-\chi} dV. \quad (1.23)$$

To prove this, define for $x < 0$

$$T(x) = -\log(1 - e^x), \quad \eta(x) = \frac{-x}{1 - e^x} - 1, \quad \lambda(x) = -\frac{\eta'(x)}{T'(x)}.$$

The inequality $-x > 1 - e^x$ gives $\eta > 0$. Also $\eta' = -[1 - (1 - x)e^x]/(1 - e^x)^2 < 0$, whereas $T' > 0$, so $\lambda > 0$. Direct differentiation gives

$$\eta T' - \eta' = 1, \quad \eta T'' - \eta'' - \frac{(\eta')^2}{\lambda} = 0, \quad \frac{e^{-T}}{\eta + \lambda} = e^x.$$

Use the weight $h = e^{-\chi - T(\Phi)}$ on the trivial line bundle and evaluate the twisting functions at Φ . The twisted curvature is

$$\begin{aligned} B_0 &= \eta i \partial \bar{\partial}(\chi + T(\Phi)) - i \partial \bar{\partial} \eta - i \lambda^{-1} \partial \eta \wedge \bar{\partial} \eta \\ &= \eta i \partial \bar{\partial} \chi + i \partial \bar{\partial} \Phi \geq i \partial \bar{\partial} \Phi. \end{aligned}$$

Let Λ denote contraction by the Euclidean Kähler form and $\bar{\partial}_h^*$ the weighted adjoint. For a compactly supported $(n, 1)$ -form v , the twisted Bochner identity and the weighted Cauchy–Schwarz inequality give

$$\langle [B_0, \Lambda]v, v \rangle_h \leq \|\sqrt{\eta + \lambda} \bar{\partial}_h^* v\|_h^2 + \|\sqrt{\eta} \bar{\partial} v\|_h^2. \quad (1.24)$$

More explicitly, the cross term is bounded by $\lambda |\bar{\partial}_h^* v|^2 + \lambda^{-1} |(\bar{\partial} \eta)^* v|^2$; the latter term is exactly the commutator contribution of $i \lambda^{-1} \partial \eta \wedge \bar{\partial} \eta$. The terms of type $(n + 1, 1)$ vanish, and the remaining connection norm has a favorable sign.

The Hilbert space existence argument applied to (1.24) therefore gives

$$\int \frac{|u|^2 h}{\eta + \lambda} dV \leq \int |b|_A^2 h dV.$$

To see the coefficient, project a test form to $\ker \bar{\partial}$. On this kernel the second term of (1.24) vanishes, and the Cauchy–Schwarz inequality in the curvature norm bounds the functional $v \mapsto \langle b, v \rangle_h$ by $(\int |b|_A^2 h)^{1/2} \|\sqrt{\eta + \lambda} \bar{\partial}_h^* v\|_h$. The Riesz representation theorem gives a solution with the asserted norm. The twisting functions are bounded on Ω , since Φ is smooth and bounded away from both $-\infty$ and 0. The argument first uses a complete Kähler metric; approximating the Euclidean metric by the Euclidean metric plus small positive multiples of a complete metric gives the Euclidean statement. Under the identification with canonical-bundle-valued forms, the $(n, 0)$ norm integral and the curvature-dual $(n, 1)$ integral have the same coordinate expressions as above. Since $h = e^{-\chi}(1 - e^\Phi)$, the identities for T, η, λ now give (1.23).

Step 2: division for smooth weights. Put $v_i = e^{\phi_i}/S$ and $\ell = (v_1 f, v_2 f)$. Equip $\mathbb{C}^2$ with the diagonal metric $(e^{-\phi_1}, e^{-\phi_2})$. Then ℓ is orthogonal to the kernel line of the sum map, generated by $(1, -1)$, and $|\ell|^2 = |f|^2/S$. Write $\delta = \phi_1 - \phi_2$. The Hessian formula gives

$$\begin{aligned} A &= v_1(\phi_{1,j\bar{k}}) + v_2(\phi_{2,j\bar{k}}) + v_1 v_2(\delta_j \bar{\delta}_{\bar{k}}), \\ \bar{\partial}(v_1 f) &= f v_1 v_2 \bar{\partial} \delta. \end{aligned}$$

Thus $v_1 v_2 |\bar{\partial} \delta|_A^2 \leq 1$ and, for $b = \bar{\partial}(v_1 f)$,

$$|b|_A^2 e^{-\chi} \leq \frac{|f|^2 e^{-\psi}}{S^2}.$$

Solve (1.23) for this b and set $F = \ell - u(1, -1)$. Since $v_1 + v_2 = 1$, the vector $F = (F_1, F_2)$ is holomorphic and its components sum to f . The squared norm of $(1, -1)$ is $e^{-\phi_1} + e^{-\phi_2} = S e^{-\phi_1 - \phi_2}$. Orthogonality and (1.23) consequently give

$$\begin{aligned} \int |F|^2 e^{-\psi} &= \int \frac{|f|^2 e^{-\psi}}{S} + \int |u|^2 e^{\Phi - \chi} \\ &\leq \int \frac{|f|^2 e^{-\psi}}{S^2}. \end{aligned}$$

This proves (1.22) for smooth weights.

Step 3: general weights. Exhaust Ω by bounded pseudoconvex domains with compact closures in Ω . On each of them, convolve the weights on a slightly larger neighborhood and add a sufficiently small positive multiple of $|z|^2$. These smooth plurisubharmonic weights dominate the original weights, converge to them almost everywhere, preserve $S < 1$ on the chosen closure, and make Φ strictly plurisubharmonic. The corresponding integrals J are bounded by the original one. On every compact subset the weights have common upper bounds, so (1.22) gives uniform unweighted local L^2 bounds for both components. The holomorphic mean-value

inequality and a diagonal extraction give holomorphic limits. Almost-everywhere convergence of the weights and Fatou's lemma yield (1.22) on Ω , and $F_1 + F_2 = f$ passes to the limit. $\square$

Proposition 1.16.1 *Let ψ and ϕ be plurisubharmonic functions on Ω with $\phi < 0$, and let $p > 1$. For holomorphic f with $I = \|f\|_{\psi+\phi}^2 < +\infty$, define*

$$c = \inf\{\|g\|_{\psi}^2 : g \in \mathcal{O}(\Omega), \quad f - g \in \Gamma(\Omega, \mathcal{I}(p\phi + \psi))\}.$$

Then $c \leq (1 - 1/p)I$.

Proof For $t > 0$, apply Lemma 1.16.5 with

$$\phi_1 = \log \frac{t}{1+t} + p\phi, \quad \phi_2 = -\log(1+t).$$

Their exponential sum is $S = (1 + te^{p\phi})/(1+t) < 1$. The integral J of the lemma is finite, since $\|f\|_{\psi}^2 \leq I$ and $S \geq 1/(1+t)$. The first component F_1 belongs to $\Gamma(\Omega, \mathcal{I}(p\phi + \psi))$, so the second component $F_2 = f - F_1$ is admissible for c , and the norm estimate gives

$$\frac{c}{1+t} \leq \int_{\Omega} \frac{|f|^2 e^{-\psi}}{(1 + te^{p\phi})^2} dV.$$

Set $t = x^p$ and integrate over $x > 0$. With $\kappa_k = \int_0^{\infty} (1 + x^p)^{-k} dx$, Tonelli's theorem and the change of variable $x \mapsto xe^{\phi}$ give $c\kappa_1 \leq I\kappa_2$; the pole set of ϕ is Lebesgue null. Since $p > 1$, both integrals are finite, and integrating the derivative of $x/(1 + x^p)$ over $(0, \infty)$ gives $\kappa_2 = (1 - 1/p)\kappa_1$. The argument does not require the infimum to be attained. $\square$

Theorem 1.16.2 *Let ψ and $\phi_1, \dots, \phi_r$ be plurisubharmonic functions on Ω , with $r \geq 1$ and $\phi_i < 0$, and choose $p_i > 1$. For holomorphic f with*

$$I = \|f\|_{\psi + \sum_i \phi_i}^2 < +\infty,$$

put

$$c = \inf \left\{ \|g\|_{\psi}^2 : g \in O(\Omega), \quad f - g \in \sum_{i=1}^r \Gamma(\Omega, \mathcal{I}(p_i \phi_i + \psi)) \right\}.$$

Then

$$c \leq \prod_{i=1}^r \left(1 - \frac{1}{p_i}\right) I. \quad (1.25)$$

For $r \leq n$, this constant is optimal for the stated class of data.

Proof Set $\psi_i = \psi + \sum_{j>i} \phi_j$, $a_i = 1 - 1/p_i$, and $f_0 = f$. For arbitrary $\varepsilon_i > 0$, **Proposition 1.16.1** successively gives holomorphic f_i such that

$$\begin{aligned} \|f_i\|_{\psi_i}^2 &\leq a_i \|f_{i-1}\|_{\psi_i + \phi_i}^2 + \varepsilon_i, \\ f_{i-1} - f_i &\in \Gamma(\Omega, \mathcal{I}(p_i \phi_i + \psi_i)). \end{aligned}$$

Since $\psi_i \leq \psi$, these ideals are contained in $\mathcal{I}(p_i \phi_i + \psi)$. As $f - f_r$ is the sum of the differences $f_{i-1} - f_i$, the function f_r is admissible for c . Moreover, $\psi_i + \phi_i = \psi_{i-1}$ for $i \geq 1$ and $\psi_r = \psi$, so iteration gives

$$c \leq \left(\prod_i a_i \right) I + \sum_{i=1}^r \varepsilon_i \prod_{j>i} a_j.$$

Letting every ε_i tend to zero proves (1.25).

For sharpness when $r \leq n$, take the unit polydisk $\Omega = \Delta^n$, $f = 1$, $\psi = 0$, and $\phi_i = p_i^{-1} \log |z_i|^2$ for $i \leq r$. By **Lemma 1.16.1**, $\mathcal{I}(p_i \phi_i) = (z_i)$. Every admissible g equals one on $Y = \{z_1 = \dots = z_r = 0\}$, hence $g(0) = 1$. Orthogonality of the monomials on the polydisk gives $\|g\|_0^2 \geq \pi^n$, with equality for $g = 1$. Direct radial integration gives $I = \pi^n \prod_i p_i / (p_i - 1)$, so equality holds in (1.25). $\square$

The congruence condition in **Theorem 1.16.2** involves a sum of global sections, and the successive remainders in its proof are global; a condition on a single germ would not produce them. The estimate holds for any number of weights, whereas the optimality assertion uses distinct coordinate directions and therefore requires $r \leq n$.

1.16.2 The optimal constant in dimension one

In this subsection, $\Omega \subset \mathbb{C}$ is a pseudoconvex domain with Euclidean area dV , and we use the weighted norms and spaces of global sections of **Section 1.16.1**. In one

variable, every multiplier ideal is determined by vanishing orders at points. This allows us to combine the weights into a single one before applying the one-weight estimate, and leads to a better constant than the product bound.

Lemma 1.16.6 *For a subharmonic function u on Ω and $x \in \Omega$,*

$$\mathcal{I}(u)_x = (z - x)^{\lfloor v(u, x) \rfloor} \mathcal{O}_{\Omega, x}. \quad (1.26)$$

These ideals form a locally principal ideal sheaf.

Proof With the normalization of dd^c fixed in the conventions, $\mu = \text{dd}^c u$ is a positive Radon measure and $a = \mu(\{x\}) = v(u, x)$. After removal of this atom, the distribution $u - a \log |z - x|^2$ has positive complex Hessian, so it has a subharmonic representative v , and $\text{dd}^c v$ has no atom at x . Since subharmonic functions that agree almost everywhere agree everywhere,

$$u = a \log |z - x|^2 + v.$$

We claim that, for each $t > 0$, the function e^{-tv} is integrable on some neighborhood of x . Indeed, since $\text{dd}^c v$ has no atom at x , there is a disk $D = D(x, R) \Subset \Omega$ with $M = (\text{dd}^c v)(D) < 1/t$. On D write

$$v(z) = \int_D \log |z - y|^2 d(\text{dd}^c v)(y) + h(z),$$

where h is harmonic: the integral is locally integrable by Fubini's theorem and has complex Hessian $\text{dd}^c v$ on D , so it differs from v by a harmonic distribution. If $M = 0$, the claim follows from harmonicity. For $M > 0$, Jensen's inequality for the probability measure $(\text{dd}^c v)/M$ gives

$$\exp \left(-t \int_D \log |z - y|^2 d(\text{dd}^c v)(y) \right) \leq \frac{1}{M} \int_D |z - y|^{-2tM} d(\text{dd}^c v)(y).$$

Since $tM < 1$, the integral of $|z - y|^{-2tM}$ over $z \in D(x, R/2)$ is bounded uniformly in $y \in D$. The harmonic function h is bounded below on this smaller disk, so Tonelli's theorem proves the claim. (Truncating the logarithmic kernel justifies Jensen's inequality at its poles.)

A nonzero holomorphic germ of order k at x is a unit times $(z - x)^k$. Since v is locally bounded above, weighted integrability requires $k + 1 > a$; equality is excluded by the logarithmic divergence of the radial integral. Conversely, if $k + 1 > a$, choose $b > 1$ such that $b(a - k) < 1$. Then $|z - x|^{2k-2a}$ belongs locally to L^b , and e^{-v} belongs locally to $L^{b/(b-1)}$ by the claim, so Hölder's inequality proves integrability. Thus the germ belongs to $\mathcal{I}(u)_x$ exactly when $k \geq \lfloor a \rfloor$.

The points y with $v(u, y) \geq 1$ form a locally finite set, since each of them carries an atom of mass at least one of the locally finite measure $\text{dd}^c u$. Near any point, therefore, the ideal sheaf is generated by a single power of a coordinate, which proves the last assertion. $\square$

The distance condition below involves a sum of spaces of global sections. In one variable, this sum coincides with the space of global sections of the sum of the ideal sheaves.

Lemma 1.16.7 *If $u_1, \dots, u_r$ are subharmonic functions on Ω , then*

$$\Gamma\left(\Omega, \sum_{i=1}^r \mathcal{I}(u_i)\right) = \sum_{i=1}^r \Gamma(\Omega, \mathcal{I}(u_i)). \quad (1.27)$$

Proof For $r = 1$ there is nothing to prove, so let $r \geq 2$. Put $J_i = \mathcal{I}(u_i)$ and $J = \sum_i J_i$. By Lemma 1.16.6, these sheaves are locally free of rank one. At each point, the order of J is the smallest of the orders of the J_i , and a local generator of an ideal J_i attaining this order also generates J . Consequently the sum map $\bigoplus_i J_i \rightarrow J$ is locally split, and its kernel E is a holomorphic vector bundle of rank $r - 1$.

Fix $f \in \Gamma(\Omega, J)$. Gluing local holomorphic lifts of f with a smooth partition of unity gives a smooth section s of $\bigoplus_i J_i$ whose image is f . Since f is holomorphic, $\beta = \bar{\partial}s$ is an E -valued $(0, 1)$ -form. It suffices to solve $\bar{\partial}v = \beta$ for a section v of E , for then $s - v$ is a holomorphic lift of f .

We solve this equation using a bundle metric of positive curvature. Choose a smooth strictly subharmonic exhaustion function $\rho \geq 1$ of Ω . The Kähler metric

$$\omega_* = i \, dz \wedge d\bar{z} + i \partial \bar{\partial} \rho^2$$

is complete: it dominates $2i \partial \rho \wedge \bar{\partial} \rho$, so ρ has bounded gradient with respect to it, and therefore every curve leaving all compact subsets has infinite length.

Equip E with a smooth Hermitian metric h . Choose a smooth increasing convex function χ on $[1, +\infty)$ so that the metric $h_\chi = h e^{-\chi(\rho)}$ has

$$i \Theta_{E, h_\chi} \geq \omega_* \, \text{Id}_E, \quad \int_{\Omega} |\beta|_{h_\chi, \omega_*}^2 \, dV_{\omega_*} < +\infty.$$

These two requirements can be imposed successively on the compact sublevel sets of ρ : increase χ' so that $\chi'(\rho)$ times the positive Hessian of ρ dominates the negative part of the curvature, and increase χ so that the integral over each shell $\{m \leq \rho < m+1\}$ is at most 2^{-m} . Increasing the slopes preserves the inequalities already achieved.

Use the global frame dz of the canonical bundle K_Ω to identify E -valued $(0, q)$ -forms with $(E \otimes K_\Omega^{-1})$ -valued $(1, q)$ -forms, and give K_Ω^{-1} its flat coordinate metric. Its curvature is zero, and ω_* dominates the Euclidean metric, so the identified form β remains L^2 . The Bochner–Kodaira inequality for compactly supported forms w of type $(1, 1)$ gives

$$\|\bar{\partial}^* w\|^2 \geq \langle [i \Theta_{E, h_\chi}, \Lambda_{\omega_*}] w, w \rangle \geq \|w\|^2.$$

Here we used that there are no $(1, 2)$ -forms. By completeness, cutoffs and smoothing extend this inequality to the domain of the adjoint. Since β is L^2 , the Cauchy–Schwarz inequality bounds the functional $w \mapsto \langle w, \beta \rangle$ by $\|\beta\| \|\bar{\partial}^* w\|$, and the Riesz representation theorem gives a distributional solution v of $\bar{\partial}v = \beta$. Thus $s - v$

is distributionally holomorphic, hence holomorphic in every bundle chart, and it is the required global lift. No global weighted norm condition is imposed on its components. $\square$

Theorem 1.16.3 *Let ψ and $\phi_1, \dots, \phi_r$ be subharmonic functions on Ω , with $r \geq 1$ and $\phi_i < 0$, and choose $p_i > 1$. For holomorphic f with $I = \|f\|_{\psi + \sum_i \phi_i}^2 < +\infty$, define*

$$c = \inf \left\{ \|g\|_{\psi}^2 : g \in \mathcal{O}(\Omega), \quad f - g \in \sum_{i=1}^r \Gamma(\Omega, \mathcal{I}(p_i \phi_i + \psi)) \right\}, \quad s = \sum_{i=1}^r \frac{1}{p_i}.$$

Then

$$c \leq \max\{1 - s, 0\} I. \quad (1.28)$$

For every fixed choice of the exponents, this constant is optimal over the stated class of data. If $s \geq 1$, the function $g = 0$ is admissible.

Proof Put $J_i = \mathcal{I}(p_i \phi_i + \psi)$ and $J = \sum_i J_i$. At a point x , write $A = \nu(\psi, x)$ and $B_i = \nu(\phi_i, x)$. By [Lemma 1.16.6](#), the order of J_x is $\min_i \lfloor A + p_i B_i \rfloor$.

Suppose first that $s < 1$, and put $P = 1/s > 1$. The numbers P/p_i sum to one, so

$$\min_i p_i B_i \leq \sum_i \frac{P}{p_i} p_i B_i = P \sum_i B_i.$$

Taking integer parts and using [Lemma 1.16.6](#) gives $\mathcal{I}(P \sum_i \phi_i + \psi) \subseteq J$. By [Lemma 1.16.7](#), every global section of this smaller ideal sheaf lies in $\sum_i \Gamma(\Omega, J_i)$, so every remainder admissible for the one-weight problem is admissible for c . [Proposition 1.16.1](#) with $\phi = \sum_i \phi_i$ and $p = P$ therefore gives $c \leq (1 - 1/P)I = (1 - s)I$.

Now let $s \geq 1$. Since $I < +\infty$, we have $f \in \Gamma(\Omega, \mathcal{I}(\psi + \sum_i \phi_i))$. If $f \equiv 0$ there is nothing to prove; otherwise let k be its order at x . Then $k + 1 > A + \sum_i B_i$. If its germ did not belong to J_x , we would have $k + 1 \leq A + p_i B_i$ for every i . With $L = k + 1 - A > 0$, this would give $\sum_i B_i \geq sL \geq L$, a contradiction. Hence $f \in \Gamma(\Omega, J)$, and [Lemma 1.16.7](#) shows that $g = 0$ is admissible.

For sharpness when $s < 1$, take the unit disk, $\psi = 0$, $f = 1$, and $\phi_i = p_i^{-1} \log |z|^2$. Then $J_i = (z)$ for all i , so an admissible g has $g(0) = 1$. Orthogonality of the monomials on the disk gives $c = \pi$, attained by $g = 1$, whereas $I = \pi/(1 - s)$. If $s \geq 1$, keep these weights and take $f = z^q$ with an integer $q \geq 0$ satisfying $q + 1 > s$. Then $I = \pi/(q + 1 - s) > 0$ and $c = 0$, so the constant 0 cannot be replaced by a negative number. $\square$

Consequently, for $r \geq 2$ the product constant of [Theorem 1.16.2](#) is not optimal on plane domains. The argument above relies on all local ideals being principal; it does not determine the optimal constant when $n \geq 2$ and $r > n$.

1.16.3 Distance for several hyperplane weights

In this subsection, $n \geq 2$, $B \subset \mathbb{C}^n$ is the unit ball, and dV is Euclidean volume. If the weights have logarithmic poles along several hyperplanes through the origin, every admissible remainder must take a prescribed value at their common zero. On the other hand, the input norm stays finite as long as the combined radial exponent is below the dimension. Together these observations give a positive distance even in part of the range where the planar distance of [Theorem 1.16.3](#) vanishes.

Example 1.16.1 Fix $r > n$ and $p > r/n$. There are negative plurisubharmonic functions $\phi_1, \dots, \phi_r$ on B for which

$$I = \int_B e^{-\sum_i \phi_i} dV < +\infty$$

and

$$\inf \left\{ \int_B |g|^2 dV : g \in O(B), \quad 1 - g \in \sum_{i=1}^r \Gamma(B, \mathcal{I}(p\phi_i)) \right\} = \frac{\pi^n}{n!} > 0. \quad (1.29)$$

In particular, for $r/n < p \leq r$, the distance is positive although $\sum_i 1/p = r/p \geq 1$.

Proof Choose distinct real numbers $t_1, \dots, t_r$ and unit linear forms

$$\ell_i(z) = \frac{\sum_{k=0}^{n-1} t_i^k z_{k+1}}{(\sum_{k=0}^{n-1} t_i^{2k})^{1/2}}.$$

Any n of these forms are linearly independent, since the determinant of their unnormalized coefficients is a nonzero Vandermonde determinant. Put $\phi_i = p^{-1} \log |\ell_i|^2$. Since the coefficient vectors of the ℓ_i have norm one, $|\ell_i(z)| < 1$ on B , so the ϕ_i are negative plurisubharmonic functions. By [Lemma 1.16.1](#), $\mathcal{I}(p\phi_i) = (\ell_i)$.

At a nonzero point, at most $n - 1$ of the forms vanish. These forms are linearly independent and can be used as part of a holomorphic coordinate system, while the other forms are bounded away from zero on a small neighborhood of the point. Hence

$$W(z) = \prod_{i=1}^r |\ell_i(z)|^{-2/p}$$

is locally integrable off the origin, because each factor $|\ell_i|^{-2/p}$ has exponent $2/p < 2$ (note that $p > r/n > 1$). By compactness, W is integrable on every closed annulus. Set $s = r/p$ and let $d\sigma$ denote surface measure on the unit sphere. Homogeneity and polar integration over such an annulus show that

$$A = \int_{|\zeta|=1} \prod_i |\ell_i(\zeta)|^{-2/p} d\sigma(\zeta) < +\infty.$$

Tonelli then gives

$$I = A \int_0^1 \rho^{2n-1-2s} d\rho = \frac{A}{2(n-s)} < +\infty,$$

since $s < n$. This takes care of the common zero at the origin as well as of the individual hyperplanes.

Every global section of (ℓ_i) vanishes at the origin. Thus every admissible g in (1.29) satisfies $g(0) = 1$. For each $z \in B$, the holomorphic function $\lambda \mapsto g(\lambda z)$ is defined on a disk of radius greater than one, and the submean inequality for the subharmonic function $|g(\lambda z)|^2$ gives

$$\frac{1}{2\pi} \int_0^{2\pi} |g(e^{i\tau} z)|^2 d\tau \geq |g(0)|^2 = 1.$$

Integrating in z and using the rotation invariance of B proves $\int_B |g|^2 dV \geq \text{Vol}(B) = \pi^n/n!$, also when the integral is infinite. The constant $g = 1$ is admissible and attains this bound. $\square$

Hence, for these equal exponents, the optimal universal constant in an estimate of the distance by a multiple of I is at least $\pi^n/(n!I) > 0$. In particular, the vanishing of the optimal constant for $s \geq 1$ in Theorem 1.16.3 does not extend to higher dimensions. The example does not determine the optimal constant for $r > n$.

1.17 Lelong numbers and divisorial estimates

Lelong numbers measure the logarithmic concentration of a positive current. Along a divisor, a lower bound for the generic Lelong number allows us to subtract the corresponding multiple of the divisor without losing positivity. At points, the local mass formula controls Lelong numbers under convergence and uniformly in a fixed background. For a prime divisor E on a complex manifold, $[E]$ denotes its current of integration, and $\nu(w, E)$ is the generic Lelong number along E of a quasi-plurisubharmonic function w , as defined in Section 1.13.

We use the following local consequence of Siu's decomposition theorem, recalled in [Xia] and [Dem11]. If T is a closed positive $(1, 1)$ -current and E is a prime divisor, the restriction of (the coefficient measures of) T to E equals the generic Lelong number of T along E times $[E]$. In particular, removing finitely many of these divisorial components from T leaves a positive current. Distinct prime divisors do not contribute overlapping mass, since their intersections have codimension at least two. All these are local statements about closed currents.

Lemma 1.17.1 *Let M be a complex manifold, let β be a smooth real $(1, 1)$ -form on M , let $w \in \text{PSH}(M, \beta)$, and let $E_1, \dots, E_N$ be distinct prime divisors on M , with $N \geq 1$. Then*

$$\beta + \text{dd}^c w - \sum_{j=1}^N v(w, E_j)[E_j] \geq 0.$$

The form β need not be closed.

Proof Work on a coordinate ball and choose a smooth function ρ with $\text{dd}^c \rho \geq \beta$. The current

$$T = \text{dd}^c(w + \rho) = (\beta + \text{dd}^c w) + (\text{dd}^c \rho - \beta)$$

is closed and positive. A smooth form, viewed through its coefficient measures, assigns zero mass to every proper analytic set. Thus T and $\beta + \text{dd}^c w$ have the same restriction to $\bigcup_j E_j$, and the consequence of Siu's theorem stated above identifies this restriction with $\sum_j v(w, E_j)[E_j]$. Subtracting it from the positive current $\beta + \text{dd}^c w$ leaves the restriction of $\beta + \text{dd}^c w$ to the complement of $\bigcup_j E_j$, which is positive. This proves the inequality locally, hence globally. Note that $\beta + \text{dd}^c w$ itself need not be closed. $\square$

Order makes the support theorem a rigidity statement for potentials: two ordered quasi-plurisubharmonic functions whose Hessians agree outside an analytic set already differ by a constant.

Lemma 1.17.2 *Let $u \leq v$ be quasi-plurisubharmonic on a connected compact complex manifold X , and let $Z \subsetneq X$ be analytic. If $\text{dd}^c u = \text{dd}^c v$ on $X \setminus Z$, then $v = u + C$ for a real constant C .*

Proof The current $S = \text{dd}^c(v - u)$ is real, closed, of order zero and supported on Z . By the support theorem in [Dem12, Chapter III, Corollaries 2.11 and 2.14, pp. 141–143],

$$S = \sum_{j=1}^m c_j [Z_j], \quad c_j = v(v, Z_j) - v(u, Z_j) \leq 0, \quad (1.30)$$

where Z_j are the prime divisorial components of Z . Indeed, the support theorem first gives real constants c_j such that $S - \sum_j c_j [Z_j]$ is supported in codimension at least two; this closed current of order zero then vanishes by the same theorem. Near a generic smooth point of Z_j , with local equation $z_1 = 0$, the function $v - u - c_j \log |z_1|^2$ has zero complex Hessian and is therefore smooth and pluriharmonic. This identifies c_j with the difference of the generic Lelong numbers, and $c_j \leq 0$ because $u \leq v$.

Thus $\text{dd}^c(u - v) = -S \geq 0$. Hence the locally integrable distribution $u - v$ has a global plurisubharmonic representative, which is constant by the maximum principle on the compact connected manifold X . Since quasi-plurisubharmonic functions that agree almost everywhere agree everywhere, $v = u + C$ for a constant C . $\square$

Every closed real $(1, 1)$ -current is the sum of a smooth closed form and the complex Hessian of a global distribution, and positivity of the current makes this

potential quasi-plurisubharmonic. This decomposition allows us to attach an ordinary singularity type to a divisorial current.

Lemma 1.17.3 *Let Z be a complex manifold and T a closed real $(1, 1)$ -current on Z . There are a smooth closed real $(1, 1)$ -form β and a real distribution v such that*

$$T = \beta + dd^c v.$$

If $T \geq 0$, then v is quasi-plurisubharmonic. Any two distributional potentials in such decompositions differ by a smooth function.

Proof The local dd^c -Poincaré lemma gives real distributional potentials v_i on the sets of a cover of Z by coordinate neighborhoods, with $T = dd^c v_i$; for positive T these potentials are plurisubharmonic. See [Dem12, Chapter III, Section 1.18 and Proposition 1.19]. On overlaps $dd^c(v_i - v_j) = 0$. Taking the Euclidean trace shows that $v_i - v_j$ is a harmonic distribution, so it is smooth by elliptic regularity.

Choose a smooth locally finite partition of unity (χ_i) subordinate to the cover and put $v = \sum_i \chi_i v_i$, each term being extended by zero as a distribution. On the j th neighborhood,

$$v - v_j = \sum_i \chi_i (v_i - v_j)$$

is smooth. Thus $\beta = T - dd^c v = -dd^c(v - v_j)$ is smooth on each neighborhood, hence on Z , and it is real and closed. For positive T , the same identity expresses v locally as a plurisubharmonic function plus a smooth function. Finally, if $T = \beta + dd^c v = \beta' + dd^c v'$ are two such decompositions, then $dd^c(v - v') = \beta' - \beta$ is smooth; taking a smooth Hermitian trace and applying elliptic regularity shows that $v - v'$ is smooth. $\square$

For a potential whose complex Hessian is a divisorial current minus a smooth form, ordinary domination, ideal domination and the corresponding inequalities for generic Lelong numbers along the divisors are all equivalent. Countably many divisors are allowed, provided the divisorial current has finite mass.

Lemma 1.17.4 *Let Y be a connected compact complex manifold. Let (D_j) be a finite or countable family of distinct prime divisors on Y and $c_j > 0$ real coefficients such that $S = \sum_j c_j [D_j]$ is a positive current of finite mass, and let β be a smooth real $(1, 1)$ -form on Y . Let $v \in \text{QPSH}(Y)$ satisfy*

$$dd^c v = S - \beta.$$

Then, for $a \in \text{QPSH}(Y)$, the following conditions are equivalent:

$$a \preceq v, \quad a \preceq_I v, \quad v(a, D_j) \geq c_j \quad \text{for every } j.$$

Proof We first note that $v(v, D_j) = c_j$. Indeed, the restriction of S to D_j is $c_j [D_j]$: distinct divisors intersect in codimension at least two, and such sets carry no mass of any divisor current, also after countable summation. Smooth forms give every divisor zero mass. The local form of Siu's decomposition, applied after a smooth correction, therefore gives $v(v, D_j) = c_j$.

Ordinary domination implies ideal domination by [Proposition 1.12.2](#), and ideal domination implies the asserted inequalities for generic Lelong numbers by [Theorem 1.16.1](#). It remains to prove that these inequalities imply ordinary domination.

Choose a Hermitian form Λ with $a \in \text{PSH}(Y, \Lambda)$. By [Lemma 1.17.1](#) and the inequalities $\nu(a, D_j) \geq c_j$, each finite partial sum of S can be subtracted from $\Lambda + \text{dd}^c a$ without losing positivity. Letting the partial sums increase to S gives

$$\Lambda + \text{dd}^c a - S \geq 0.$$

Consequently $\text{dd}^c(a - v) \geq \beta - \Lambda$. Hence the integrable function $a - v$ has a quasi-plurisubharmonic representative, which is bounded above on the compact manifold Y . This yields $a \leq v + C$ almost everywhere, and [Lemma 1.3.3](#) extends this inequality everywhere. Thus $a \preceq v$. $\square$

Together, the two preceding lemmas attach a canonical ordinary singularity type to a countable divisorial current of finite mass.

Corollary 1.17.1 *Let Z be a connected compact complex manifold, let (D_j) be a finite or countable family of distinct prime divisors on Z , and let $c_j > 0$. Suppose that $S = \sum_j c_j [D_j]$ is a closed positive current of finite mass. Then there are quasi-plurisubharmonic functions v on Z satisfying*

$$\text{dd}^c v = S - \beta$$

for a smooth closed real $(1, 1)$ -form β , and any two such functions differ by a smooth function. In particular, they determine a canonical ordinary singularity type, which depends only on S .

Proof [Lemma 1.17.3](#), applied to $T = S$, gives the decomposition, with v quasi-plurisubharmonic since $S \geq 0$, and shows that any two such potentials differ by a smooth function. By [Proposition 1.12.1](#), they have the same ordinary singularity type. $\square$

Lemma 1.17.5 *Let u_j, u be quasi-plurisubharmonic functions on a complex manifold with a common smooth lower curvature bound, that is, $\text{dd}^c u_j \geq -\beta$ and $\text{dd}^c u \geq -\beta$ for one smooth real $(1, 1)$ -form β . If $u_j \rightarrow u$ in L_{loc}^1 , then at every point x ,*

$$\nu(u, x) \geq \limsup_j \nu(u_j, x).$$

Proof On a coordinate ball about x , add one smooth function to all the potentials to make them plurisubharmonic, and write p_j, p for the resulting functions. Let n be the dimension and κ the Euclidean form of the chart. Distributional convergence gives weak convergence of the positive trace measures $\text{dd}^c p_j \wedge \kappa^{n-1}$ to $\text{dd}^c p \wedge \kappa^{n-1}$. For every sufficiently small radius r such that the sphere of radius r about x has zero mass for the limit measure, the masses of the balls converge. The Lelong monotonicity formula bounds each $\nu(p_j, x)$ by the normalized trace mass of p_j on such a ball. Taking the upper limit in j , and then letting these radii decrease to zero, gives

$\limsup_j v(p_j, x) \leq v(p, x)$. Since smooth additions do not change Lelong numbers, this proves the lemma. $\square$

Lemma 1.17.6 *Let Z be a connected compact complex manifold and let β be a smooth real $(1, 1)$ -form. There is a finite constant C_β such that*

$$v(v, z) \leq C_\beta \quad \text{for every } v \in \text{PSH}(Z, \beta) \text{ and every } z \in Z.$$

In particular, the generic Lelong numbers of all $v \in \text{PSH}(Z, \beta)$ along all prime divisors are bounded by C_β . No normalization of the potentials is needed.

Proof Since adding a constant does not change Lelong numbers, we may assume that $\sup_Z v = 0$. By [Theorem 1.4.1](#), these normalized potentials have a common L^1 bound. Cover Z by finitely many triples of concentric coordinate balls, a smaller, an intermediate and a larger one, such that the smaller balls cover Z . On each larger ball choose a fixed smooth quadratic function r with $\text{dd}^c r \geq \beta$, so that $p = v + r$ is plurisubharmonic there. The functions p obtained in this way have uniformly bounded local L^1 norms.

Write $d = \dim Z$ and let κ be the Euclidean form in the chart. Choose a nonnegative smooth cutoff χ supported in the larger ball and equal to one on an intermediate ball. Positivity and distributional integration by parts give

$$\int_{\text{intermediate ball}} \text{dd}^c p \wedge \kappa^{d-1} \leq \int \chi \text{dd}^c p \wedge \kappa^{d-1} = \int p \text{dd}^c \chi \wedge \kappa^{d-1} \leq C \|p\|_{L^1}.$$

Every point of the smaller ball is the center of a Euclidean ball of a fixed radius contained in the intermediate ball. The local Lelong monotonicity formula, recalled in [\[Xia\]](#), bounds the Lelong number at this center by a fixed multiple of the trace mass of the intermediate ball. The finite cover gives one bound on Z . Since smooth additions and additive constants do not change Lelong numbers, this proves the assertion for the original potentials. $\square$

The Bergman estimates also control Lelong numbers on a fixed local modification. A *local divisor over X* is a prime divisor E on the source of a local modification $\pi : Z \rightarrow U$ of a coordinate neighborhood $U \subset X$, that is, a modification with smooth source Z . For a quasi-plurisubharmonic function u on X , let $v(u \circ \pi, E)$ be the generic Lelong number of $u \circ \pi$ along E . For a holomorphic function or an ideal sheaf, ord_E denotes the generic vanishing order along E (for an ideal, the minimum of the orders of its local generators). Let $\text{Jac } \pi$ be the holomorphic Jacobian determinant of π in local coordinates. Write

$$v_E(u) = v(u \circ \pi, E), \quad A_U(E) = 1 + \text{ord}_E(\text{Jac } \pi).$$

The second number is the *log discrepancy* of E . Local modifications are not required to extend over the compact manifold.

Lemma 1.17.7 *For a quasi-plurisubharmonic function u on X , every local divisor E over X , and every real $m > 0$, one has*

$$\max \left\{ v_E(u) - \frac{A_U(E)}{m}, 0 \right\} \leq \frac{1}{m} \operatorname{ord}_E \mathcal{I}(mu) \leq v_E(u).$$

Here $\operatorname{ord}_E \mathcal{I}(mu)$ is the order along E of the pulled-back ideal. Consequently, if locally $a_m = m^{-1} \log \sum_k |f_{m,k}|^2 + O(1)$, where the $f_{m,k}$ generate $\mathcal{I}(mu)$, then $v_E(a_m) \rightarrow v_E(u)$ as $m \rightarrow \infty$.

Proof The upper estimate follows from the local Bergman lower bound in [Proposition 1.14.1](#): the logarithm of the sum of squared moduli of local generators of $\mathcal{I}(mu)$, divided by m , is at least u up to a locally bounded term. Pulling back and taking generic Lelong numbers along E reverses this inequality.

For the lower estimate, take a local generator f of the ideal and set $k = \operatorname{ord}_E(f \circ \pi)$. Near a generic point of E , choose a local coordinate z_1 defining E . Divisorial removal ([Lemma 1.17.1](#)), after a smooth correction, gives

$$u \circ \pi \leq v_E(u) \log |z_1|^2 + C.$$

Shrink around a point where the factors of $f \circ \pi$ and of the Jacobian complementary to the powers of z_1 do not vanish. The change-of-variables formula and local integrability of $|f|^2 e^{-mu}$ then require integrability in z_1 of

$$|z_1|^{2(k+A_U(E)-1-mv_E(u))}.$$

This implies $k + A_U(E) > mv_E(u)$, and in particular the weaker non-strict lower bound in the statement. Taking the minimum over a finite set of local generators and using that orders are nonnegative proves the lower estimate. Since $v_E(a_m) = m^{-1} \operatorname{ord}_E \mathcal{I}(mu)$, the last assertion follows by letting $m \rightarrow \infty$. $\square$

For rational $m > 0$, the function a_m has analytic singularities in the sense of [Section 1.13](#); the estimate for real m does not require this.

Blowing up a point converts the divisorial estimate into a pointwise order bound on any local modification.

Lemma 1.17.8 *Let U be a complex manifold of dimension n , let u be plurisubharmonic on U , and let $\pi : Y \rightarrow U$ be a modification with smooth source. Fix $y \in Y$ and an integer $m \geq 1$. Write J_π for the holomorphic Jacobian in local coordinates near y . If a nonzero holomorphic germ g at $\pi(y)$ belongs to $\mathcal{I}(mu)$, then*

$$\operatorname{ord}_y(g \circ \pi) \geq mv(u \circ \pi, y) - n - \operatorname{ord}_y J_\pi.$$

Proof If $n \geq 2$, let $\rho : \tilde{Y} \rightarrow Y$ be the blowup of y and let E be its exceptional divisor. For $n = 1$, take ρ to be the identity and $E = \{y\}$. Set $F = \pi \circ \rho$ and write J_F for its local holomorphic Jacobian determinant. Generic orders along E give

$$v(u \circ F, E) = v(u \circ \pi, y), \quad \operatorname{ord}_E(g \circ F) = \operatorname{ord}_y(g \circ \pi).$$

On a standard blowup chart the Jacobian of ρ has order $n - 1$ along E . The chain rule therefore gives the log discrepancy over U as

$$A_U(E) = 1 + \text{ord}_E J_F = n + \text{ord}_Y J_\pi.$$

Since $g \in I(mu)$, the order of $g \circ F$ along E is at least the order of this ideal. The lower estimate in [Lemma 1.17.7](#), applied to F , therefore proves the inequality. $\square$

Lemma 1.17.9 *Let v be quasi-plurisubharmonic on X , and let a have analytic singularities on X . If $v \preceq_I a$, then $v \preceq a$. More precisely, it suffices to assume the finitely many inequalities*

$$v(v \circ \pi, E) \geq v(a \circ \pi, E)$$

for the prime components E of the divisor obtained by principalizing, on one log resolution π , the ideal of an analytic presentation of a .

Proof Principalize the coherent ideal of an analytic presentation of a by a log resolution $\pi : Y \rightarrow X$ with smooth Y . In suitable local coordinates $z_1, \dots, z_n$ on Y ,

$$a \circ \pi = \sum_{i=1}^r b_i \log |z_i|^2 + B, \quad b_i \geq 0, \quad B \in L_{\text{loc}}^\infty,$$

where $r \leq n$. The finitely many inequalities in the statement give $v(v \circ \pi, \{z_i = 0\}) \geq b_i$; if $v \preceq_I a$, these inequalities follow from [Theorem 1.16.1](#). Add a smooth local function to $v \circ \pi$ to make it plurisubharmonic. Divisorial removal for this closed positive complex Hessian shows that

$$v \circ \pi - \sum_i b_i \log |z_i|^2$$

has a quasi-plurisubharmonic representative; here the difference is first interpreted off the divisor, or as a locally integrable distribution. Such a representative is locally bounded above. Since B is locally bounded, $v \circ \pi \leq a \circ \pi + C$ on each relatively compact chart of Y , away from the divisor. Since π is proper, finitely many such charts cover the inverse image of a smaller coordinate neighborhood in X , which makes C uniform there. Push the inequality down off the analytic exceptional set; as quasi-plurisubharmonic functions are determined by their values almost everywhere, it then holds everywhere. Finitely many neighborhoods cover the compact manifold, so $v \leq a + C$ globally.

The only input from resolution of singularities is the principalization of a coherent ideal. Divisorial removal is applied to the closed positive complex Hessian obtained after a local smooth correction, so no closed background on X is needed. $\square$

Lemma 1.17.10 *Let u, v be quasi-plurisubharmonic on X , and let s have analytic singularities on X . Suppose that $u + v \leq s + O(1)$, and let U_m, V_m be quasi-plurisubharmonic functions of analytic types $(1/m, \mathcal{I}(mu))$ and $(1/m, \mathcal{I}(mv))$. Then there are numbers $\delta_m \downarrow 0$ such that*

$$U_m + V_m \leq (1 - \delta_m)s + O(1) \quad \text{for all sufficiently large integers } m.$$

The bounded error may depend on m .

Proof If s is bounded, upper bounds for U_m and V_m give the assertion with $\delta_m = 1/m$ for $m > 1$. Otherwise principalize the ideal of s by a log resolution $\pi : \tilde{X} \rightarrow X$ with smooth $\tilde{X}$. Let E_i be the components of the resulting divisor, with positive coefficients c_i in $s \circ \pi$; in local coordinates z_i defining these components, the singular part of $s \circ \pi$ is $\sum_i c_i \log |z_i|^2$. Set $A_i = 1 + \text{ord}_{E_i}(\text{Jac } \pi)$. The hypothesis and [Lemma 1.17.7](#) give

$$\nu(U_m \circ \pi, E_i) + \nu(V_m \circ \pi, E_i) \geq \nu(u \circ \pi, E_i) + \nu(v \circ \pi, E_i) - \frac{2A_i}{m} \geq c_i - \frac{2A_i}{m}.$$

Choose a positive integer $N \geq \max_i 2A_i/c_i$ and put $\delta_m = N/m$, which is less than one for large m . Then the right-hand side above is at least $(1 - \delta_m)c_i$. After a smooth local correction, divisorial removal from the positive Hessian of $(U_m + V_m) \circ \pi$ shows that

$$(U_m + V_m) \circ \pi - (1 - \delta_m) \sum_i c_i \log |z_i|^2$$

has a quasi-plurisubharmonic representative, which is locally bounded above. A finite cover of $\tilde{X}$ by charts and descent along the proper map π , as in the proof of [Lemma 1.17.9](#), therefore give $U_m + V_m \leq (1 - \delta_m)s + O(1)$. The bounded constant may depend on m . $\square$

1.18 Potential regularity and metric distance

A Hölder modulus of continuity of the potential controls the trace mass of a positive current on small balls. Averaging the lengths of segments against this trace measure then bounds the distance of the metric defined by the current on its regular locus. This turns regularity of the potential into a metric estimate without any pointwise bound on the Hessian.

Let $U \subset \mathbb{C}^n$ be a coordinate domain with Euclidean form $\omega_E = \text{dd}^c |z|^2$ and Euclidean volume $d\lambda$. Let $0 < \alpha \leq 1$, let θ be a smooth real $(1, 1)$ -form on U , and let $\nu \in C^{0, \alpha}(U)$ satisfy $T = \theta + \text{dd}^c \nu \geq 0$. Write $\mu = T \wedge \omega_E^{n-1}$ for the trace measure of T .

Theorem 1.18.1 *For every open set $V \Subset U$ there are constants $C, r_0 > 0$ such that*

$$\mu(B(x, r)) \leq Cr^{2n-2+\alpha}, \quad x \in V, \quad 0 < r < r_0. \quad (1.31)$$

The total variation of every coefficient measure of T is bounded by a constant multiple of μ . Hence the coefficient measures of T vanish on sets of zero Hausdorff $(2n - 2 + \alpha)$ -measure, and all Lelong numbers of v vanish. The estimate implies neither absolute continuity of μ nor a pointwise bound for the Hessian of v .

Suppose in addition that T is a smooth Hermitian form η on $U \setminus A$ for a proper analytic subset $A \subset U$. For $x, y \in U \setminus A$, let $d_\eta^U(x, y)$ be the infimum of the η -lengths of piecewise smooth paths in $U \setminus A$ joining x and y . Then every point of U has a neighborhood $V \Subset U$ such that, for a constant C ,

$$d_\eta^U(x, y) \leq C|x - y|^{\alpha/2}, \quad x, y \in V \setminus A. \quad (1.32)$$

In particular, all sequences in $V \setminus A$ converging to a given point of $A \cap V$ are Cauchy for d_η^U and have a common limit in the metric completion. If these local hypotheses hold in charts covering X , with a proper analytic subset $A \subset X$ and a Hermitian form η on $X \setminus A$, then the metric completion of $X \setminus A$ for its intrinsic η -distance is compact, and the identity of $X \setminus A$ extends to a continuous surjection of X onto it. The metric η is incomplete when $A \neq \emptyset$. Both exponents in (1.31) and (1.32) are sharp.

Proof Choose a nonnegative cutoff function χ equal to one on $B(x, r)$ and supported in $B(x, 2r)$, with second derivatives bounded by Cr^{-2} . Positivity and integration by parts, after subtracting the constant $v(x)$ from v , give

$$\mu(B(x, r)) \leq C_1 r^{2n} + C_2 r^{2n-2} \operatorname{osc}_{B(x, 2r)} v \leq Cr^{2n-2+\alpha}.$$

Here we used that the constant $v(x)$ integrates to zero against $\operatorname{dd}^c \chi \wedge \omega_E^{n-1}$. The matrix (a_{ij}) of Radon–Nikodym derivatives of the coefficient measures with respect to μ is positive semidefinite almost everywhere, so $|a_{ij}| \leq (a_{ii} + a_{jj})/2$. A ball cover proves the assertion about Hausdorff null sets. After a smooth local correction making v plurisubharmonic, dividing (1.31) by r^{2n-2} shows that all Lelong numbers vanish.

For the distance estimate, let $m = 2n$ and let τ be the Euclidean trace of η . Then $\tau \, d\lambda \leq C\mu$ on the regular locus and $|\xi|_\eta \leq C\sqrt{\tau}|\xi|_E$ for tangent vectors ξ . Polar integration bounds the average η -length of the segments from x to the points of $B(x, R)$ by a constant times $\int_{B(x, R)} \sqrt{\tau}(\zeta) |\zeta - x|^{1-m} d\lambda(\zeta)$. On a dyadic annulus of radius s , the Cauchy–Schwarz inequality and (1.31) bound the contribution to this integral by $Cs^{1-m}s^{m/2}s^{(m-2+\alpha)/2} = Cs^{\alpha/2}$. Summing over the annuli gives the bound $CR^{\alpha/2}$.

Now let $x, y \in V \setminus A$, and average the lengths of the broken segments $[x, z] \cup [z, y]$ over z in the ball of radius $|x - y|/2$ about the midpoint of x and y . By the preceding bound, some such path has length at most $C|x - y|^{\alpha/2}$. For almost every z , both segments avoid A : proper analytic sets are locally countable unions of smooth strata of real codimension at least two, and the cones from a fixed regular point over these strata have zero volume. If V is small enough, all these paths stay inside U .

By this estimate, all regular sequences converging to a point of A have a common limit in the completion, and the identity of the regular locus extends continuously across A . By compactness, the image of this extension is the entire completion;

different points of A may be identified. A sequence converging to a point of A cannot converge in the metric to a regular point, since η is bounded below by a positive multiple of the Euclidean metric on a small closed neighborhood of that point. Hence the metric η is incomplete when A is nonempty. Finally, the local model $v = |z|^\alpha + |w|^2$, in coordinates $(z, w) \in \mathbb{C} \times \mathbb{C}^{n-1}$, has trace mass of exact order $r^{2n-2+\alpha}$ on balls centered on $\{z = 0\}$, and the distance to $\{z = 0\}$ is of exact order $|z|^{\alpha/2}$; this proves both sharpness claims. In later applications to potentials with logarithmic poles, the theorem is applied to the positive residual current that remains after the divisorial part has been removed. $\square$

1.18.1 Dini moduli and limits of distances

The annular argument of [Theorem 1.18.1](#) also applies to a continuous potential whose modulus of continuity is not a power; what matters is a Dini condition on the square root of the modulus. This gives uniform distance estimates for families whose Hölder constants are not controlled.

Keep the coordinate domain $U \subset \mathbb{C}^n$ with its Euclidean form ω_E and volume $d\lambda$, but now let $v \in C^0(U)$ and let θ be a smooth real $(1, 1)$ -form with $T = \theta + dd^c v \geq 0$. On the relatively compact charts under consideration, choose a nondecreasing function $m : (0, r_0) \rightarrow [0, +\infty)$ with $m(r) \rightarrow 0$ as $r \rightarrow 0$ such that

$$|v(x) - v(y)| \leq m(|x - y|), \quad |x - y| < r_0.$$

Put

$$D(r) = r + \int_0^r \frac{\sqrt{m(t)}}{t} dt. \quad (1.33)$$

Theorem 1.18.2 *Assume that $D(r_0/2) < +\infty$ and that T is a smooth Hermitian form η on $U \setminus A$ for a proper analytic subset $A \subset U$. Then every point of U has a neighborhood $V \Subset U$ with constants $C, r_1 > 0$ such that, for $x, y \in V$,*

$$d_\eta^U(x, y) \leq CD(8|x - y|), \quad x, y \notin A, \quad |x - y| < r_1.$$

The constants depend only on the charts and an upper bound for $|\theta|$; the dependence on v enters only through D . All sequences in $V \setminus A$ converging to a given point of $A \cap V$ have a common limit in the metric completion. If these hypotheses hold on a finite cover of a compact connected manifold by charts, the metric completion of the regular locus is compact, and the identity of the regular locus extends to a continuous surjection of the manifold onto it. If A is nonempty, the metric η on the regular locus is incomplete.

Proof Write $d = 2n$ and $\mu = T \wedge \omega_E^{n-1}$. The same cutoff calculation as in [Theorem 1.18.1](#), with a constant subtracted from v , gives

$$\mu(B(x, s)) \leq C(s^d + s^{d-2}m(2s)).$$

This uses only the bound for θ ; closedness of θ is not needed. If τ is the Euclidean trace of η , then $\tau \, d\lambda \leq C\mu$ on the regular locus. Polar integration bounds the average length of the segments from a regular point x to the points of $B(x, R)$ by

$$C \int_{B(x, R)} \sqrt{\tau(\zeta)} |\zeta - x|^{1-d} \, d\lambda(\zeta).$$

On an annulus of outer radius s , the Cauchy–Schwarz inequality and the trace bound make the contribution to this integral at most

$$C s^{1-d} s^{d/2} (s^d + s^{d-2} m(2s))^{1/2} \leq C (s + \sqrt{m(2s)}).$$

For $s_j = 2^{-j} R$, monotonicity gives

$$\sum_{j \geq 0} \sqrt{m(2s_j)} \leq \frac{1}{\log 2} \int_0^{4R} \frac{\sqrt{m(t)}}{t} \, dt.$$

Indeed, $\sqrt{m(2s_j)} \log 2$ is at most the integral of $\sqrt{m(t)}/t$ over $[2s_j, 4s_j]$, and these intervals have disjoint interiors; no doubling condition on m is needed. The average length is therefore at most $CD(4R)$.

For $x, y \in V \setminus A$, average the lengths of the broken segments $[x, z] \cup [z, y]$ over z in the ball of radius $|x - y|/2$ about the midpoint of x and y , applying the preceding bound with $R = 2|x - y|$ at each endpoint. Since the volume of this ball is comparable to R^d , some broken path has length at most $CD(8|x - y|)$. As in the proof of [Theorem 1.18.1](#), almost every such path avoids A , and for small V it stays inside U .

Since $D(r_0/2) < +\infty$, we have $D(r) \rightarrow 0$ as $r \rightarrow 0$. Hence any two regular sequences converging to the same point are Cauchy and have the same limit in the completion. The argument for the completion in the proof of [Theorem 1.18.1](#) applies with this modulus. A positive lower bound for η near a regular point prevents a sequence converging to a point of A from converging in the metric to the regular point. This also proves incompleteness when A is nonempty. $\square$

Corollary 1.18.1 *In the setting of [Theorem 1.18.2](#), let V be as in the theorem. For $0 < \beta \leq 1$, a modulus $m(r) \leq Cr^\beta$ gives $d_\eta^U(x, y) \leq C'|x - y|^{\beta/2}$ for sufficiently close $x, y \in V \setminus A$. If instead*

$$m(r) \leq C(-\log r)^{-a}, \quad a > 2,$$

then for sufficiently close $x, y \in V \setminus A$,

$$d_\eta^U(x, y) \leq C'(-\log |x - y|)^{1-a/2}.$$

These are only sufficient conditions; we do not claim that the Dini condition is necessary.

Proof Integrating the square root of the power modulus gives a multiple of $r^{\beta/2}$. For the logarithmic modulus, the substitution $s = -\log t$ gives

$$\int_0^r \frac{(-\log t)^{-a/2}}{t} dt = \frac{(-\log r)^{1-a/2}}{a/2 - 1}.$$

In either case the term r in $D(r)$ is bounded by the asserted rate for small r . The theorem now gives both estimates; the fixed dilation of the argument of D changes only the constants. $\square$

Corollary 1.18.2 *Let ω_0 be a Hermitian form on X and d_{ω_0} the distance of the associated Riemannian metric. For each j , let $T_j = \theta_j + \text{dd}^c v_j \geq 0$, where θ_j is a smooth real $(1, 1)$ -form, v_j is continuous, and T_j is a smooth Hermitian form off a proper analytic subset A_j . Assume*

$$|\theta_j|_{\omega_0} \leq \Lambda, \quad |v_j(x) - v_j(y)| \leq m(d_{\omega_0}(x, y)),$$

with one fixed Λ and one nondecreasing modulus m tending to zero such that the function in (1.33) satisfies $D(r_0/2) < +\infty$. By Theorem 1.18.2, the identity of $X \setminus A_j$ extends to a continuous surjection of X onto the metric completion of $X \setminus A_j$; let d_j be the pseudometric on X obtained by pulling back the completed distance. Then the diameters of the d_j are uniformly bounded, and a subsequence converges uniformly on $X \times X$ to a continuous pseudometric. If $T_j \geq c\omega_0$ on the regular loci for one $c > 0$, the limit is a metric and dominates $\sqrt{c} d_{\omega_0}$.

Proof A finite fixed chart cover and the theorem give common constants $C, r_1 > 0$ such that

$$d_j(x, y) \leq CD(Cd_{\omega_0}(x, y)), \quad d_{\omega_0}(x, y) < r_1.$$

For a pair meeting A_j , approximate it by regular pairs in the manifold topology. The completed distance and D are continuous, so the same estimate holds for all such pairs in $X \times X$. No uniform bound on the geometry of the analytic sets enters the constants. Dividing a minimizing geodesic of d_{ω_0} into a uniformly bounded number of short pieces and using the triangle inequality gives a uniform diameter bound. The triangle inequality also gives

$$|d_j(x, y) - d_j(x', y')| \leq d_j(x, x') + d_j(y, y'),$$

so the distance functions are equicontinuous. The Arzelà–Ascoli theorem gives a subsequence d_{j_k} converging uniformly on $X \times X$ to a function d_∞ . Nonnegativity, symmetry, vanishing on the diagonal and the triangle inequality pass to the limit. The lower bound $T_j \geq c\omega_0$ gives $d_j \geq \sqrt{c} d_{\omega_0}$, first for regular pairs and then for all pairs, which proves the last assertion.

Without this lower bound the limit may degenerate. For $\varepsilon_j \downarrow 0$, take $\theta_j = \varepsilon_j \omega_0$ and $v_j = 0$, with $A_j = \emptyset$. These data satisfy the hypotheses with $m(r) = r^2$, and $d_j = \sqrt{\varepsilon_j} d_{\omega_0}$ converges uniformly to zero. $\square$

1.19 Obstacle envelopes

Given an obstacle function, one looks for the largest θ -plurisubharmonic function lying below it. The local upper-envelope theorem constructs this envelope as soon as the competitors have a common upper bound, and normalized compactness provides such a bound for an obstacle that is finite almost everywhere or prescribed on a non-pluripolar compact set. Letting the obstacles $\min(u + C, 0)$ increase with C produces the envelope $P_\theta[u]$ of the ordinary singularity type of u .

A smooth real $(1, 1)$ -form θ is called *big* if there are $\rho \in \text{PSH}(X, \theta)$ and $\delta > 0$ such that

$$\theta + \text{dd}^c \rho \geq \delta \omega.$$

Here ω is any Hermitian form; changing it changes δ but not the condition. The definition does not require θ to be closed.

Let θ be a smooth real $(1, 1)$ -form. For an extended-real function f on X , defined at least outside a pluripolar set (the *obstacle*), write

$$P_\theta(f) = (\sup\{v \in \text{PSH}(X, \theta) : v \leq f \text{ q.e.}\})^*.$$

As in [Section 1.6](#), q.e. (quasi-everywhere) means outside a pluripolar set. The functions v in the supremum are called *competitors*; the empty supremum is $-\infty$. For obstacles $f_1, \dots, f_N$, we write $P_\theta(f_1, \dots, f_N) = P_\theta(\min_i f_i)$; when the f_i belong to $\text{PSH}(X, \theta)$, this is their *rooftop envelope*. For an upper semicontinuous obstacle, the pointwise constraint $v \leq f$ gives the same competitors: by the local submean inequality and upper semicontinuity of f , a quasi-plurisubharmonic function lying below f almost everywhere lies below it everywhere.

If the family of competitors is nonempty and uniformly bounded above, then $P_\theta(f) \in \text{PSH}(X, \theta)$. To apply the local upper-envelope theorem while keeping the exact lower bound $-\theta$, fix a constant positive form κ in local coordinates. For each $\epsilon > 0$, shrink the coordinate neighborhood and choose a constant form θ' with $-\epsilon\kappa \leq \theta - \theta' \leq \epsilon\kappa$. A smooth function r with $\text{dd}^c r = \theta' + \epsilon\kappa$ makes every competitor plus r plurisubharmonic, so the local envelope theorem gives $\theta + \text{dd}^c P_\theta(f) \geq -2\epsilon\kappa$ there. Letting ϵ tend to zero proves the exact bound. The same local theorem shows that the regularization changes the supremum only on a pluripolar set.

The following observation gives the upper bound for an unbounded obstacle. Suppose that $f \leq A$, for a real constant A , on a Borel set E with $\text{Vol}(E) = \int_E dV > 0$, where dV is the volume form fixed in [Theorem 1.4.1](#). If h is a competitor, put $\tilde{h} = h - \sup_X h$. By [Theorem 1.4.1](#),

$$(\sup_X h - A) \text{Vol}(E) \leq \int_E |\tilde{h}| dV \leq C_\theta \quad \text{whenever } \sup_X h > A.$$

Thus $\sup_X h \leq A + C_\theta/\text{Vol}(E)$ for every competitor. In particular, the competitors for a measurable obstacle that is finite almost everywhere have a common upper bound: apply this to a sublevel set $\{f \leq A\}$ of positive volume.

An obstacle bound on a non-pluripolar compact set also bounds every competitor globally, even when that set has zero smooth volume.

Lemma 1.19.1 *Let θ be a smooth real $(1, 1)$ -form on X , let $K \subseteq X$ be compact and non-pluripolar, and let $w \in C(K, \mathbb{R})$. There is a constant $C = C(\theta, K, w)$ such that every $a \in \text{PSH}(X, \theta)$ satisfying $a \leq w$ quasi-everywhere on K has $\sup_X a \leq C$.*

Proof Otherwise there are such functions a_j with

$$M_j := \sup_X a_j \geq 2^j + \max_K w.$$

The normalized functions $v_j = a_j - M_j \leq 0$ have uniformly bounded L^1 norms by [Theorem 1.4.1](#). Choose $A > 0$ with $\theta \leq A\omega$. The partial sums

$$s_N = \sum_{j=1}^N 2^{-j} v_j$$

decrease, have uniformly bounded L^1 norms, and satisfy $\text{dd}^c s_N \geq -A\omega$. By [Corollary 1.4.1](#), their limit s is a quasi-plurisubharmonic function; in particular, s is not identically $-\infty$.

Let $N_j \subseteq K$ be a pluripolar set outside which $a_j \leq w$ on K . On $K \setminus \bigcup_j N_j$ one has $v_j \leq -2^j$ for every j , hence $s = -\infty$. The pole set $\{s = -\infty\}$ of the quasi-plurisubharmonic function s is pluripolar, and so is the countable union of the N_j . Their union would contain all of K , contradicting the hypothesis on K . $\square$

Suppose that $\text{PSH}(X, \theta)$ is nonempty. Then the envelope of the zero obstacle,

$$V_\theta = P_\theta(0),$$

belongs to $\text{PSH}(X, \theta)$: the competitors are bounded above by zero, and they include $u - \sup_X u$ for every $u \in \text{PSH}(X, \theta)$. In particular,

$$u - \sup_X u \leq V_\theta \quad (u \in \text{PSH}(X, \theta)).$$

A potential $v \in \text{PSH}(X, \theta)$ has *minimal singularities* if $u \preceq v$ for every $u \in \text{PSH}(X, \theta)$. By the last inequality, V_θ has minimal singularities, and every potential v with minimal singularities satisfies $v \sim V_\theta$. If $\theta \geq 0$, then 0 is a competitor, and hence $V_\theta = 0$.

Lemma 1.19.2 *Let η be a smooth semipositive real $(1, 1)$ -form on X . If an obstacle f is finite almost everywhere and bounded below quasi-everywhere by a constant, then $P_\eta(f)$ is a bounded η -plurisubharmonic function.*

Proof Since $\eta \geq 0$, constants are η -plurisubharmonic, so the constant lower bound of f is a competitor. The finite-sublevel argument above gives a common upper bound for all competitors. Hence $P_\eta(f)$ is an η -plurisubharmonic function lying between these two constants. $\square$

Proposition 1.19.1 *If $f \in C^0(X)$, then $P_\omega(f)$ is continuous. Moreover,*

$$\|P_\omega(f) - P_\omega(g)\|_\infty \leq \|f - g\|_\infty \quad (f, g \in C^0(X)).$$

Proof The constant $\min_X f$ is a competitor, so $p = P_\omega(f)$ is bounded. The local envelope theorem gives $p \leq f$ quasi-everywhere, and continuity of f makes this inequality hold everywhere. By [Theorem 1.11.1](#), there are smooth ω -plurisubharmonic functions $v_j \downarrow p$. Fix $\epsilon > 0$. The continuous functions $v_j - f$ decrease to a function that is at most zero, so $v_j \leq f + \epsilon$ everywhere for all large j ; otherwise the decreasing compact sets $\{v_j - f \geq \epsilon\}$ would have nonempty intersection. Hence $v_j - \epsilon$ is a competitor, and

$$p \leq v_j \leq p + \epsilon.$$

Thus $v_j \rightarrow p$ uniformly, which proves continuity. The last inequality follows from the monotonicity of P_ω in the obstacle and the identity $P_\omega(g + c) = P_\omega(g) + c$ for constants c , applied with $c = \|f - g\|_\infty$. $\square$

Definition 1.19.1 For $u \in \text{PSH}(X, \theta)$, set

$$P_\theta[u] = \left(\lim_{C \rightarrow +\infty} P_\theta(u + C, 0) \right)^* = (\sup\{h \in \text{PSH}(X, \theta) : h \preceq u, h \leq 0\})^*.$$

We call u an *envelope fixed point*, or an *ordinary model*, if $P_\theta[u] = u$; in the Kähler literature such potentials are called *model potentials*. For $F \in C^\infty(X, \mathbb{R})$, replacing the constraint $h \leq 0$ by $h \leq F$ defines $P_{\theta, F}[u]$.

The two expressions agree, because the family in the second one is the increasing union over C of the families defining $P_\theta(u + C, 0)$. They do not change if zero is replaced by V_θ , since every θ -plurisubharmonic function below zero lies below V_θ . The competitors include $u - \sup_X u$ and are bounded above by zero, so $P_\theta[u] \in \text{PSH}(X, \theta)$ and $u - \sup_X u \leq P_\theta[u] \leq 0$. In particular, $u \preceq P_\theta[u]$; this does not assert that $P_\theta[u] - u$ is bounded.

Directly from the definition, $P_\theta[u]$ depends only on the ordinary singularity type of u , and

$$u \preceq v \implies P_\theta[u] \leq P_\theta[v].$$

Replacing the condition $h \preceq u$ by $h \sim_I u$ gives the multiplier-ideal envelope $P_\theta[u]_I$ of [Definition 15.2.1](#). This is a different operator; its relation to $P_\theta[u]$ is studied in [Chapter 15](#).

For a bounded obstacle in a big background, exceptional sets in the competitor inequality can be removed by a small singular perturbation.

Lemma 1.19.3 *Let θ be big, let f be a bounded function on X , and let $u \in \text{PSH}(X, \theta)$ satisfy $u \leq f$ quasi-everywhere. Then there are $u_t \in \text{PSH}(X, \theta)$, $t > 0$, such that $u_t \leq f$ everywhere and $u_t \rightarrow u$ almost everywhere as $t \downarrow 0$.*

Proof Choose $\rho \in \text{PSH}(X, \theta)$ with $\theta + \text{dd}^c \rho \geq \kappa \omega$ for some $\kappa > 0$. The exceptional set $E = \{u > f\}$ is pluripolar. The global form of Josefson's theorem on compact complex manifolds gives a quasi-plurisubharmonic function χ with $\chi = -\infty$ on E ; see [Xia, Theorem 1.1.5]. After rescaling and adding a constant, we may assume that $\chi \leq 0$ and $\text{dd}^c \chi \geq -\omega$. Subtract a constant from ρ so that $\rho \leq \inf_X f$. With $s = t/\kappa$, put

$$u_t = \frac{u + t\chi + s\rho}{1 + s}.$$

All three functions in the numerator are finite almost everywhere, so u_t is not identically $-\infty$. Moreover,

$$\theta + \text{dd}^c u_t = \frac{\theta + \text{dd}^c u + t\text{dd}^c \chi + s(\theta + \text{dd}^c \rho)}{1 + s} \geq 0.$$

Outside E , both u and ρ are at most f , while $\chi \leq 0$, so $u_t \leq f$. On E the numerator is $-\infty$. Finally, $u_t \rightarrow u$ wherever all three functions are finite, which is a set of full measure. $\square$

For an obstacle prescribed only on a compact set, the same perturbation shows that pluripolar exceptions in the constraint do not change the regularized envelope.

Proposition 1.19.2 *Let θ be big, let $K \subseteq X$ be compact and non-pluripolar, and let ψ be a bounded real function on K . Set*

$$\begin{aligned} R &= \sup\{u \in \text{PSH}(X, \theta) : u \leq \psi \text{ on } K\}, \\ Q &= \sup\{u \in \text{PSH}(X, \theta) : u \leq \psi \text{ q.e. on } K\}. \end{aligned}$$

Then $R^ = Q^*$ belongs to $\text{PSH}(X, \theta)$ and has minimal singularities; it is bounded if $\theta \geq 0$. Moreover, this regularized envelope does not change if the pointwise constraint is imposed only on $K \setminus E$, for any pluripolar subset $E \subseteq K$.*

Proof Put $m = \inf_K \psi$ and $M = \sup_K \psi$. Since θ is big, $\text{PSH}(X, \theta)$ is nonempty, and $V_\theta \leq 0$; hence $V_\theta + m$ belongs to the family defining R . Applying Lemma 1.19.1 with the constant obstacle M gives a common upper bound C for the larger family defining Q . The upper-envelope argument at the beginning of Section 1.19 therefore shows that R^* and Q^* belong to $\text{PSH}(X, \theta)$.

Now fix a competitor u for Q and define a bounded function on X by

$$f(x) = \begin{cases} \psi(x), & x \in K, \\ \max\{\sup_X u, M\}, & x \notin K. \end{cases}$$

Then $u \leq f$ quasi-everywhere. By Lemma 1.19.3, there are $u_t \in \text{PSH}(X, \theta)$ satisfying $u_t \leq f$ everywhere and $u_t \rightarrow u$ almost everywhere. Each u_t is a competitor for R , so $R^* \geq u$ almost everywhere, and Lemma 1.3.3 gives this inequality everywhere. Taking the supremum over u and regularizing yields $R^* \geq Q^*$; the inclusion of the competitor families gives the reverse inequality.

Write $F = R^* = Q^*$. Since $F \leq C$, the potential $F - C$ is a competitor for V_θ . Thus

$$V_\theta + m \leq F \leq V_\theta + C,$$

which proves minimal singularities and, when $\theta \geq 0$, boundedness.

Finally, if $E \subseteq K$ is pluripolar, the family constrained on $K \setminus E$ lies between the families defining R and Q , so its regularized supremum also equals F . Note that this argument uses the upper bound obtained from the compact set K , even when $K \setminus E$ is not compact. $\square$

A potential with minimal singularities stays away from the poles of a strictly positive potential with analytic singularities, in the following sense.

Lemma 1.19.4 *Let $\rho \in \text{PSH}(X, \theta)$ have analytic singularities with smooth remainder and satisfy $\theta + \text{dd}^c \rho \geq \varepsilon \omega$ for some $\varepsilon > 0$. Set $\Omega = \{\rho > -\infty\}$. If $\varphi \in \text{PSH}(X, \theta)$ has minimal singularities and is continuous on Ω , then $\varphi - \rho$ is continuous, bounded below, and proper on Ω : all its sublevel sets are compact in Ω .*

Proof Adding constants to ρ and φ does not affect the assertions, so we may assume that $\rho \leq 0$ and $\sup_X \varphi = 0$. Since φ has minimal singularities, there is a constant C with $\varphi \geq V_\theta - C$. Choose $M \geq 0$ with $\theta \geq -M\omega$. If $a \in (0, 1)$ is sufficiently close to one, then

$$\theta + \text{dd}^c(a\rho) = a(\theta + \text{dd}^c \rho) + (1-a)\theta \geq (a\varepsilon - (1-a)M)\omega > 0.$$

Thus $a\rho$ is a competitor for V_θ , and therefore

$$0 \geq \varphi \geq V_\theta - C \geq a\rho - C,$$

and hence

$$\varphi - \rho \geq (1-a)(-\rho) - C. \quad (1.34)$$

By hypothesis φ is continuous on Ω , and ρ is smooth there because it has analytic singularities with smooth remainder. Hence $\varphi - \rho$ is continuous on Ω , and by (1.34) it is bounded below. Since $\rho \rightarrow -\infty$ at $X \setminus \Omega$, the sets $\{\rho \geq -c\}$ are compact subsets of Ω , and (1.34) places every sublevel set of $\varphi - \rho$ in one of them. Being closed in Ω , each sublevel set is therefore compact. $\square$

1.19.1 A hyperplane Green envelope on the ball

For a logarithmic pole along a hyperplane section of the unit ball, the envelope can be computed explicitly by restricting to the complex lines normal to the hyperplane. The example also shows how envelopes of bounded obstacles recover the finite part of a logarithmic pole, and that continuity inside the domain does not imply continuity up to the boundary.

In this subsection let $n \geq 2$, let $m \geq 1$ be an integer, and write

$$B = \{(\zeta, w) \in \mathbb{C} \times \mathbb{C}^{n-1} : |\zeta|^2 + |w|^2 < 1\}, \quad D = B \cap \{\zeta = 0\}.$$

Define G_m as the pointwise supremum of the functions $u \in \text{PSH}(B)$ such that $u \leq 0$ and, near every point of D , $u \leq m \log |\zeta|^2 + C$ for some local constant C . In particular, $u = -\infty$ on D . The constants need not stay bounded as the point of D approaches ∂B .

Proposition 1.19.3 *The envelope G_m is given by*

$$G_m(\zeta, w) = m \log \frac{|\zeta|^2}{1 - |w|^2}. \quad (1.35)$$

It is plurisubharmonic and continuous on B with values in $[-\infty, 0)$. The finite part $G_m - m \log |\zeta|^2$, first defined off D , extends smoothly across D as the plurisubharmonic function

$$H_m(w) = -m \log(1 - |w|^2).$$

Proof The function $-\log(1 - |w|^2)$ is smooth and plurisubharmonic on $|w| < 1$: its complex Hessian is

$$\left(\frac{\delta_{jk}}{1 - |w|^2} + \frac{\bar{w}_j w_k}{(1 - |w|^2)^2} \right)_{j,k}.$$

Thus the right-hand side of (1.35) is plurisubharmonic; it is negative on B and satisfies the pole condition, so it is a competitor. For the reverse inequality, fix a competitor u and a point w with $|w| < 1$. The restriction $u(\cdot, w)$ is either identically $-\infty$ or subharmonic on the disk of radius $R = (1 - |w|^2)^{1/2}$. In the latter case, $u(\zeta, w) - m \log |\zeta|^2$ is subharmonic on the punctured disk and, by the pole condition, bounded above near zero, so it extends as a subharmonic function across zero.

Since $u \leq 0$, this extension is at most $-m \log r^2$ on every circle $|\zeta| = r < R$. The maximum principle and then $r \uparrow R$ give

$$u(\zeta, w) \leq m \log \frac{|\zeta|^2}{R^2}.$$

On D both sides are $-\infty$. Taking the supremum over u proves the formula. Near a point of D , the function H_m is bounded and the logarithmic term tends to $-\infty$, which proves continuity there as an extended-real function. $\square$

For a finite continuous obstacle Φ on B , put

$$P_B \Phi = (\sup\{v \in \text{PSH}(B) : v \leq \Phi\})^*.$$

The local upper-envelope theorem used in [Section 1.19](#) applies whenever this family is nonempty and locally uniformly bounded above. Continuity of Φ ensures that the regularized envelope still satisfies $P_B \Phi \leq \Phi$.

Proposition 1.19.4 For $t > 0$, define

$$\Phi_t(\zeta, w) = \min\{-m \log |\zeta|^2, t\}, \quad V_t = P_B \Phi_t,$$

with $\Phi_t = t$ on D . Then $0 \leq V_t \leq t$, and

$$-m \log(1 - (1 - e^{-t/m})|w|^2) \leq V_t(\zeta, w) \leq H_m(w). \quad (1.36)$$

In particular, $V_t \uparrow H_m$ pointwise on all of B , including D . The convergence is uniform on every compact subset, with

$$0 \leq H_m - V_t \leq \frac{me^{-t/m}R^2}{1 - R^2} \quad \text{where } |w| \leq R < 1. \quad (1.37)$$

Proof The obstacle is continuous, nonnegative and at most t . Zero is a competitor, so the upper-envelope theorem gives $V_t \in \text{PSH}(B)$ with $0 \leq V_t \leq \Phi_t \leq t$. Consequently $m \log |\zeta|^2 + V_t$ is a competitor for G_m , and **Proposition 1.19.3** gives $V_t \leq H_m$ off D . At a point $(0, w)$, the submean inequality on any sufficiently small circle in the normal line gives the same bound, since H_m does not depend on ζ .

For the lower bound, set $a_t = 1 - e^{-t/m}$ and $F_t(w) = -m \log(1 - a_t|w|^2)$. The Hessian calculation above, with $|w|^2$ replaced by $a_t|w|^2$, shows that F_t is plurisubharmonic. Moreover, $0 \leq F_t \leq t$, and $F_t \leq H_m \leq -m \log |\zeta|^2$ on $B \setminus D$ because $|\zeta|^2 < 1 - |w|^2$. Thus $F_t \leq \Phi_t$ everywhere, and hence $F_t \leq V_t$. Finally,

$$H_m - F_t = m \log \left(1 + \frac{e^{-t/m}|w|^2}{1 - |w|^2} \right) \leq \frac{me^{-t/m}|w|^2}{1 - |w|^2}.$$

This proves (1.37) and the convergence; the monotonicity of V_t in t follows from that of Φ_t . $\square$

Example 1.19.1 At every point $p = (0, w_0) \in \partial B$ with $|w_0| = 1$, the cluster set of G_m at p , that is, the set of limits of G_m along sequences in B converging to p , is all of $[-\infty, 0]$. Indeed, set $w_s = (1 - s^2)^{1/2}w_0$ for $0 < s < 1$. For every fixed $0 < a < 1$, the points (as, w_s) belong to B , tend to p as $s \rightarrow 0$, and satisfy $G_m = m \log a^2$. Choosing $a = a_s < 1$ with $a_s \rightarrow 1$ gives the limit zero, whereas the points (s^2, w_s) give $G_m = m \log s^2 \rightarrow -\infty$. These realize every value in $[-\infty, 0]$, and negativity excludes all others. Thus G_m , although continuous on B , has no continuous extension to any point of ∂B in the closure of D .

1.20 The minimum principle

An infimum of plurisubharmonic functions need not be plurisubharmonic. Kiselman's minimum principle describes an important exception: the infimum over a real parameter t of a family u_t whose complexification $u_{\operatorname{Re} z}$ is plurisubharmonic in the joint variables. Freezing the coefficients of the background form, we show that the principle preserves the exact lower curvature bound $-\theta$.

Lemma 1.20.1 *Let $I \subset \mathbb{R}$ be a nonempty open interval, set $S_I = \{z \in \mathbb{C} : \operatorname{Re} z \in I\}$, and let $\pi : X \times S_I \rightarrow X$ be the projection. Let $(u_t)_{t \in I}$ be a family of functions on X such that $U(x, z) = u_{\operatorname{Re} z}(x)$ is quasi-plurisubharmonic on $X \times S_I$ and $\pi^* \theta + \operatorname{dd}^c U \geq 0$. For each x , the function $t \mapsto u_t(x)$ is finite and convex or identically $-\infty$. The finite alternative holds for almost every x .*

Proof A local smooth correction making U plurisubharmonic can be chosen to depend only on x . Hence the restriction of U to $\{x\} \times S_I$ is subharmonic or identically $-\infty$. In the first case its distributional Laplacian is the second derivative of $t \mapsto u_t(x)$, which is therefore nonnegative. The resulting convex representative is finite on I , and by the submean inequality it agrees everywhere with the subharmonic function. Finally, U is locally integrable on the product, and Fubini's theorem, applied on products of coordinate balls with a fixed rectangle in S_I , excludes the identically $-\infty$ alternative for almost every x . $\square$

Corollary 1.20.1 *Let $I \subset \mathbb{R}$ be a nonempty open interval. A radial function $z \mapsto q(\log |z|^2)$ is subharmonic on the annulus $\{z : \log |z|^2 \in I\}$ if and only if q is finite and convex on I . If the function identically equal to $-\infty$ is also regarded as subharmonic, the alternative $q \equiv -\infty$ has to be added.*

Proof The holomorphic covering map $z = e^{w/2}$ pulls the function back to $q(\operatorname{Re} w)$, and the argument of Lemma 1.20.1 proves necessity. Conversely, a finite convex function q has nonnegative distributional second derivative. Thus $q(\operatorname{Re} w)$ is subharmonic, and subharmonicity descends through the local biholomorphisms of the covering. $\square$

Proposition 1.20.1 *Under the hypotheses of Lemma 1.20.1, the function*

$$q(x) = \inf_{t \in I} u_t(x)$$

is either θ -plurisubharmonic or identically $-\infty$; in particular, the infimum need not be regularized. If I is bounded, then $q \in \operatorname{PSH}(X, \theta)$.

Proof The classical local Kiselman principle states that if a plurisubharmonic function on the product of a domain with a strip does not depend on the imaginary part of the strip variable, then its infimum over the real part is plurisubharmonic or identically $-\infty$; the interval of the real part may be unbounded. We use this local result from [Xia].

Fix $x_0 \in X$, choose local holomorphic coordinates centered at x_0 , and let κ be their Euclidean form. Fix $\eta > 0$. On a sufficiently small coordinate ball the constant form $\beta = \theta(x_0)$ satisfies

$$\beta - \eta\kappa \leq \theta \leq \beta + \eta\kappa.$$

Choose a quadratic function r with $\text{dd}^c r = \beta + \eta\kappa$. Then $U + r \circ \pi$ is plurisubharmonic on the product of the ball with S_I . Its infimum over the parameter is $q + r$, so the local principle shows that $q + r$ is plurisubharmonic or identically $-\infty$ on the ball; in the first case

$$\text{dd}^c q \geq -\beta - \eta\kappa \geq -\theta - 2\eta\kappa.$$

In a fixed atlas, the Euclidean forms are bounded by a fixed multiple of ω , so letting $\eta \downarrow 0$ proves the exact lower bound $\text{dd}^c q \geq -\theta$. Since a plurisubharmonic function cannot be identically $-\infty$ on a nonempty open set, the local alternative propagates across overlapping balls on the connected manifold X . Thus either $q \in \text{PSH}(X, \theta)$ or $q \equiv -\infty$. No regularization is needed, because an infimum of upper semicontinuous functions is upper semicontinuous.

Now suppose that I is bounded. By [Lemma 1.20.1](#), the function $t \mapsto u_t(x)$ is finite and convex for almost every x , and a supporting affine function at any point of I bounds it from below on the bounded interval I . Hence $q(x) > -\infty$ almost everywhere, which excludes the alternative $q \equiv -\infty$. $\square$

For example, the proposition applies to $u_t - t\tau$ for a fixed real number τ . On an unbounded interval the infimum may be identically $-\infty$; this alternative will encode the cutoff of a test curve ([Definition 17.1.1](#)).

1.20.1 Pointwise Legendre transforms

The minimum principle can also show that a supremum is already upper semicontinuous. For a concave family of potentials, the regularized Legendre transform is a potential on a product. The minimum principle identifies its inverse transforms with the original family everywhere, and applying the one-variable duality once more identifies the regularization with the pointwise supremum. We first state this duality precisely, including its behavior at the endpoints; the general Legendre–Fenchel theorem is recalled in [[Xia](#), appendix on convex analysis].

Lemma 1.20.2 *Let $c \in \mathbb{R}$. Suppose $g : \mathbb{R} \rightarrow [-\infty, 0]$ is upper semicontinuous, concave and decreasing, finite somewhere, and equal to $-\infty$ on (c, ∞) . Then*

$$f(t) = \sup_{\tau < c} (g(\tau) + t\tau), \quad t > 0,$$

is finite and convex, satisfies $f(t) \leq ct$, and obeys

$$g(\tau) = \inf_{t > 0} (f(t) - t\tau), \quad \lim_{t \downarrow 0} f(t) = \sup_{\tau < c} g(\tau).$$

Conversely, every finite convex f on $(0, \infty)$ with $f(t) \leq ct$ is recovered by the first formula from $g(\tau) = \inf_{t>0} (f(t) - t\tau)$, and satisfies the same endpoint identity. The formulas also hold for $g \equiv -\infty$, with $f \equiv -\infty$.

Proof Since g is decreasing and finite somewhere, it is finite on a half-line $(-\infty, \tau_1)$. Hence the defining supremum is finite for $t > 0$: it is bounded above by ct and below by any one of its finite terms. Concavity and upper semicontinuity give $g(c) = \lim_{\tau \uparrow c} g(\tau)$, so including $\tau = c$ does not change the supremum. The Legendre transform $t \mapsto \sup_{\tau} (g(\tau) + t\tau)$ of $-g$ is infinite for $t < 0$. At $t = 0$ it equals $m = \sup_{\tau < c} g(\tau)$, and the bounds

$$g(\tau) + t\tau \leq f(t) \leq m + ct$$

show that $f(t) \rightarrow m$ as $t \downarrow 0$. The biconjugacy theorem for the closed convex function $-g$ therefore gives the inverse formula; the value at $t = 0$ may be omitted without changing the infimum.

Conversely, start with f . At each $t > 0$, choose the slope p of a supporting line of f . The upper bound $f(s) \leq cs$ as $s \rightarrow \infty$ forces $p \leq c$. If $p < c$, the supporting line gives $g(p) = f(t) - tp$, so the first formula recovers $f(t)$. If $p = c$, then $f(s) - cs$ is constant for $s \geq t$, because this function is convex and bounded above, hence decreasing, while its supporting line at t is horizontal. Consequently, for every $\tau < c$,

$$f(t) - ct \leq g(\tau) \leq f(t) - t\tau.$$

and letting $\tau \uparrow c$ again recovers $f(t)$. In particular, g is finite somewhere. As an infimum of affine functions with slopes $-s < 0$, it is upper semicontinuous, concave and decreasing. Letting $s \downarrow 0$ in the bound $f(s) - s\tau \leq s(c - \tau)$ gives $g \leq 0$, and letting $s \rightarrow \infty$ gives $g = -\infty$ for $\tau > c$. The endpoint identity now follows from the first part. The case of functions identically equal to $-\infty$ follows directly from the formulas. $\square$

Fix $c \in \mathbb{R}$, and let $\Gamma_\tau \in \text{PSH}(X, \theta)$ for $\tau < c$ be functions with $\Gamma_\tau \leq 0$ such that $\tau \mapsto \Gamma_\tau(x)$ is concave and decreasing for every x . Extend the family to $\tau = c$ by the decreasing limit $\Gamma_c = \lim_{\tau \uparrow c} \Gamma_\tau$, and by $\Gamma_\tau \equiv -\infty$ for $\tau > c$. Define the forward transform of the family by

$$U_t(x) = \sup_{\tau < c} (\Gamma_\tau(x) + t\tau), \quad t > 0. \quad (1.38)$$

For a family $(u_t)_{t>0}$, the inverse transform is

$$\widehat{u}_\tau(x) = \inf_{t>0} (u_t(x) - t\tau). \quad (1.39)$$

Lemma 1.20.3 *At each x , the extended function $\tau \mapsto \Gamma_\tau(x)$ is upper semicontinuous and concave, or identically $-\infty$. Its forward transform satisfies*

$$\Gamma_\tau(x) = \inf_{t>0} (U_t(x) - t\tau) \quad (\tau \in \mathbb{R}).$$

Proof Fix $\tau < c$ and let $\tau_j \uparrow \tau$. The decreasing limit of the functions Γ_{τ_j} dominates Γ_τ , so it belongs to $\text{PSH}(X, \theta)$. Choose $r \in (\tau, c)$. Outside the pole set of Γ_r , the concave function $s \mapsto \Gamma_s(x)$ is finite near τ and hence continuous there. Thus the decreasing limit equals Γ_τ almost everywhere, and hence everywhere by [Lemma 1.3.3](#). This proves left continuity at every $\tau < c$; at c it holds by definition. Since the function is decreasing, left continuity gives upper semicontinuity, also where the value is $-\infty$, and concavity survives the extension. The inverse formula is [Lemma 1.20.2](#) at each x . $\square$

Theorem 1.20.1 *For the preceding family $(\Gamma_\tau)_{\tau < c}$, the pointwise supremum in (1.38) is already upper semicontinuous on $X \times (0, \infty)$. Its complexification $U(x, z) = U_{\text{Re } z}(x)$ is quasi-plurisubharmonic on $X \times \{\text{Re } z > 0\}$ and satisfies $\pi^*\theta + \text{dd}^c U \geq 0$, where $\pi : X \times \{\text{Re } z > 0\} \rightarrow X$ is the projection. Each slice belongs to $\text{PSH}(X, \theta)$.*

Proof Each term $(x, z) \mapsto \Gamma_\tau(x) + \tau \text{Re } z$ of the supremum satisfies the current inequality on the product, since $\text{Re } z$ is pluriharmonic. The bound $\Gamma_\tau \leq 0$ gives $U_t \leq ct$, while any fixed $\tau_0 < c$ gives the minorant $\Gamma_{\tau_0} + t\tau_0$. By the local upper-envelope theorem, as in [Section 1.19](#), the upper semicontinuous regularization V of U on the product is quasi-plurisubharmonic, satisfies $\pi^*\theta + \text{dd}^c V \geq 0$, and agrees with U almost everywhere. It does not depend on $\text{Im } z$ and satisfies $V_t \leq ct$. The pointwise supremum U is measurable, since by the left continuity in [Lemma 1.20.3](#) the parameters may be restricted to rational numbers.

By Fubini's theorem, there is a set $Z \subset X$ of zero smooth volume, containing the pole set of Γ_{τ_0} , such that $U_t(x) = V_t(x)$ for almost every $t > 0$ whenever $x \notin Z$. For such x , both sides are finite convex functions of t , by [Lemmas 1.20.1](#) and [1.20.2](#), so by continuity the equality holds for every $t > 0$.

For each $\tau < c$, [Proposition 1.20.1](#) gives

$$\chi_\tau = \inf_{t > 0} (V_t - t\tau) \in \text{PSH}(X, \theta) \cup \{-\infty\}.$$

Off Z it equals Γ_τ by [Lemma 1.20.3](#). In particular, χ_τ is not identically $-\infty$, and [Lemma 1.3.3](#) gives $\chi_\tau = \Gamma_\tau$ everywhere. At each x , the convex function $t \mapsto V_t(x)$ can be recovered from these inverse transforms by [Lemma 1.20.2](#), also when it is identically $-\infty$. We obtain

$$V_t(x) = \sup_{\tau < c} (\chi_\tau(x) + t\tau) = U_t(x).$$

Finally, the minorant $\Gamma_{\tau_0} + t\tau_0$ shows that no slice U_t is identically $-\infty$, so every slice belongs to $\text{PSH}(X, \theta)$. $\square$

1.21 Chern-connection regularization

Convolution in local coordinates does not directly produce global approximants with a controlled lower curvature bound. Demailly's regularization instead averages over the

fibers of the tangent bundle, using the Chern connection of ω , and a Kiselman-type minimum of these averages controls the loss of positivity. The classical curvature estimate for this minimum holds in a Hermitian background, while the L^1 and gradient bounds for the averages are elementary.

Fix $C_0 > 0$ and $u \in \text{PSH}(X, \omega)$ with $-C_0 \leq u \leq 0$. Distances, gradients and norms of tensors are taken with respect to the Riemannian metric associated with ω .

For small $t > 0$, let $R_t u$ be Demailly's regularization of u formed with the Chern connection of ω . It averages u over the image of the ball of radius t in each tangent space, with a fixed smooth nonnegative radial kernel of integral one. The map used for this purpose is a smooth realization of the holomorphic part of the formal fiberwise expansion of the exponential map; it need not be holomorphic in the fiber. The following classical estimate controls the Kiselman-type transform of these averages, including its mixed base–fiber terms; see [Section 33.1](#) for the sources.

Lemma 1.21.1 *There are constants $A, K > 0$ and $t_* > 0$, depending only on (X, ω) and C_0 , such that $R_t u$ is smooth for $0 < t < t_*$,*

$$-C_0 \leq R_t u \leq 0, \quad R_t u + Kt^2 \downarrow u \quad \text{as } t \downarrow 0.$$

For $0 < \delta < t_*$ and $c > 0$, the bounded function

$$\Phi_{c, \delta} = \inf_{0 < t \leq \delta} \{R_t u + K(t^2 - \delta^2) + K(t - \delta) - c \log(t/\delta)\}$$

is quasi-plurisubharmonic and satisfies

$$\omega + \text{dd}^c \Phi_{c, \delta} \geq -(Ac + 2K\delta)\omega.$$

At every point, the infimum is attained at some $t > 0$.

We use only this curvature estimate from the classical theory. The linear term $K(t - \delta)$ is needed in the Hermitian case, where it absorbs the mixed base–fiber terms in the complex Hessian of the regularization. Since $-c \log(t/\delta)$ tends to $+\infty$ as $t \downarrow 0$ while u is bounded, the infimum is attained away from zero. We need neither smoothness of the minimizing radius nor smoothness of the transform across the region where this radius equals δ .

Next we prove two elementary estimates for the averaging operators. They do not rely on any volume identity from Kähler geometry.

Lemma 1.21.2 *For all sufficiently small $t > 0$,*

$$\|R_t u - u\|_{L^1(dV)} \leq C t^2, \quad \|\nabla R_t u\|_\infty \leq C/t.$$

The constants are uniform for $-C_0 \leq u \leq 0$.

Proof Let z be local coordinates on X and $\xi \in \mathbb{C}^n$ the fiber variable with respect to a smooth orthonormal frame of the tangent bundle. Write $\rho(|\xi|^2)$ for the fixed radial averaging kernel, normalized with respect to Lebesgue measure $d\xi$ and supported in $|\xi| \leq 1$. In these coordinates the averaging map F gives

$$R_t u(z) = \int u(F(z, t\xi)) \rho(|\xi|^2) d\xi, \quad F(z, 0) = z.$$

The map F is smooth in these variables, and its fiber differential at zero is an isomorphism. Let R_t^* be the formal adjoint of R_t with respect to dV , so that $\int_X (R_t a) b dV = \int_X a R_t^* b dV$. We first claim that

$$R_t^* 1 = 1 + O(t^2)$$

uniformly. To see this, insert a smooth partition of unity in the variable z , each term being compactly supported in a chart on which the frame is defined. For fixed ξ , change variables $x = F(z, t\xi)$ on a neighborhood of the support of a term. The inverse map and its Jacobian have uniform Taylor expansions in t . The term of order zero in the transformed density is the chosen partition function at x , and the term of order one is linear in ξ , so it integrates to zero against the even radial kernel. The remaining density is bounded by $C t^2 dV(x)$, since the second derivatives of all maps, partition functions and volume coefficients are bounded on these finitely many compact charts. Summing over the partition functions proves the claim.

Consequently,

$$\left| \int_X (R_t u - u) dV \right| = \left| \int_X u (R_t^* 1 - 1) dV \right| \leq C t^2.$$

By [Lemma 1.21.1](#), $R_t u - u \geq -K t^2$. A real function $a \geq -K t^2$ satisfies $|a| \leq a + 2K t^2$; applying this to $a = R_t u - u$ and integrating gives the first estimate.

For the derivative bound, change variables in the fiber to write $R_t u(z) = \int_X u(x) k_t(z, x) dV(x)$. In local coordinates the smooth kernel k_t is supported where $|x - z| \leq C t$ and satisfies

$$|\nabla_z k_t(z, x)| \leq C t^{-2n-1}.$$

Indeed, the inverse fiber map and its Jacobian have uniformly bounded derivatives, and differentiating the rescaled radial argument introduces at most one factor t^{-1} in addition to t^{-2n} . Since the kernel is smooth with compact support, there are no boundary terms. Integration over a ball of volume at most $C t^{2n}$ gives $\int |\nabla_z k_t| dV \leq C/t$, and multiplication by the uniform bound for u proves the assertion. $\square$

The first estimate relies on the cancellation of the odd first-order term against the even kernel, and not on conservation of Monge–Ampère mass.

1.21.1 The general curvature modulus

Let θ now be any smooth real $(1, 1)$ -form and let $u \in \text{PSH}(X, \theta) \cap L^\infty(X)$. We use the same averaging operators and the same metric.

We first state the classical input for this background. The classical Chern-connection regularization theorem applies to the closed current $\text{dd}^c u$ with the smooth, possibly nonclosed, lower bound $-\theta$; the curvature of the Chern connection on the tangent bundle is bounded by a fixed multiple of ω . The theorem gives a constant $K_0 > 0$ such that

$$R_t u + K_0 t^2 \downarrow u.$$

To state its curvature estimate, use local coordinates z on X and a complex radius variable w , and put $t = |w|$. Write $\zeta \in T_z^{1,0} X$ and $\eta \in \mathbb{C}$ for the base and radius components of a tangent vector, and set $\lambda(z, t) = t \partial_t (R_t u(z) + K_0 t^2)$. Then λ is nonnegative and increasing in t , and there are constants $A, C > 0$ and a function $\epsilon_0(t) \geq 0$ with $\epsilon_0(t) \downarrow 0$ as $t \downarrow 0$ such that the complex Hessian of $(z, w) \mapsto R_{|w|} u(z)$ is bounded below by the base form $-\theta - A\lambda(z, t)\omega - \epsilon_0(t)\omega$, evaluated on ζ , minus mixed and vertical error terms bounded by $C(|\zeta||\eta| + |\eta|^2)$. This is the classical regularization estimate for a smooth lower bound.

Lemma 1.21.3 *For K sufficiently large, there is an increasing function $\epsilon(\delta) \geq 0$ tending to zero at zero such that, for every small $\delta > 0$ and every $c > 0$, the function*

$$\Phi_{c, \delta} = \inf_{0 < t \leq \delta} \{R_t u + K(t^2 - \delta^2) + K(t - \delta) - c \log(t/\delta)\}$$

is bounded and quasi-plurisubharmonic and satisfies

$$\theta + \text{dd}^c \Phi_{c, \delta} \geq -(Ac + \epsilon(\delta))\omega.$$

The infimum is attained away from zero. Moreover, $R_t u + Kt^2 \downarrow u$ as $t \downarrow 0$.

Proof Take $K \geq K_0$ and put $H(z, t) = R_t u(z) + Kt^2 + Kt$. As a function of $\log t$, H is increasing and strictly convex, because $R_t u + K_0 t^2$ has nonnegative increasing logarithmic derivative and the added terms have positive second logarithmic derivative. Its logarithmic derivative $\tilde{\lambda} = t \partial_t H$ is at least λ .

The complex Hessian of $K|w|$ has a positive vertical term proportional to $K/|w|$. For sufficiently small $|w| = t$, this term absorbs the vertical error and, by the inequality

$$C|\zeta||\eta| \leq C't|\zeta|^2 + \frac{K}{8t}|\eta|^2,$$

also the mixed error. After increasing the constants and replacing λ by the larger $\tilde{\lambda}$, we find that the complex Hessian of $(z, w) \mapsto H(z, |w|)$ is bounded below by the

base form

$$-\theta - (A\tilde{\lambda} + \epsilon(t))\omega,$$

where ϵ is an increasing majorant of $\epsilon_0(t) + C't$.

Since u is bounded, the term $-c \log(t/\delta)$ tends uniformly to $+\infty$ as $t \downarrow 0$, so the minimum occurs on a compact interval of radii away from zero. Strict convexity in $\log t$ makes the minimizing radius unique. At an interior minimum $\tilde{\lambda} = c$, while at the upper endpoint $t = \delta$ one has $\tilde{\lambda} \leq c$. No differentiability of the minimizing radius is needed.

In more detail, localize near a point of X and fix $a > 0$. By continuity of the minimizers and of $\tilde{\lambda}$, there is an interval of radii containing the minimizers at all nearby points on which $\tilde{\lambda} \leq c + a$. If the minimum is attained at the upper endpoint, keep the upper endpoint δ ; an open interval approaching it has the same infimum. Because of the uniform logarithmic term, the lower endpoint can be chosen below all minimizers, and since $\tilde{\lambda}$ is increasing, the bound $\tilde{\lambda} \leq c + a$ holds throughout the chosen interval. The local Kiselman minimum principle for functions depending only on $|w|$, applied after a local quadratic correction, now gives the lower curvature bound with error $A(c + a) + \epsilon(\delta)$, up to an arbitrarily small error from freezing the smooth base forms. Letting these errors and a tend to zero proves the asserted current inequality and the quasi-plurisubharmonicity. Finally, $K \geq K_0$ preserves the monotone convergence of $R_t u + Kt^2$ to u . $\square$

The classical theorem only gives some modulus ϵ ; we do not claim that $\epsilon(\delta)$ is linear in δ . The cancellation and kernel arguments in the proof of [Lemma 1.21.2](#) still give

$$\|R_t u - u\|_{L^1(dV)} \leq Ct^2, \quad \|\nabla R_t u\|_\infty \leq C/t,$$

because the averaging map is unchanged, u is bounded, and these arguments use only the monotone lower bound $R_t u - u \geq -Kt^2$.

For continuous potentials, the curvature loss of the averages becomes uniformly small.

Lemma 1.21.4 *Let α be a smooth real $(1, 1)$ -form on X , and let $u \in \text{PSH}(X, \alpha) \cap C^0(X)$. There are smooth real functions u_j and numbers $\epsilon_j \downarrow 0$ such that $u_j \rightarrow u$ uniformly and*

$$\alpha + \text{dd}^c u_j \geq -\epsilon_j \omega.$$

Proof Use the Chern averaging operators and the classical estimate stated before [Lemma 1.21.3](#), with α in place of θ . For some $K_0, A > 0$ and $\epsilon_0(t) \rightarrow 0$, put $\lambda(x, t) = t \partial_t (R_t u(x) + K_0 t^2)$. The estimate with vanishing radius component gives

$$\alpha + \text{dd}^c R_t u \geq -(A\lambda(\cdot, t) + \epsilon_0(t))\omega.$$

The function λ is nonnegative, continuous for $t > 0$, and increasing in t . For fixed x , the convex function $s \mapsto R_{e^s} u(x) + K_0 e^{2s}$ has the finite limit $u(x)$ as $s \rightarrow -\infty$. Its nonnegative derivative must therefore tend to zero, since a positive limit of the derivative would make the function tend to $-\infty$. Thus $\lambda(x, t) \rightarrow 0$ as $t \rightarrow 0$, and for any sequence $t_j \downarrow 0$, Dini's theorem gives $\|\lambda(\cdot, t_j)\|_\infty \rightarrow 0$.

The averaging kernels have mass one and only sample points at distance at most Ct from the base point. Uniform continuity of u therefore gives $\|R_t u - u\|_\infty \rightarrow 0$. Set $u_j = R_{t_j} u$, and let $\varepsilon_j \rightarrow 0$ be a decreasing positive majorant of $A\|\lambda(\cdot, t_j)\|_\infty + \epsilon_0(t_j)$. $\square$

1.21.2 A linear error for a smooth background

Throughout this subsection, θ is a smooth real $(1, 1)$ -form that is big. By [Theorem 1.15.2](#) and the remark following it, there is a strict potential $\rho \in \text{PSH}(X, \theta)$, that is, $\theta + \text{dd}^c \rho \geq \varepsilon \omega$ for some $\varepsilon > 0$, which is smooth outside an analytic pole set and has a smooth remainder after resolution. Put $\Omega = X \setminus \{\rho = -\infty\}$. For normalized potentials that are locally bounded on Ω , the next lemma improves the curvature error of [Lemma 1.21.3](#) to a linear one.

Lemma 1.21.5 *Let $a \in \text{PSH}(X, \theta)$ satisfy $\sup_X a = 0$, and suppose that a is locally bounded on Ω . There are constants $A, K, C > 0$ such that the averaging operators R_t of [Lemma 1.21.1](#) satisfy*

$$R_t a + Kt^2 \downarrow a, \quad \|R_t a - a\|_{L^1(\text{dV})} \leq Ct^2.$$

For small $\delta > 0$ and $c > 0$, the transform on Ω

$$\Phi_{c, \delta} = \inf_{0 < t \leq \delta} \{R_t a + K(t^2 - \delta^2) + K(t - \delta) - c \log(t/\delta)\}$$

extends canonically to X and satisfies

$$a - K(\delta^2 + \delta) \leq \Phi_{c, \delta} \leq R_\delta a \leq 0, \quad \theta + \text{dd}^c \Phi_{c, \delta} \geq -(Ac + C\delta)\omega. \quad (1.40)$$

At each point of Ω the infimum is attained at a positive radius. On every compact set $K_1 \Subset \Omega$, for sufficiently small t , $\|\nabla R_t a\|_{L^\infty(K_1)} \leq C_{K_1}/t$.

Proof Step 1: the classical expansion. Apply the classical Chern-connection regularization expansion to the closed current $\text{dd}^c a$ and the smooth lower bound $-\theta$. It gives monotonicity and logarithmic convexity: for a constant $K_0 > 0$, the function $\lambda(x, t) = t\partial_t(R_t a(x) + K_0 t^2)$ is nonnegative and increasing in t . Instead of inferring a rate from the unspecified modulus in that theorem, we estimate the error terms of the expansion directly, using the smoothness of θ .

Choose the auxiliary curvature form to be $A\omega$, with A large enough that the Chern curvature plus $A\omega \otimes \text{Id}$ is nonnegative on every decomposable tensor. Equivalently, after absorbing the normalization constants, the Chern curvature coefficients $R_{j\bar{k}\ell\bar{m}}$ in a unitary frame satisfy

$$\sum R_{j\bar{k}\ell\bar{m}} \xi_j \bar{\xi}_k \zeta_\ell \bar{\zeta}_m \geq -A|\xi|^2|\zeta|^2$$

for all tangent vectors ξ, ζ . Such an A exists by compactness. Pairing this inequality with the nonnegative eigenvalues of a positive complex Hessian bounds its curvature contraction from below by $-A$ times its trace, with no further error term.

Step 2: a frozen quadratic correction. Fix $x \in X$ and a complex radius variable $w \neq 0$, and put $t = |w|$. Write $\xi \in T_x^{1,0} X$ and $\tau \in \mathbb{C}$ for the base and radius components of a tangent vector. In a coordinate chart of uniform size about x , write $\beta = \text{dd}^c |z|^2$ and choose a quadratic function $q_{x,t}$ with

$$\text{dd}^c q_{x,t} = \theta(x) + Bt\beta,$$

where the constant B is chosen so large that $a + q_{x,t}$ is plurisubharmonic on a ball of radius of order t containing the support of the averages at x and at nearby points. This is possible by the bound $\|\theta(y) - \theta(x)\| \leq C|y - x|$ on such a ball. For the Hessian calculation at (x, w) , the quadratic function is held fixed; its coefficients and all needed derivatives are uniformly bounded.

Step 3: the error terms. By normalized compactness, $\|a\|_{L^1}$ is bounded. On each fixed larger chart, add one fixed strictly plurisubharmonic quadratic function Q to a . For the trace measure $\mu = \text{dd}^c(a + Q) \wedge \beta^{n-1}$, the local Lelong mass inequality and a bound for the mass of a fixed larger ball give $\mu(B(x, t)) \leq Ct^{2n-2}$. The coefficients of $\partial\bar{\partial}(a + q_{x,t})$ are controlled in total variation by those of $\text{dd}^c(a + Q)$ plus a uniformly bounded smooth form. Write $|\partial\bar{\partial}(a + q_{x,t})|$ for the sum of the total variations of its coefficient measures. The rescaled averaging kernels are supported in $B(x, Ct)$ and bounded by a constant times t^{-2n} , so their integrals against this measure are bounded by

$$Ct^{-2n}|\partial\bar{\partial}(a + q_{x,t})|(B(x, Ct)) \leq C't^{-2}.$$

Thus the terms of the expansion with a coefficient $O(t^3)$ contribute $O(t)$, and the remainder of the expansion of order two is $O(t)$ as well. The mixed and vertical contributions are bounded by $C(|\xi||\tau| + |\tau|^2)$. By the choice of A , the curvature term is bounded below by $-A\lambda(x, t)|\xi|^2$; here the radial term of the same expansion identifies the relevant mass with λ up to $O(t^2)$. Subtracting the regularization of $q_{x,t}$ restores $-\theta(x)$: its base Hessian differs from $\text{dd}^c q_{x,t}$ by $O(t)$, its mixed and vertical Hessians are bounded, and its radial logarithmic derivative is $O(t^2)$. The extra term $Bt\beta$ also costs only $O(t)$. For a real $(1, 1)$ -form α , write $\alpha[v]^2$ for its associated Hermitian quadratic form evaluated on v . Consequently, for a fixed constant $C_1 > 0$, the complex Hessian of $(x, w) \mapsto R_{|w|}a(x)$ satisfies

$$\text{dd}_{x,w}^c R_{|w|}a[\xi, \tau]^2 \geq -\theta_x[\xi]^2 - (A\lambda(x, t) + Ct)|\xi|^2 - C_1(|\xi||\tau| + |\tau|^2).$$

All constants are independent of x, t, c, δ and uniform for normalized a . In particular, setting $\xi = 0$ in the same expansion gives a uniform lower bound for the vertical Hessian. Adding a fixed multiple of $|w|^2$ makes the function subharmonic in w , which gives the logarithmic convexity and monotonicity above with a uniform constant K_0 .

Step 4: the minimum. Take $K \geq K_0$ and add $K(t^2 + t)$ to the regularization. The positive vertical Hessian of $K|w|$ absorbs the mixed term by the inequality

$$C_1|\xi||\tau| \leq C't|\xi|^2 + \frac{K}{8t}|\tau|^2,$$

and it absorbs the remaining bounded vertical error for small t . The logarithmic derivative of the corrected function is at least λ . The Kiselman minimum argument with an upper endpoint, as in the proof of [Lemma 1.21.3](#), therefore gives the last inequality in (1.40), now with error $C\delta$. On compact subsets of Ω , local boundedness of a makes the term $-c \log(t/\delta)$ dominate uniformly as $t \downarrow 0$, so that the minimum is attained away from zero. As before, minimizers at the upper endpoint are handled without differentiating their radius.

Step 5: the remaining bounds. The other bounds in (1.40) follow from the monotonicity of $R_t a + Kt^2$ and from evaluation at $t = \delta$. In particular, the transform is bounded above near the analytic set $X \setminus \Omega$. The removable singularity theorem therefore extends it across this set, and local freezing and passage to the limit preserve the exact smooth lower bound for its Hessian. Its lower bound $a - K(\delta^2 + \delta)$ also extends, since quasi-plurisubharmonic functions are determined by their values off an analytic set.

The adjoint computation in the proof of [Lemma 1.21.2](#) gives $R_t^* 1 = 1 + O(t^2)$. It only needs $a \in L^1$, since

$$\left| \int_X (R_t a - a) \, dV \right| \leq Ct^2 \|a\|_1.$$

Together with $R_t a - a \geq -Kt^2$, this proves the stated L^1 estimate. Finally, near K_1 the smoothing kernel only samples a fixed larger compact subset of Ω , on which a is bounded. The kernel derivative estimate in the proof of [Lemma 1.21.2](#) then gives the bound C_{K_1}/t . $\square$

1.22 Pullback and descent

Pullback by a holomorphic map preserves the inequality $\theta + \text{dd}^c u \geq 0$. Conversely, on a submersion with compact connected fibers, a potential that is positive with respect to a pulled-back background, which has no vertical component, must be constant on the fibers and therefore descends. Potentials also descend under modifications, and there a Jacobian factor accounts for the change in multiplier-ideal integrability.

1.22.1 Holomorphic disks

A smooth background form need not have local dd^c -potentials, but its pullback to a disk does, since a real $(1, 1)$ -form on a disk is closed. Testing on holomorphic disks therefore characterizes the exact lower curvature bound in a way that is preserved by holomorphic maps.

Lemma 1.22.1 *Let θ be a smooth real $(1, 1)$ -form on a complex manifold M , and let u be quasi-plurisubharmonic on M . Then $\theta + dd^c u \geq 0$ if and only if the following condition holds: for every holomorphic map $f : \Delta \rightarrow M$ from the unit disk such that $u \circ f$ is not identically $-\infty$, and for every smooth function a on an open subset of Δ with $dd^c a = f^* \theta$, the function $u \circ f + a$ is subharmonic there.*

Proof Suppose first that $\theta + dd^c u \geq 0$. On a coordinate ball, convolve u and θ with a smooth nonnegative radial kernel. The resulting smooth functions u_ϵ satisfy

$$dd^c u_\epsilon \geq -\theta_\epsilon, \quad \theta_\epsilon \longrightarrow \theta \quad \text{smoothly.}$$

Write $u = p - r$ locally, with p plurisubharmonic and r smooth. The convolutions p_ϵ decrease to p . On a smaller disk on which $u \circ f$ is not identically $-\infty$, $p_\epsilon \circ f$ therefore converges in L^1_{loc} to $p \circ f$, while $r_\epsilon \circ f$ converges smoothly. Pulling back the smooth inequality and passing to the limit in the sense of distributions gives $dd^c(u \circ f) + f^* \theta \geq 0$. Since $u \circ f = p \circ f - r \circ f$ is the sum of a subharmonic and a smooth function, this distributional inequality makes $u \circ f + a$ subharmonic.

Conversely, test on affine complex lines in a coordinate ball. For a fixed nonzero constant direction ξ , local integrability of u implies that the restriction of u to almost every line parallel to ξ is not identically $-\infty$. Fubini's theorem, applied to nonnegative smooth test functions, then gives positivity of the scalar distribution obtained by evaluating the Hermitian coefficient matrix of $\theta + dd^c u$ on ξ . Positivity for a countable dense set of constant directions proves positivity of the Hermitian matrix of coefficient measures, which is the current inequality. $\square$

Consequently, holomorphic pullback preserves the inequality $\theta + dd^c u \geq 0$ wherever the pulled-back function is not identically $-\infty$; apply the disk criterion to the compositions with the given map. We also use descent of subharmonicity under the finite map $\rho(t) = t^k$, $k \geq 1$, of the disk. If $h \circ \rho$ is subharmonic, local inverse branches of ρ show that h is subharmonic off zero. Moreover, h is bounded above near zero, and its value at zero is its upper limit there, since

$$h(0) = (h \circ \rho)(0) = \limsup_{t \rightarrow 0, t \neq 0} h(t^k) = \limsup_{z \rightarrow 0, z \neq 0} h(z).$$

By the removable-singularity theorem, h is subharmonic at zero as well.

1.22.2 Compact fibers

The connected components of the fibers of a submersion determine a finite covering of the base, and potentials first descend to this covering.

Lemma 1.22.2 *Let $p : M \rightarrow Y$ be a surjective holomorphic submersion between connected compact complex manifolds. There is a factorization*

$$M \xrightarrow{\pi} Y' \xrightarrow{r} Y, \quad p = r \circ \pi,$$

where Y' is a connected compact complex manifold, r is a finite unramified holomorphic covering and π is a surjective holomorphic submersion with connected fibers. The points of $r^{-1}(y)$ correspond to the connected components of $p^{-1}(y)$, which are the fibers of π over those points.

Proof Fix a Hermitian metric on M . The orthogonal complement of $\ker dp$ gives a smooth horizontal lift of tangent vectors on Y . Around $y_0 \in Y$ choose a coordinate ball B centered at y_0 , with compact closure inside a larger coordinate ball. For $y \in B$, lift the straight segment from y_0 to y . The ordinary differential equation for horizontal transport has a solution along the whole segment, since its projection remains in the compact closure of B , whose inverse image is compact. Smooth dependence on the starting point and on y , together with transport along the reversed segment, gives a smooth trivialization

$$p^{-1}(B) \simeq B \times p^{-1}(y_0)$$

over B .

The compact manifold $p^{-1}(y_0)$ has finitely many connected components. The trivialization partitions $p^{-1}(B)$ into finitely many open and closed pieces, each of which meets every fiber in one connected component. On overlaps, two such local partitions identify the same fiber components, and their labels differ by locally constant permutations. Glue one copy of each base ball for every component, using these identifications. Equivalently, take the quotient of M that identifies points in the same connected component of a fiber. The local partitions make this quotient a Hausdorff covering space: distinct points over one base point lie on different sheets, and points over different base points are separated by their images in Y .

Call the quotient Y' and its projection r . Coordinates of Y on each sheet give holomorphic charts with holomorphic transition maps, so r is a local biholomorphism. It is a finite covering, and Y' is compact because a finite covering of a compact space is compact. Locally, the quotient map π is p restricted to one of the open pieces, so it is a holomorphic submersion with the asserted connected fibers. Surjectivity of π and connectedness of M make Y' connected. $\square$

Proposition 1.22.1 *Let $\pi : Y \rightarrow X$ be a surjective holomorphic submersion between connected compact complex manifolds, with connected fibers. Let θ be a smooth real $(1, 1)$ -form on X . Pullback gives a bijection*

$$\text{PSH}(X, \theta) \longrightarrow \text{PSH}(Y, \pi^*\theta).$$

Every member on the right is constant on each fiber, with the value $-\infty$ allowed on an entire fiber.

Proof On a coordinate ball $V \subset X$, choose a smooth function ρ with $\text{dd}^c \rho \geq \theta$. If $u \in \text{PSH}(Y, \pi^*\theta)$, then $u + \rho \circ \pi$ is plurisubharmonic on $\pi^{-1}(V)$. Its restriction to a fiber is plurisubharmonic or identically $-\infty$, and since the fiber is compact and connected, the maximum principle shows that it is constant in either case. As $\rho \circ \pi$ is constant on fibers, $u = v \circ \pi$ for a uniquely defined function v on X .

A holomorphic submersion admits local holomorphic sections. Composing $u + \rho \circ \pi$ with such a section shows that $v + \rho$ is plurisubharmonic or identically $-\infty$ on a smaller ball. The latter alternative would make $u = -\infty$ on a nonempty open set, which is impossible for a quasi-plurisubharmonic function. Hence v is quasi-plurisubharmonic. Distributional differentiation in local product coordinates gives

$$\pi^*(\theta + \text{dd}^c v) = \pi^*\theta + \text{dd}^c u \geq 0.$$

Positivity of a pulled-back current of this form implies positivity on the base: test in product coordinates against products with a nonnegative compactly supported volume form of integral one in the fiber variables. It follows that $v \in \text{PSH}(X, \theta)$.

Conversely, by [Lemma 1.22.1](#), the pullback of a θ -plurisubharmonic function by π is $\pi^*\theta$ -plurisubharmonic; in local product coordinates it is clearly not identically $-\infty$. The pullback map is injective because π is surjective. $\square$

1.22.3 Modifications

Proposition 1.22.2 *Let $\pi : Y \rightarrow X$ be a modification of connected compact complex manifolds, and let θ be a smooth real $(1, 1)$ -form on X . Pullback gives a bijection*

$$\text{PSH}(X, \theta) \longrightarrow \text{PSH}(Y, \pi^*\theta).$$

Proof Let $S \subset X$ be a proper analytic subset over whose complement π is an isomorphism, and put $D = \pi^{-1}(S)$. By [Lemma 1.22.1](#), pullback preserves the curvature inequality, and the pullback of a θ -plurisubharmonic function is not identically $-\infty$, since π is an isomorphism off D . The pullback map is injective because π is surjective.

To prove surjectivity, let $b \in \text{PSH}(Y, \pi^*\theta)$, and define $u = b \circ \pi^{-1}$ off S . On a coordinate neighborhood in X , choose a smooth function ρ with $\text{dd}^c \rho \geq \theta$. Then $b + \rho \circ \pi$ is plurisubharmonic on the inverse image of this neighborhood. By

properness, its local upper bounds give a local upper bound for $u + \rho$ near S , so the removable-singularity theorem extends $u + \rho$ plurisubharmonically across S . The resulting quasi-plurisubharmonic extensions of u agree almost everywhere on overlaps, hence everywhere, and glue to a function on X .

The current $\theta + \text{dd}^c u$ is positive off S . Locally it is the sum of the positive current $\text{dd}^c(u + \rho)$ and the smooth form $\theta - \text{dd}^c \rho$. The smooth form gives S zero mass, so the restriction of $\theta + \text{dd}^c u$ to S is positive as well. Thus $u \in \text{PSH}(X, \theta)$. The plurisubharmonic functions $b + \rho \circ \pi$ and $(u + \rho) \circ \pi$ agree off D , hence almost everywhere, hence everywhere. Therefore $b = u \circ \pi$. $\square$

Pullback by a modification preserves L^1 convergence within a family with a common lower curvature bound. Compactness controls the pullbacks near the exceptional locus, where a direct change of variables would involve a vanishing Jacobian.

Lemma 1.22.3 *Let $\pi : Y \rightarrow X$ be a modification between connected complex manifolds, and let θ be a smooth real $(1, 1)$ -form on X . If $v_j \rightarrow v$ in $L^1_{\text{loc}}(X)$ and all v_j, v belong to $\text{PSH}(X, \theta)$, then*

$$v_j \circ \pi \longrightarrow v \circ \pi \quad \text{in } L^1_{\text{loc}}(Y).$$

In particular, on compact manifolds this is convergence in L^1 .

Proof By Lemma 1.4.1, the functions v_j are uniformly bounded above on relatively compact subsets of X . The pullbacks are therefore locally uniformly bounded above and have the common smooth lower curvature bound $-\pi^*\theta$. After a smooth local correction, the compactness theorem for plurisubharmonic functions shows that every subsequence has a further subsequence that either converges in L^1_{loc} or tends locally uniformly to $-\infty$ on each connected coordinate region in Y .

Every such region meets the complement of the exceptional locus. There π is a biholomorphism, and change of variables gives L^1_{loc} convergence to $v \circ \pi$, which excludes convergence to $-\infty$. Each subsequential limit agrees with $v \circ \pi$ off the exceptional locus, hence almost everywhere, since this analytic set has smooth volume zero. Thus the limit is unique, and applying this argument on a countable cover by coordinate regions proves convergence of the whole sequence in $L^1_{\text{loc}}(Y)$. $\square$

Convergence in capacity is also preserved by modifications. The comparison takes place away from small neighborhoods of the exceptional sets, so no uniform comparison of capacities on the whole manifolds is needed.

Lemma 1.22.4 *Let $\pi : Y \rightarrow X$ be a modification between connected compact complex manifolds, equipped with Hermitian forms ω_Y, ω_X . Write $\text{Cap}_Y = \text{Cap}_{\omega_Y}$ and $\text{Cap}_X = \text{Cap}_{\omega_X}$ for the Hermitian capacities of [Section 1.8](#). For quasi-plurisubharmonic functions v_j, v on X ,*

$$v_j \longrightarrow v \text{ in capacity on } X \iff v_j \circ \pi \longrightarrow v \circ \pi \text{ in capacity on } Y.$$

Proof Choose a proper analytic subset $S \subset X$ such that π is an isomorphism outside $D = \pi^{-1}(S)$. Both S and D have capacity zero. For $\epsilon > 0$, choose an open neighborhood V of D of capacity less than ϵ . By properness, there is a neighborhood U_0 of S with $\pi^{-1}(U_0) \subset V$; shrink it to an open set U with $\text{Cap}_X(U) < \epsilon$. The inverse of π is biholomorphic near the compact set $X \setminus U$. A finite cover by nested coordinate charts and the comparison of local and global capacities in [Section 1.8](#) give a constant C_ϵ such that, for every Borel set $E \subset X$,

$$\begin{aligned} \text{Cap}_Y(\pi^{-1}E) &\leq \epsilon + C_\epsilon \text{Cap}_X(E), \\ \text{Cap}_X(E) &\leq \epsilon + C_\epsilon \text{Cap}_Y(\pi^{-1}E). \end{aligned}$$

Apply these inequalities to $E = \{|v_j - v| > \delta\}$ for each fixed $\delta > 0$, omitting the pluripolar pole sets, and let first $j \rightarrow \infty$ and then $\epsilon \downarrow 0$. $\square$

1.22.4 Multiplier ideals under modifications

Throughout this subsection, $\pi : Y \rightarrow X$ is a modification of connected compact complex manifolds of dimension n . There is an analytic subset $S \subset X$ of codimension at least two such that π is an isomorphism over $X \setminus S$. Let K_X and K_Y be the canonical line bundles. Set $D = \pi^{-1}(S)$ and

$$R_\pi = K_Y \otimes \pi^* K_X^{-1}.$$

The determinant of the differential of π is a canonical holomorphic section J_π of R_π ; in local coordinates its coefficient is the holomorphic Jacobian determinant $\text{Jac } \pi$, and its zeros are contained in D . These standard facts about modifications of complex manifolds include the case $n = 1$, in which every modification is an isomorphism.

Lemma 1.22.5 *Let a be quasi-plurisubharmonic on X . Pullback followed by multiplication with J_π induces an isomorphism*

$$\pi_*(R_\pi \otimes I(a \circ \pi)) = I(a).$$

More precisely, for every holomorphic line bundle M on X , the map

$$s \longmapsto J_\pi \pi^* s$$

is an isomorphism

$$H^0(X, M \otimes I(a)) \simeq H^0(Y, \pi^* M \otimes R_\pi \otimes I(a \circ \pi)).$$

Proof The assertion is local on X . In coordinates and local frames, the map sends a holomorphic coefficient f to $(f \circ \pi) \text{Jac } \pi$. By the change-of-variables formula, local integrability of

$$|f|^2 e^{-a} \quad \text{and} \quad |f \circ \pi|^2 |\text{Jac } \pi|^2 e^{-a \circ \pi}$$

are equivalent. For the implication from integrability on Y to integrability near a point of X , take a smaller relatively compact neighborhood of the point; by properness, its inverse image has compact closure, so finitely many charts on which the integrability holds suffice. Smooth positive coordinate densities are comparable on these charts, and analytic exceptional sets have smooth volume zero, so they do not change the integrals.

It remains to show that every section on Y is of the form $J_\pi \pi^* s$. Divide it by J_π off D and use the inverse of π there; this gives a holomorphic section of M off S . Since S has codimension at least two, Hartogs' extension theorem gives a holomorphic section s on X . Its image $J_\pi \pi^* s$ agrees with the given section off D , hence everywhere by the identity theorem. The integrability equivalence then places s in the required multiplier ideal. The same argument on each open set proves the sheaf identity as well as the global identification. $\square$

Note that the lemma does not identify $\pi^* I(a)$ with $I(a \circ \pi)$: the Jacobian is part of the holomorphic coefficient on Y and cannot be removed from the integrability test.

We also need the invariance of the ideal order $\preceq_I$ of [Section 1.12](#), which involves all positive weights. The proof is local, so that we never have to extend a modification of a small open subset of Y to a global one.

Lemma 1.22.6 *For quasi-plurisubharmonic a, b on X ,*

$$a \preceq_I b \iff a \circ \pi \preceq_I b \circ \pi.$$

The assertion is local on X and also holds for a proper bimeromorphic map between noncompact smooth complex manifolds.

Proof The reverse implication follows at every positive weight from the sheaf identity in [Lemma 1.22.5](#): tensor the inclusion of ideals on Y with R_π and apply the left-exact direct image functor. The proof of that sheaf identity is local on the target, since properness makes each fiber compact and gives the required finite cover by integrability charts; compactness of the manifolds themselves is not needed.

For the forward implication, fix a coordinate neighborhood $W \subset Y$, a local modification $\sigma : Z \rightarrow W$ with smooth source, and a prime divisor E on Z . After shrinking W around the point under consideration, its image is contained in a coordinate neighborhood $U \subset X$. Put $F = \pi \circ \sigma$ and

$$A_F(E) = 1 + \text{ord}_E \text{Jac } F.$$

The map F is holomorphic, and it is injective and biholomorphic off a proper analytic subset; it need not be a proper modification of U .

Let m be a positive integer, and let ν_E and ord_E be the generic Lelong number and the generic vanishing order along E , as in [Section 1.17](#). The proof of [Lemma 1.17.7](#) applies to the map F on relatively compact coordinate patches and gives

$$\max \left\{ \nu_E(a \circ F) - \frac{A_F(E)}{m}, 0 \right\} \leq \frac{1}{m} \text{ord}_E(I(ma)O_Z) \leq \nu_E(a \circ F).$$

In more detail, the upper inequality follows by pulling back the local Bergman lower bound on U . For the lower one, a germ $f \in I(ma)$ pulls back to a coefficient $(f \circ F) \text{Jac } F$ that is square integrable against $e^{-ma \circ F}$, because on a relatively compact patch of Z the change-of-variables integral is bounded by the integral over the image of the patch. Generic divisorial removal and the one-variable integral then give

$$\text{ord}_E(f \circ F) + A_F(E) > m\nu_E(a \circ F).$$

This estimate only uses the injectivity of F off the exceptional set and the compactness of the patch, not properness of F over U . The same estimates hold for b .

The hypothesis gives $I(ma) \subseteq I(mb)$ for every $m > 0$, so the orders of the pulled-back ideals satisfy the reverse inequality. Letting $m \rightarrow \infty$ in the two estimates proves

$$\nu_E(a \circ F) \geq \nu_E(b \circ F).$$

This holds for every local divisor over Y . Blowing up a point on the source of any local modification recovers the Lelong number at that point as a generic Lelong number along the exceptional divisor; in dimension one the point already is a divisor. The local criterion in [Theorem 1.16.1](#) now gives $a \circ \pi \preceq_I b \circ \pi$. No extension of σ beyond its local domain was used. $\square$

Lemma 1.22.7 *For a proper bimeromorphic map $\rho : Z \rightarrow Y$ between complex manifolds and quasi-plurisubharmonic functions a, b on Y ,*

$$a \sim_I b \iff a \circ \rho \sim_I b \circ \rho.$$

The statement is local on Y .

Proof Apply the local order equivalence of [Lemma 1.22.6](#) to both (a, b) and (b, a) . Together, the two order relations are equivalent to equality of the multiplier ideals at every positive weight. $\square$

1.22.5 Restriction of analytic approximants

A quasi-plurisubharmonic function with zero generic Lelong number along a submanifold may still restrict to the function identically equal to $-\infty$ ([Section 1.13](#)). Analytic regularization removes this obstruction: the restrictions of the analytic approximants are quasi-plurisubharmonic, and a fixed lower curvature bound controls their generic Lelong numbers along divisors on every fixed modification.

Corollary 1.22.1 *Let θ be a smooth real $(1, 1)$ -form and $u \in \text{PSH}(X, \theta)$, and let u_m , with curvature errors ϵ_m , be the approximants of [Corollary 1.15.1](#). Let $Y \subset X$ be a connected compact complex submanifold along which the generic Lelong number of u vanishes:*

$$v(u, Y) = \inf_{y \in Y} v(u, y) = 0.$$

Then each restriction $u_m|_Y$ is quasi-plurisubharmonic on Y ; in particular, it is not identically $-\infty$. If $\pi : Z \rightarrow Y$ is a modification with smooth compact source and $E \subset Z$ is a prime divisor, then

$$\sup_m v((u_m|_Y) \circ \pi, E) < \infty.$$

Proof For each m , choose $y \in Y$ with $v(u, y) < 1/m$. Skoda's local integrability criterion gives $\mathcal{I}(mu)_y = \mathcal{O}_{X,y}$, so the image ideal $\mathcal{I}(mu)\mathcal{O}_Y$ does not vanish identically. Since u_m has analytic type $(1/m, \mathcal{I}(mu))$, [Proposition 1.13.1](#) shows that $u_m|_Y$ is quasi-plurisubharmonic on Y . Its pullback to Z is quasi-plurisubharmonic as well, since π is biholomorphic off a proper analytic subset.

Restricting and pulling back the curvature inequality of [Corollary 1.15.1](#), which is allowed by [Lemma 1.22.1](#), gives

$$\pi^*(\theta|_Y) + \text{dd}^c((u_m|_Y) \circ \pi) \geq -\epsilon_m \pi^*(\omega|_Y).$$

Since the errors ϵ_m are bounded, a sufficiently large multiple of a single Hermitian form on Z dominates $\pi^*(\theta|_Y) + \epsilon_m \pi^*(\omega|_Y)$ for all m . [Lemma 1.17.6](#), applied on Z in this fixed background, therefore bounds the generic Lelong numbers along E uniformly in m . $\square$

1.23 Integration against non-pluripolar measures

For uniformly bounded potentials, L^1 convergence with respect to a smooth volume form can be transferred to any fixed finite measure that does not charge pluripolar sets. Passing to bounded exponentials extends this to families that are only bounded above. The same mechanism applies to moving mixed Monge–Ampère measures of bounded potentials and to smoothings of a fixed measure.

1.23.1 A fixed measure

Cegrell’s fixed-measure convergence lemma states that a uniformly bounded sequence of plurisubharmonic functions converging in L^1_{loc} converges in $L^1(\nu)$ on compact subsets, for every finite non-pluripolar measure ν . The usual formulation, which allows passing to a subsequence, gives the same conclusion: apply it to every subsequence after extracting a further subsequence converging almost everywhere for the smooth volume, and use the subsequence criterion for convergence. This is the classical fixed-measure argument used in [GZ17, Section 11.1.2], and we use this local lemma as a standard input.

Lemma 1.23.1 *Let ν be a finite non-pluripolar measure on X . If uniformly bounded quasi-plurisubharmonic functions a_j, a have a common smooth lower curvature bound and $a_j \rightarrow a$ in $L^1(X)$, then*

$$\int_X |a_j - a| d\nu \longrightarrow 0.$$

If instead $u_j, u \in \text{PSH}(X, \theta)$ have a common upper bound and $u_j \rightarrow u$ in $L^1(X)$, then, for every $b > 0$,

$$\int_X |e^{bu_j} - e^{bu}| d\nu \longrightarrow 0.$$

Proof For the first statement, add a fixed smooth strictly plurisubharmonic function on each of finitely many coordinate balls, so that the resulting functions are uniformly bounded and plurisubharmonic there. Apply the local lemma on smaller compact balls covering X and sum the integrals; the added functions cancel in the differences.

For the second statement, choose $A > 0$ with $A\omega \geq \theta$. If $u_j \leq C$, the convex chain rule gives $\text{dd}^c e^{bu_j} \geq -bAe^{bC}\omega$, also for unbounded u_j by bounded truncation; here the exponential is given the value zero at a pole. Thus the functions e^{bu_j} are uniformly bounded and quasi-plurisubharmonic, with a common lower curvature bound. They converge in $L^1(dV)$, because the exponential is Lipschitz with constant be^{bC} on $(-\infty, C]$. The first statement now applies. $\square$

1.23.2 Vanishing exponents

Proposition 1.23.1 *Let $\varphi \in \text{PSH}(X, \theta)$ be unbounded below, and for each $\lambda > 0$ let u_λ be a quasi-plurisubharmonic function with $u_\lambda \sim \varphi$. Then, for each $\lambda > 0$, the function λu_λ has infinite distance in $L^\infty(dV)$ from every constant. In particular, λu_λ cannot converge uniformly on X to a finite constant as $\lambda \downarrow 0$.*

Proof Since $\varphi \leq u_\lambda + C$ for a constant C , the function u_λ is unbounded below. Every nonempty strict sublevel set $\{u_\lambda < t\}$ of the upper semicontinuous function u_λ is open, hence of positive smooth volume. Thus u_λ , and with it λu_λ , is essentially unbounded below, and both conclusions follow. $\square$

A vanishing exponent gives convergence of the exponentials to one, even when the normalized potentials vary.

Lemma 1.23.2 *Let $v_j \in \text{PSH}(X, \theta)$ satisfy $\sup_X v_j = 0$, and let $\lambda_j > 0$ decrease to zero. For every finite non-pluripolar measure μ ,*

$$\int_X |e^{\lambda_j v_j} - 1| d\mu \longrightarrow 0.$$

If $f \in L^p(dV)$ for some $p > 1$, then more precisely

$$\int_X |e^{\lambda_j v_j} - 1| |f| dV \leq C_p \lambda_j \|f\|_{L^p(dV)}.$$

The constant depends on the fixed background, p and dV .

Proof Choose a Hermitian form $\Omega \geq \theta$, so that $v_j \in \text{PSH}(X, \Omega)$. By [Lemma 1.8.1](#), for every $T > 1$,

$$\text{Cap}_\Omega(\{v_j < -T\}) \leq C/T$$

uniformly in j . Since $v_j \leq 0$ and $1 - e^{-x} \leq x$ for $x \geq 0$, splitting the integral at this sublevel set gives

$$\int_X (1 - e^{\lambda_j v_j}) d\mu \leq \lambda_j T \mu(X) + \mu(\{v_j < -T\}).$$

By [Lemma 1.8.5](#), the second term is uniformly small when T is large, and for this fixed T the first term tends to zero as $j \rightarrow \infty$. This proves the general assertion; here the exponential is given the value zero at a pole, and pole sets have zero μ -measure.

For the quantitative assertion, [Lemma 1.5.1](#), applied in the background Ω , gives a uniform L^q bound for $-v_j$, where $q = p/(p-1)$. Hölder's inequality and the bound

$$0 \leq 1 - e^{\lambda_j v_j} \leq \lambda_j |v_j|$$

give the claimed estimate for every j . $\square$

1.23.3 Measures with bounded potentials

The fixed measure can be replaced by moving mixed Monge–Ampère measures of uniformly bounded potentials, provided these potentials converge in capacity. Since ω need not be closed, the proof has to control the torsion terms that appear in integration by parts.

Lemma 1.23.3 *Let $a_j, a, w_j, w \in \text{PSH}(X, \omega)$ be uniformly bounded, and write $\omega_v = \omega + \text{dd}^c v$. If $a_j \rightarrow a$ in $L^1(X)$ and $w_j \rightarrow w$ in capacity, then, for $0 \leq k \leq n$,*

$$\int_X |a_j - a| \omega_{w_j}^k \wedge \omega^{n-k} \rightarrow 0.$$

The same conclusion holds if, instead of $a_j, a \in \text{PSH}(X, \omega)$, the uniformly bounded functions a_j, a have any fixed smooth lower curvature bound.

Proof By Lemma 1.4.1, the tail envelopes $A_j = (\sup_{\ell \geq j} a_\ell)^*$ decrease to a . Since $a \leq \max(a_j, a) \leq A_j$, monotone convergence in capacity of bounded potentials (Lemma 1.8.6) implies

$$\alpha_j := \max(a_j, a) \rightarrow a \quad \text{in capacity.}$$

We split $|a_j - a| = (\alpha_j - a) + (\alpha_j - a_j)$. The integral of the first part against the moving products tends to zero by Lemma 1.8.3.

For the second part, put $h_j = \alpha_j - a_j \geq 0$. We compare its integrals against the measures with indices j and ℓ . The case $k = 0$ follows from the assumed L^1 convergence. For $k \geq 1$, put $z = w_j - w_\ell$ and

$$T = \sum_{s=0}^{k-1} \omega_{w_j}^s \wedge \omega_{w_\ell}^{k-1-s} \wedge \omega^{n-k}.$$

Factorization and Stokes' theorem on the compact manifold X give

$$\begin{aligned} \int_X h_j (\omega_{w_j}^k - \omega_{w_\ell}^k) \wedge \omega^{n-k} \\ = \int_X h_j \text{dd}^c z \wedge T = \int_X z \text{dd}^c (h_j T). \end{aligned}$$

Since ω is not assumed to be closed, T need not be closed, and the product rule reads

$$\text{dd}^c (h_j T) = \text{dd}^c h_j \wedge T + dh_j \wedge \text{d}^c T - \text{d}^c h_j \wedge \text{d} T + h_j \text{dd}^c T. \quad (1.41)$$

None of the terms involving derivatives of T need vanish.

We estimate the four terms. Since $\text{dd}^c h_j = \omega_{\alpha_j} - \omega_{a_j}$, the absolute contribution of the first is at most

$$\int_X |z| (\omega_{\alpha_j} + \omega_{a_j}) \wedge T.$$

It tends to zero as $j, \ell \rightarrow \infty$ by [Lemma 1.8.3](#), since $w_j - w_\ell \rightarrow 0$ in capacity. Differentiating each factor shows that $dT = d\omega \wedge R$ and $d^c T = d^c \omega \wedge R$, where R is a positive linear combination of mixed products of bidegree $(n-2, n-2)$. Moreover, $dd^c T$ is a sum of terms consisting of $dd^c \omega$ times mixed products of degree $n-2$, or of $d\omega \wedge d^c \omega$ times mixed products of degree $n-3$; terms of negative degree are absent. These smooth torsion factors are bounded in absolute value by fixed multiples of ω^2 and ω^3 , respectively. As h_j is uniformly bounded, the contribution of $h_j dd^c T$ also tends to zero, by the same capacity estimate.

For the two gradient terms, the pointwise Cauchy–Schwarz inequality for a positive mixed product gives, for example,

$$\left| \int_X z dh_j \wedge d^c \omega \wedge R \right|^2 \leq C \left(\int_X |z| dh_j \wedge d^c h_j \wedge \omega \wedge R \right) \left(\int_X |z| \omega^2 \wedge R \right).$$

The second factor tends to zero, and the first is uniformly bounded. Indeed, if p is any of the uniformly bounded potentials and S any positive mixed product of degree $n-1$ occurring here, then

$$\int_X dp \wedge d^c p \wedge S = \frac{1}{2} \int_X p^2 dd^c S - \int_X p dd^c p \wedge S.$$

Expand $dd^c S$ with all its torsion terms as above, and write $dd^c p = \omega_p - \omega$. Boundedness of p and [Lemma 1.8.3](#) bound both integrals uniformly. Finally, $dh_j \wedge d^c h_j \leq 2d\alpha_j \wedge d^c \alpha_j + 2da_j \wedge d^c a_j$ as positive quadratic forms, which proves the asserted bound. The other gradient term is estimated in the same way. In dimension one, $T = 1$ and all torsion terms in (1.41) vanish.

These integration-by-parts and energy identities hold for smooth potentials. They extend to bounded potentials through smooth decreasing approximations in the Hermitian background, using the local Bedford–Taylor chain rule, its gradient products and quasi-continuity; equivalently, they follow from the bounded current calculus of [Section 1.7](#). Only the common bound on the potentials enters the estimates.

We have shown that the difference between the integrals of h_j against the measures with indices j and ℓ tends to zero as $j, \ell \rightarrow \infty$. For a fixed index ℓ , the measure $\omega_{w_\ell}^k \wedge \omega^{n-k}$ is a fixed finite non-pluripolar measure, and [Lemma 1.23.1](#), applied separately to $\alpha_j \rightarrow a$ and $a_j \rightarrow a$ in $L^1(X)$, gives

$$\int_X h_j \omega_{w_\ell}^k \wedge \omega^{n-k} \longrightarrow 0 \quad \text{as } j \rightarrow \infty.$$

Choosing first ℓ large and then letting $j \rightarrow \infty$, we conclude that the integrals of h_j against $\omega_{w_j}^k \wedge \omega^{n-k}$ tend to zero. Together with the estimate for $\alpha_j - a$, this proves the result. If the a_j only have some other fixed lower curvature bound, choose a Hermitian form $\Omega \geq \omega$ such that they are Ω -plurisubharmonic. By [Section 1.8](#), convergence in capacity is unchanged by this replacement. Apply the result just proved with Ω in place of ω ; by positivity, the original mixed measures are bounded by their counterparts for Ω . $\square$

1.23.4 Smoothing the measure

Convolution in coordinate charts gives smooth approximations of a finite measure. For a varying quasi-plurisubharmonic integrand, the submean inequality transfers the error to the original measure; this gives the additional control needed beyond weak convergence of the measures themselves.

For a smooth real $(1, 1)$ -form θ with $\text{PSH}(X, \theta) \neq \emptyset$ and a non-pluripolar probability measure ν on X , put

$$A_\theta(\nu) = \sup \left\{ \int_X (-w) d\nu : w \in \text{PSH}(X, \theta), \sup_X w = 0 \right\}.$$

This number may be infinite. It is finite for Monge–Ampère measures of bounded potentials.

Lemma 1.23.4 *Let $\psi \in \text{PSH}(X, \omega)$ be bounded, and put $\nu = (\omega + \text{dd}^c \psi)^n$. There is a finite constant C , depending only on ω , θ , dV and $\|\psi\|_\infty$, such that*

$$\int_X (-w) d\nu \leq C \quad (w \in \text{PSH}(X, \theta), \sup_X w = 0).$$

Proof Choose finitely many pairs of concentric coordinate balls $B'_a \Subset B_a$ such that the B'_a cover X , and fixed smooth functions q_a, r_a on B_a with $\text{dd}^c q_a \geq \omega$ and $\text{dd}^c r_a \geq \theta$, with $r_a \leq 0$. Then $\psi + q_a$ is bounded and plurisubharmonic, $w + r_a$ is negative and plurisubharmonic, and positivity of bounded products gives

$$\int_{B'_a} (-w) d\nu \leq \int_{B'_a} (-w - r_a) (\text{dd}^c(\psi + q_a))^n \leq C_a (1 + \|w\|_{L^1(B_a)}).$$

The last step is the weighted Chern–Levine–Nirenberg estimate of [Section 1.6](#). Summing over the cover and using the normalized L^1 bound of [Theorem 1.4.1](#) proves the lemma. $\square$

To construct the smoothings, choose finitely many coordinate balls B_a and smooth functions $\eta_a \geq 0$ with compact support in B_a and $\sum_a \eta_a = 1$. Let $\chi \geq 0$ be a smooth radial kernel of integral one supported in the unit ball of $\mathbb{C}^n$, and fix $\epsilon_j \downarrow 0$ so small that all convolutions below stay in the corresponding coordinate ball. For a function F , let $S_{a,j}F$ be its convolution, in the chart of B_a , with the kernel $\epsilon_j^{-2n} \chi(\cdot/\epsilon_j)$. For a probability measure ν on X , define a smooth probability measure ν_j by convolving each coordinate measure $\eta_a \nu$ with the same kernel and adding the extensions by zero. It is characterized by the identity

$$\int_X F d\nu_j = \sum_a \int_X \eta_a S_{a,j} F d\nu. \quad (1.42)$$

for Borel functions F ; since the kernel is even, the same convolution occurs on the right. This identity first holds for nonnegative Borel functions and then for integrable signed functions. In particular, $\nu_j \rightarrow \nu$ weakly.

Lemma 1.23.5 *Let ν be a non-pluripolar probability measure with $A_\theta(\nu) < \infty$, and let ν_j be its smoothings defined by (1.42). Then*

$$\sup_j A_\theta(\nu_j) < \infty.$$

Moreover, let z_j, z be quasi-plurisubharmonic functions with a common upper bound and a common smooth lower curvature bound, and suppose that $z_j \rightarrow z$ both in $L^1(X)$ and in $L^1(\nu)$. Then

$$\int_X |z_j - z| d\nu_j \rightarrow 0. \quad (1.43)$$

Consequently, for every $\lambda > 0$,

$$e^{\lambda z_j} \nu_j \rightarrow e^{\lambda z} \nu.$$

Proof On each coordinate ball B_a choose a fixed smooth function q_a with $\text{dd}^c q_a \geq \theta$. If $w \in \text{PSH}(X, \theta)$ and $\sup_X w = 0$, then $w + q_a$ is plurisubharmonic, and the submean inequality gives

$$-S_{a,j} w \leq -w + S_{a,j} q_a - q_a \leq -w + C.$$

with a constant independent of w and j . Integrating and using (1.42) proves $A_\theta(\nu_j) \leq A_\theta(\nu) + C$.

For the second assertion, the tail envelopes

$$H_j = \left(\sup_{k \geq j} z_k \right)^*$$

decrease to z by Lemma 1.4.1. Enlarge the functions q_a so that $H_j + q_a, z_j + q_a$ and $z + q_a$ are all plurisubharmonic. Since $H_j \geq z_j$ and $H_j \geq z$, we have $|z_j - z| \leq 2H_j - z_j - z$, and the identity (1.42) and the submean inequality imply

$$\begin{aligned} \int_X |z_j - z| d\nu_j &\leq \sum_a \int_X \eta_a S_{a,j} (2H_j - z_j - z) d\nu \\ &\leq 2 \sum_a \int_X \eta_a (S_{a,j} (H_j + q_a) - (z + q_a)) d\nu + \int_X (z - z_j) d\nu. \end{aligned}$$

All these integrals are well defined: each function on the larger side of a submean inequality is bounded above, and its negative part is controlled by that of the integrable function on the smaller side plus a constant.

Radial averages of a plurisubharmonic function decrease when the radius decreases. Therefore $S_{a,j}(H_j + q_a)$ decreases to $z + q_a$ on the support of η_a : to identify the

limit, fix an index k , use $H_j \leq H_k$ for $j \geq k$, let $j \rightarrow \infty$ in the radius, and then let $k \rightarrow \infty$; the reverse inequality is the submean inequality. The nonnegative integrand in the second line of the last display is dominated on this compact support by a constant minus z , which is ν -integrable, so its integral tends to zero by dominated convergence. The final integral tends to zero by convergence in $L^1(\nu)$. This proves (1.43).

Since the exponential is Lipschitz on the common range of the functions, (1.43) also gives $\int_X |e^{\lambda z_j} - e^{\lambda z}| d\nu_j \rightarrow 0$. If $\zeta > 0$ is smooth, then $\zeta e^{\lambda z} = e^{\lambda z + \log \zeta}$ is bounded and quasi-plurisubharmonic. For any fixed bounded quasi-plurisubharmonic function F , the same local submean argument and dominated convergence in (1.42) give

$$\int_X F d\nu_j \rightarrow \int_X F d\nu.$$

Applying this to $F = \zeta e^{\lambda z}$ gives $\int_X \zeta e^{\lambda z_j} d\nu_j \rightarrow \int_X \zeta e^{\lambda z} d\nu$ for every smooth $\zeta > 0$. Since every smooth function is a difference of two positive smooth functions, the convergence holds for all smooth test functions, and uniformly bounded masses together with uniform approximation of continuous functions by smooth ones prove weak convergence. $\square$

1.24 Curvature of line bundles

Let M be a complex manifold and let θ be a smooth real $(1, 1)$ -form on M . To relate potentials to holomorphic sections, we ask when a current $\theta + dd^c u$, with u locally integrable, can be the curvature current of a metric on a line bundle. The transition law for the local weights of such a metric forces a closedness condition on the background.

Proposition 1.24.1 *The curvature current of a singular Hermitian metric with locally integrable weights on a holomorphic line bundle is closed. In particular, a nonclosed form θ cannot itself be the curvature current of such a metric, and $\theta + dd^c u$ is not closed on any neighborhood of a point where $d\theta \neq 0$.*

Proof Let h be a singular Hermitian metric on a holomorphic line bundle $L \rightarrow M$. Choose a local holomorphic frame e of L and write its squared norm as $|e|_h^2 = e^{-\varphi}$; the curvature current is then locally $dd^c \varphi$. If $e' = ge$ is another frame, with g holomorphic and nowhere zero, the new weight is $\varphi - \log |g|^2$. Since $\log |g|^2$ is pluriharmonic, these local currents agree on overlaps and glue to a global current, which is closed because $ddd^c = 0$. The final assertion follows from the identity

$$d(\theta + dd^c u) = d\theta$$

of currents. $\square$

Accordingly, when we study sections subject to multiplier-ideal conditions, we specify both the line bundle, whose curvature is closed, and any auxiliary Hermitian form on M . An algebraic interpretation then requires relating the invariants of the line bundle to this analytic background.

1.25 Polar curvature

For $u \in \text{PSH}(X, \theta)$, the restriction of the current $\theta + \text{dd}^c u$ to the pole set $\{u = -\infty\}$ is called the *polar curvature* of u . A bounded change of the potential preserves more than its Lelong numbers: it preserves the whole polar curvature. Indeed, a local energy estimate puts the bounded difference of two potentials in a Sobolev space, while pole sets admit smooth test functions of arbitrarily small energy, and these test functions show that no coefficient measure of the Hessian of the difference charges the pole set. Polar curvature is closed even when the pole set is not closed, so a local elliptic equation recovers it from its scalar Hermitian trace.

Lemma 1.25.1 *Let $U \subset \mathbb{R}^d$ be open and let $w \in L_{\text{loc}}^\infty(U)$. If Δw is a locally finite signed Radon measure, then $w \in W_{\text{loc}}^{1,2}(U)$.*

Proof Fix a smooth function $0 \leq \psi \leq 1$ with compact support in U , and a relatively compact open neighborhood V of its support. Mollify w inside V with a standard mollifier ρ_ε , writing $w_\varepsilon = w * \rho_\varepsilon$ and $v_\varepsilon = (\Delta w) * \rho_\varepsilon$. For small ε , integration by parts and Young's inequality give

$$\begin{aligned} \int \psi^2 |\nabla w_\varepsilon|^2 &= - \int \psi^2 w_\varepsilon v_\varepsilon - 2 \int \psi w_\varepsilon \nabla \psi \cdot \nabla w_\varepsilon \\ &\leq \|w\|_{L^\infty(V)} |\Delta w|(V) + \frac{1}{2} \int \psi^2 |\nabla w_\varepsilon|^2 + 2 \int w_\varepsilon^2 |\nabla \psi|^2. \end{aligned}$$

Absorbing the middle term on the right, we obtain a bound for $\int \psi^2 |\nabla w_\varepsilon|^2$ that is independent of ε . Taking $\psi = 1$ on a prescribed smaller compact set, weak compactness in $W^{1,2}$ and convergence of the mollifications in L^2 identify the weak limit with w . This proves the assertion. $\square$

Lemma 1.25.2 *Let v be quasi-plurisubharmonic on a complex manifold, let U be a coordinate ball with compact closure in a larger chart, and let $K \subset U \cap \{v = -\infty\}$ be compact. For every open $O \subset U$ containing K , there are real $\varphi_j \in C_c^\infty(O)$ with $0 \leq \varphi_j \leq 1$, equal to one near K , such that $\|\varphi_j\|_{W^{1,2}(U)} \rightarrow 0$. The norm uses the Euclidean coordinates.*

Proof Adding a smooth quadratic function and subtracting a constant, we obtain a negative plurisubharmonic function h on U with the same pole set as v . Put $h_M = \max(h, -M)$ for $M \geq 1$, and choose $\psi \in C_c^\infty(O)$ with $0 \leq \psi \leq 1$ and $\psi = 1$ near K . On a fixed compact neighborhood of $\text{supp } \psi$, the positive measures Δh_M have

uniformly bounded mass: choose a nonnegative smooth function χ with compact support in U , equal to one on this neighborhood, and use

$$\int \chi \Delta h_M = \int h_M \Delta \chi, \quad |h_M| \leq |h| \in L^1_{\text{loc}}(U).$$

Apply the integration-by-parts estimate of the preceding proof to mollifications of h_M . Their absolute values are at most M , and their squares are at most M times their absolute values. The uniform bounds for the mass of the Laplacians and for the local L^1 norms therefore give, after passing to the weak limit in $W^{1,2}$,

$$\int \psi^2 |\nabla h_M|^2 \leq CM, \quad \left\| \frac{-\psi h_M}{M} \right\|_{W^{1,2}(U)}^2 \leq \frac{C}{M}.$$

Here C depends on the fixed cutoffs and the local L^1 norm of h , but not on M . The second inequality also uses $h_M^2 \leq M|h|$ in the terms containing ψ and $\nabla \psi$.

The Sobolev function $-\psi h_M/M$ takes values between zero and one. It equals one on a neighborhood of K , since h is upper semicontinuous and therefore $\{h < -M\}$ is an open neighborhood of K . Extend it by zero and mollify with a sufficiently small radius: the support stays in O , the function remains equal to one on a smaller neighborhood of K , and its Sobolev norm does not increase. Letting $M \rightarrow \infty$ gives the required smooth functions. $\square$

For a current T of order zero and a Borel set B , we write $\mathbf{1}_B T$ for the restriction of T to B , taken coefficientwise on the Radon coefficient measures of T . These restrictions commute with smooth changes of coordinates.

Proposition 1.25.1 *Let u, v be quasi-plurisubharmonic functions on a complex manifold such that every point has a neighborhood on which $u - C \leq v \leq u + C$ for some constant C . Then u and v have the same pole set $S = \{u = -\infty\} = \{v = -\infty\}$, and*

$$\mathbf{1}_S \text{dd}^c u = \mathbf{1}_S \text{dd}^c v.$$

Consequently, for any smooth real $(1, 1)$ -forms θ, β ,

$$\mathbf{1}_S(\theta + \text{dd}^c u) = \mathbf{1}_S(\beta + \text{dd}^c v).$$

Proof The two local inequalities show that the pole sets agree. Off S put $w = u - v$, and give w arbitrary bounded values on S . Since S has Lebesgue measure zero, this defines the locally bounded distribution $u - v$. The coefficient measures of $\text{dd}^c w$ are locally finite, since after a smooth correction the complex Hessians of u and v are positive currents of order zero. Taking the Euclidean trace shows that Δw is a signed Radon measure, so **Lemma 1.25.1** gives $w \in W^{1,2}_{\text{loc}}$.

Consequently, the real and imaginary parts of the coefficient measures of $\text{dd}^c w$ are continuous linear functionals on $W^{1,2}_0$ of a smaller ball, since a second distributional derivative of w is a first derivative of its L^2 gradient. Let ν be any one of these real signed measures, with Jordan decomposition $\nu = \nu^+ - \nu^-$. Choose a compact set

K contained in the intersection of S with a positive set of a Hahn decomposition, so that $\nu^-(K) = 0$. For $\epsilon > 0$, take an open neighborhood O of K in the ball with $\nu^-(O) < \epsilon$. The test functions φ_j of Lemma 1.25.2, applied to u , satisfy

$$\nu^+(K) \leq \int \varphi_j d\nu^+ = \langle \nu, \varphi_j \rangle + \int \varphi_j d\nu^- \leq |\langle \nu, \varphi_j \rangle| + \epsilon.$$

By continuity on the Sobolev space, the first term tends to zero. Letting $\epsilon \downarrow 0$ and using inner regularity gives $\nu^+(S) = 0$ locally, and the same argument applied to $-\nu$ gives $\nu^-(S) = 0$. Thus all coefficient measures of $\text{dd}^c w$ vanish on S , which proves the first identity. Since smooth forms also give S zero mass, the second identity follows. $\square$

For closed positive currents, local potentials turn equality of the scalar traces into an elliptic equation. If both currents are carried by a Lebesgue null set, the resulting smooth difference vanishes.

Lemma 1.25.3 *Let T, S be closed positive $(1, 1)$ -currents on a complex manifold of dimension $n \geq 1$, both carried coefficientwise by a Borel set of Lebesgue measure zero. For any Hermitian form η ,*

$$T \wedge \eta^{n-1} = S \wedge \eta^{n-1} \implies T = S.$$

Proof On a small coordinate ball, take plurisubharmonic local potentials a, b with $T = \text{dd}^c a$ and $S = \text{dd}^c b$, by [Dem12, Chapter III, Proposition 1.19, p. 135]. Put $h = a - b \in L^1_{\text{loc}}$. The trace identity gives $\text{dd}^c h \wedge \eta^{n-1} = 0$ in the sense of distributions. Dividing by the smooth positive volume form η^n gives a scalar second-order operator with smooth coefficients whose principal matrix is a positive multiple of the inverse of the Hermitian matrix of η ; it is uniformly elliptic on every smaller ball. Local elliptic regularity therefore makes h smooth. Thus $T - S = \text{dd}^c h$ is smooth and carried by a Lebesgue null set, so its coefficient measures vanish. This proves equality locally, and hence globally. $\square$

Pushforward by a proper map commutes with restriction to the inverse image of a Borel set. Hence polar curvature is compatible with modifications, even when the pole set is not closed.

Proposition 1.25.2 *Let $\pi : Y \rightarrow X$ be a modification of connected compact complex manifolds, let θ be a smooth real $(1, 1)$ -form on X , and let $u \in \text{PSH}(X, \theta)$. Put $S = \{u = -\infty\}$ and*

$$T = \theta + \text{dd}^c u, \quad T_Y = \pi^* \theta + \text{dd}^c (u \circ \pi).$$

Then

$$\pi_*(\mathbf{1}_{\pi^{-1}(S)} T_Y) = \mathbf{1}_S T. \quad (1.44)$$

Proof By Proposition 1.22.2, $u \circ \pi \in \text{PSH}(Y, \pi^* \theta)$. Change of variables on the locus where π is an isomorphism, whose complement has Lebesgue measure zero in both

manifolds, gives $\pi_*(u \circ \pi) = u$ as distributions and $\pi_*\pi^*\theta = \theta$ as currents. Since pushforward by a proper map commutes with dd^c , we get $\pi_*T_Y = T$.

For any Borel set $B \subset X$, the coefficient measures of π_*T_Y are pushforwards of the coefficient measures of T_Y , multiplied by the smooth coefficients that arise from pulling back a test form. Restriction therefore gives $\pi_*(\mathbf{1}_{\pi^{-1}(B)}T_Y) = \mathbf{1}_B\pi_*T_Y$. Applying this to the Borel set S proves (1.44); closedness of the restricted currents is not used. $\square$

The restriction of a closed positive current to a closed complete pluripolar set is closed; the classical proof uses bounded cutoff functions. Since these cutoff functions converge pointwise to the indicator function of the complement of the pole set, the argument also applies to pole sets that are not closed.

Proposition 1.25.3 *Let X be a complex manifold of dimension $n \geq 1$, let u be quasi-plurisubharmonic on X , and let θ be a smooth real $(1, 1)$ -form. Then*

$$\text{Pol}_\theta(u) := \mathbf{1}_{\{u=-\infty\}}(\theta + \text{dd}^c u)$$

is a closed positive $(1, 1)$ -current.

Proof Locally, adding a smooth quadratic function to u and subtracting a constant gives a negative plurisubharmonic function a with pole set $S = \{u = -\infty\}$. Put $\Theta = \text{dd}^c a$. Since smooth forms give S zero mass, the polar current equals $\mathbf{1}_S\Theta$ and is positive. In dimension one it is closed for degree reasons.

Now suppose that $n \geq 2$. Choose a smooth convex nondecreasing function χ on $\mathbb{R}$ with $\chi(t) = 0$ for $t \leq 1/2$ and $\chi(1) = 1$, and a smooth function $0 \leq \vartheta \leq 1$ that vanishes near zero and equals one near one. Set

$$w_k = \chi(e^{a/k}), \quad k \geq 1.$$

These functions are bounded and plurisubharmonic, with $0 \leq w_k \leq 1$. They vanish on S and tend to one at every point outside S . Hence $\vartheta(w_k)\Theta$ converges locally, coefficientwise in total variation, to $\mathbf{1}_{X \setminus S}\Theta$. Moreover, $\vartheta'(w_k)$ vanishes on S and tends to zero everywhere.

Fix a constant strongly positive $(n-2, n-2)$ -form β and put $\Xi = \Theta \wedge \beta$. The bounded Bedford–Taylor chain rule gives

$$d(\vartheta(w_k)\Xi) = \vartheta'(w_k)dw_k \wedge \Xi.$$

Indeed, approximate w_k on a smaller ball by a decreasing sequence of smooth plurisubharmonic functions. Dominated convergence gives convergence of the corresponding ϑ -weighted currents, while the convergence of bounded Bedford–Taylor energies and the Cauchy–Schwarz inequality give convergence of the differentiated expressions; this proves the chain rule for w_k . For a smooth compactly supported test one-form α , choose a nonnegative smooth cutoff τ equal to one near its support. Since $w_k \geq 0$ and Ξ is closed and positive, bounded integration by parts gives

$$2 \int \tau \, dw_k \wedge d^c w_k \wedge \Xi \leq \int \tau \, dd^c(w_k^2) \wedge \Xi = \int w_k^2 dd^c \tau \wedge \Xi \leq C.$$

Here C depends only on the local mass of Ξ and the fixed cutoff. The Cauchy–Schwarz inequality for a positive current now yields

$$|\langle \vartheta'(w_k) \, dw_k \wedge \Xi, \alpha \rangle|^2 \leq C_\alpha \int_{\text{supp } \alpha} |\vartheta'(w_k)|^2 \Xi \wedge \kappa \longrightarrow 0,$$

where κ is the Euclidean form; the limit follows by dominated convergence with respect to the fixed locally finite trace measure. Hence $d(\vartheta(w_k)\Xi) \rightarrow 0$, and $\mathbf{1}_{X \setminus S} \Theta \wedge \beta$ is closed. Since constant strongly positive forms span all constant forms of bidegree $(n-2, n-2)$, the current $\mathbf{1}_{X \setminus S} \Theta$ is closed. Subtracting it from Θ shows that $\mathbf{1}_S \Theta$ is closed. The local currents agree on overlaps and give the asserted global current. $\square$

Chapter 2

Torsion and the variation of mass

Throughout this chapter, ω is a Hermitian form on X . If ω were closed, Stokes' theorem would make the total Monge–Ampère mass $\int_X (\omega + dd^c u)^n$ independent of the potential u . For a nonclosed Hermitian form this invariance can fail. Integration by parts expresses the mass of a smooth potential as a polynomial whose coefficients pair the potential with the complex Hessians of the powers of ω , and polarization shows that the vanishing of these Hessians is also necessary for invariance. When they do not vanish, even smooth potentials of the same singularity type can have different masses, and the usual global comparison principle fails. The masses may nevertheless remain bounded, and whether they do depends only on the manifold, not on the chosen Hermitian form.

2.1 Integration by parts with a nonclosed form

Integration by parts moves the complex Hessian of a function onto the form against which it is integrated. When that form is a power of a nonclosed $(1, 1)$ -form, its complex Hessian contains, besides the complex Hessian of the form itself, a quadratic term in its exterior derivative.

Lemma 2.1.1 *For a smooth real function f and a smooth form T of bidegree $(n-1, n-1)$,*

$$\int_X dd^c f \wedge T = \int_X f dd^c T.$$

Proof Since $d^c f$ is a one-form, $d(d^c f \wedge T) = dd^c f \wedge T - d^c f \wedge dT$, and Stokes' theorem gives the first equality in

$$\int_X dd^c f \wedge T = \int_X d^c f \wedge dT = \int_X f dd^c T.$$

For the second, recall that the integral of $d^c\sigma$ vanishes for every form σ of total degree $2n-1$, by Stokes' theorem for ∂ and $\bar{\partial}$. We apply this to $\sigma = f dT$ and use $d^c d = -dd^c$. $\square$

Lemma 2.1.2 *For a smooth real $(1, 1)$ -form θ and an integer $q \geq 1$,*

$$dd^c(\theta^q) = q \theta^{q-1} \wedge dd^c\theta + q(q-1) \theta^{q-2} \wedge d\theta \wedge d^c\theta,$$

where the second term is omitted when $q = 1$.

Proof For $q = 1$ there is nothing to prove. For $q \geq 2$, since θ has even degree, $d^c(\theta^q) = q \theta^{q-1} \wedge d^c\theta$. Applying d and using again that θ^{q-1} has even degree, we obtain

$$dd^c(\theta^q) = q(q-1) \theta^{q-2} \wedge d\theta \wedge d^c\theta + q \theta^{q-1} \wedge dd^c\theta.$$

Thus the quadratic torsion term $d\omega \wedge d^c\omega$ can make the higher powers of ω fail to be dd^c -closed even when $dd^c\omega = 0$. The mass expansion below involves the complex Hessians of all these powers separately.

2.2 The mass polynomial

For a smooth real function u on X , write $\omega_u = \omega + dd^c u$, and set

$$\mathcal{H}_\omega = \{u \in C^\infty(X, \mathbb{R}) : \omega + dd^c u > 0\}, \quad M_\omega(u) = \int_X (\omega + dd^c u)^n.$$

The set $\mathcal{H}_\omega$ of smooth strictly ω -plurisubharmonic functions is convex and open in the C^2 topology, while the mass $M_\omega(u)$ is defined for every smooth real u . Expanding it along a smooth direction gives a polynomial whose nonconstant coefficients detect the complex Hessians of the powers of the background.

Theorem 2.2.1 *For every smooth real function u ,*

$$M_\omega(u) = \int_X \omega^n + \sum_{k=1}^{n-1} \binom{n}{k} \int_X u (dd^c u)^{k-1} \wedge dd^c(\omega^{n-k}). \quad (2.1)$$

Proof Expand $(\omega + dd^c u)^n$ by the binomial theorem. The term with $k = n$ integrates to zero, since it is exact:

$$(dd^c u)^n = d(d^c u \wedge (dd^c u)^{n-1}).$$

For $1 \leq k \leq n-1$, apply **Lemma 2.1.1** with $f = u$ and $T = (dd^c u)^{k-1} \wedge \omega^{n-k}$. Since both d and d^c annihilate $dd^c u$,

$$dd^c T = (dd^c u)^{k-1} \wedge dd^c(\omega^{n-k}),$$

which gives the k th term of (2.1). When $n = 1$, the sum is empty and the mass is constant. $\square$

If every $\mathrm{dd}^c(\omega^j)$ with $1 \leq j \leq n-1$ vanishes, (2.1) shows that the mass is constant. Conversely, varying the potential in several independent directions recovers each of these forms by polarization.

Theorem 2.2.2 (Chiose) *Assume $n \geq 2$. The following conditions are equivalent:*

- (1) $\int_X (\omega + \mathrm{dd}^c u)^n$ is independent of $u \in \mathcal{H}_\omega$;
- (2) $\mathrm{dd}^c(\omega^j) = 0$ for $1 \leq j \leq n-1$;
- (3) $\mathrm{dd}^c \omega = 0$ and $\mathrm{d}\omega \wedge \mathrm{d}^c \omega = 0$.

They are also equivalent to the condition that $\int_X (\omega + \mathrm{dd}^c u)^n$ be the same for all bounded ω -plurisubharmonic functions u , where $(\omega + \mathrm{dd}^c u)^n$ is the Bedford–Taylor product of Section 1.7. Under these conditions the common mass is $\int_X \omega^n$.

Proof *Step 1: the first condition implies the second.* Let u be a smooth real function. For $|t|$ small, tu belongs to $\mathcal{H}_\omega$ for both signs of t , so the polynomial $t \mapsto \int_X (\omega + t\mathrm{dd}^c u)^n$ is constant on an interval and its nonconstant coefficients vanish. For $1 \leq j \leq n-1$ this gives

$$\int_X \omega^j \wedge (\mathrm{dd}^c u)^{n-j} = 0.$$

Replace u by a linear combination of $n-j$ smooth real functions $u_1, \dots, u_{n-j}$ and compare the coefficients of the monomial in which every parameter appears once. We obtain

$$\int_X \omega^j \wedge \mathrm{dd}^c u_1 \wedge \cdots \wedge \mathrm{dd}^c u_{n-j} = 0.$$

Integrating by parts in the first factor and using that u_1 is arbitrary, we obtain the pointwise identity

$$\mathrm{dd}^c(\omega^j) \wedge \mathrm{dd}^c u_2 \wedge \cdots \wedge \mathrm{dd}^c u_{n-j} = 0$$

for every choice of the remaining functions. At a given point, the complex Hessians of these functions can be prescribed arbitrarily: multiply a quadratic polynomial in a coordinate chart by a cutoff function equal to one near that point. Since the identity is multilinear, we may complexify it and use the quadratic monomials $z_a \bar{z}_b$. Wedge products of their complex Hessians give all coordinate forms of the complementary bidegree, and pairing with these forms shows that every coefficient of $\mathrm{dd}^c(\omega^j)$ vanishes. When $j = n-1$ there are no remaining factors, and the same conclusion follows directly from the arbitrariness of u_1 . This proves the second condition.

Step 2: the remaining equivalences for smooth potentials. The second condition implies the first by Theorem 2.2.1. For $n \geq 3$, the identities for $j = 1, 2$ and Lemma 2.1.2 give $\mathrm{dd}^c \omega = 0$ and

$$0 = \mathrm{dd}^c(\omega^2) = 2\omega \wedge \mathrm{dd}^c \omega + 2\mathrm{d}\omega \wedge \mathrm{d}^c \omega,$$

so the second condition implies the third. For $n = 2$, the second condition is $\text{dd}^c \omega = 0$, while $d\omega \wedge d^c \omega$ vanishes for degree reasons; the implication is again immediate. Conversely, [Lemma 2.1.2](#) derives all the identities of the second condition from the third.

Step 3: bounded potentials. Assume the first condition and let u be a bounded ω -plurisubharmonic function. By [Theorem 1.11.1](#), there are uniformly bounded functions $u_j \in \mathcal{H}_\omega$ decreasing to u . Their masses all equal $\int_X \omega^n$, and the continuity of the bounded products of [Section 1.7](#) along such sequences passes this common value to the limit. Conversely, every element of $\mathcal{H}_\omega$ is a bounded ω -plurisubharmonic function, so constancy for bounded potentials implies the first condition. The zero potential shows that the common mass is $\int_X \omega^n$. $\square$

In particular, a closed background has invariant mass. Under the equivalent conditions above, [\(2.1\)](#) even gives $M_\omega(u) = \int_X \omega^n$ for every smooth real u , not only for $u \in \mathcal{H}_\omega$. In dimension one the mass is always $\int_X \omega$.

The first variation of the mass involves only the complex Hessian of the power ω_u^{n-1} of the perturbed form.

Proposition 2.2.1 *For smooth real functions u, v on X ,*

$$\left. \frac{d}{dt} \right|_{t=0} M_\omega(u + tv) = n \int_X v \text{dd}^c(\omega_u^{n-1}). \quad (2.2)$$

If M_ω is constant on $\mathcal{H}_\omega$, then $\text{dd}^c(\omega_u^{n-1}) = 0$ for every $u \in \mathcal{H}_\omega$.

Proof Since $M_\omega(u + tv)$ is a polynomial in t , its derivative at $t = 0$ is

$$n \int_X \text{dd}^c v \wedge \omega_u^{n-1},$$

and [Lemma 2.1.1](#) turns this into the right-hand side of [\(2.2\)](#). For the second assertion, fix $u \in \mathcal{H}_\omega$. For every smooth real direction v , the segment $u + tv$ lies in $\mathcal{H}_\omega$ when $|t|$ is sufficiently small, so the right-hand side of [\(2.2\)](#) vanishes for all smooth real v . Hence the smooth top-degree form $\text{dd}^c(\omega_u^{n-1})$ vanishes. $\square$

Corollary 2.2.1 *If $n = 2$, then for every smooth real function u on X ,*

$$M_\omega(u) = \int_X \omega^2 + 2 \int_X u \text{dd}^c \omega.$$

Consequently, M_ω is constant on $\mathcal{H}_\omega$ if and only if $\text{dd}^c \omega = 0$.

Proof The formula is the case $n = 2$ of [\(2.1\)](#), and it shows that $\text{dd}^c \omega = 0$ implies constancy. Conversely, if the mass is constant, [Proposition 2.2.1](#) at $u = 0$ gives $\text{dd}^c \omega = 0$. $\square$

The identity $\text{dd}^c(\omega^{n-1}) = 0$ makes the first variation vanish at $u = 0$; Hermitian forms satisfying it are the Gauduchon metrics of [Chapter 4](#). On a surface this identity already gives mass invariance. In dimension three, however, [\(2.1\)](#) reads

$$M_\omega(u) = \int_X \omega^3 + 3 \int_X u \operatorname{dd}^c(\omega^2) + 3 \int_X u \operatorname{dd}^c u \wedge \operatorname{dd}^c \omega.$$

Vanishing of $\operatorname{dd}^c(\omega^2)$ removes the linear term, while $\operatorname{dd}^c \omega$ still governs the quadratic term. Thus stationarity of the mass at one potential must be distinguished from its invariance on $\mathcal{H}_\omega$; an explicit example is given in [Example 4.7.1](#).

2.3 Mass variation on a complex torus

By [Corollary 2.2.1](#), the mass on a surface varies precisely through the pairing $2 \int_X u \operatorname{dd}^c \omega$ of the potential with the complex Hessian of the background. A product of elliptic curves gives an explicit background and a family of smooth potentials for which this pairing is nonzero.

Example 2.3.1 Let $X = (\mathbb{C}/(\mathbb{Z} + i\mathbb{Z}))^2$. For $j = 1, 2$, let $z_j = x_j + iy_j$ be the standard coordinates on the universal cover $\mathbb{C}^2$, with x_j, y_j real, and put

$$\beta_j = \frac{i}{2\pi} dz_j \wedge d\bar{z}_j.$$

The forms β_j descend to X . For a real parameter t , define

$$b(x_1) = 2 + \cos(2\pi x_1), \quad \omega = \beta_1 + b(x_1)\beta_2, \quad u_t = t \cos(2\pi x_1).$$

Since $1 \leq b \leq 3$, the form ω is Hermitian. It is not closed, because $d\omega = db \wedge \beta_2$ is not identically zero.

For a function f of x_1 alone, one has $\operatorname{dd}^c f = (f''/4)\beta_1$, where the prime denotes differentiation in x_1 . Hence

$$\omega_{u_t} = (1 - \pi^2 t \cos(2\pi x_1))\beta_1 + b\beta_2 > 0 \quad \text{if } |t| < \pi^{-2}.$$

Writing $B = \int_X \beta_1 \wedge \beta_2 > 0$, we have

$$M_\omega(u_t) = (4 - \pi^2 t)B. \tag{2.3}$$

Indeed,

$$\omega_{u_t}^2 = 2(1 - \pi^2 t \cos(2\pi x_1))(2 + \cos(2\pi x_1))\beta_1 \wedge \beta_2,$$

and over a period the average of $\cos(2\pi x_1)$ is zero while that of its square is $1/2$.

Although the complex torus is Kähler, the background ω chosen above is not closed, and this already allows the mass to vary. On non-Kähler manifolds even an upper bound for the mass can fail; the Hopf manifolds of [Chapter 8](#) give examples.

Corollary 2.3.1 *In general, the total Monge–Ampère mass is not determined by the ordinary singularity type or by the multiplier ideals, even among smooth strictly ω -plurisubharmonic potentials.*

Proof The potentials u_t of [Example 2.3.1](#) are smooth on the compact manifold X , so any two of them differ by a bounded function and have the same singularity type in the sense of [Section 1.12](#). For the same reason, their multiplier ideals are the structure sheaf for every positive multiple of the weight. By [\(2.3\)](#), their masses differ. $\square$

2.4 Comparison and mass invariance

The global comparison principle of Kähler geometry compares the Monge–Ampère measures of two potentials on the set where one lies below the other. Adding a constant to a potential leaves its Monge–Ampère measure unchanged, and after a large constant shift this set becomes the whole manifold. Such an inequality would therefore compare total masses, and the varying mass of [Example 2.3.1](#) rules it out.

Proposition 2.4.1 *Suppose that every pair $u, v \in \mathcal{H}_\omega$ satisfies*

$$\int_{\{u < v\}} \omega_v^n \leq \int_{\{u < v\}} \omega_u^n. \quad (2.4)$$

Then M_ω is constant on $\mathcal{H}_\omega$.

Proof Fix $u, v \in \mathcal{H}_\omega$. By compactness there is a constant C such that $u < v + C$ everywhere. Since $\omega_{v+C} = \omega_v$, applying [\(2.4\)](#) to u and $v + C$ gives $M_\omega(v) \leq M_\omega(u)$. Exchanging the roles of u and v gives the opposite inequality. $\square$

Corollary 2.4.1 *The inequality [\(2.4\)](#) does not hold for every Hermitian form on a compact complex manifold.*

Proof Let X , ω , u_t and $B = \int_X \beta_1 \wedge \beta_2$ be as in [Example 2.3.1](#). For $-\pi^{-2} < t < 0$, set $u = 0$ and $v = u_t + C$ with $C > |t|$. Then $\{u < v\} = X$, but

$$\int_X \omega_v^2 = (4 - \pi^2 t)B > 4B = \int_X \omega_u^2.$$

Thus this pair violates [\(2.4\)](#). $\square$

The modified comparison principle of [Theorem 10.2.1](#) compensates for the derivatives of the background. Conversely, under the equivalent conditions of [Theorem 2.2.2](#), the ordinary comparison principle holds for bounded potentials, by [Theorem 11.5.2](#).

2.5 Uniform mass bounds

Although the mass varies, it may remain bounded. Set

$$\bar{v}_{\text{sm}}(\omega) = \sup_{u \in \mathcal{H}_\omega} M_\omega(u) \in (0, +\infty],$$

the supremum of the masses of smooth strictly ω -plurisubharmonic potentials. Comparing two Hermitian forms and rescaling the potentials shows that the finiteness of this supremum depends only on X .

Proposition 2.5.1 *If η is another Hermitian form and $\omega \leq C\eta$ for a constant $C > 0$, then*

$$\bar{v}_{\text{sm}}(\omega) \leq C^n \bar{v}_{\text{sm}}(\eta).$$

In particular, finiteness of $\bar{v}_{\text{sm}}$ is independent of the Hermitian form.

Proof Let $u \in \mathcal{H}_\omega$. Since $C\eta + \text{dd}^c u \geq \omega + \text{dd}^c u > 0$, the function u/C belongs to $\mathcal{H}_\eta$. The top exterior power is monotone on positive $(1, 1)$ -forms: for positive Hermitian matrices $A \leq B$, all eigenvalues of $A^{-1/2}BA^{-1/2}$ are at least one, so $\det A \leq \det B$. Applying this pointwise gives

$$\int_X (\omega + \text{dd}^c u)^n \leq C^n \int_X (\eta + \text{dd}^c (u/C))^n \leq C^n \bar{v}_{\text{sm}}(\eta).$$

Taking the supremum over u proves the inequality. Since any two Hermitian forms on the compact manifold X are comparable in both directions, the last assertion follows. $\square$

Chapter 3

Monge–Ampère energy and torsion

Throughout this chapter, ω is a Hermitian form on X , and $\omega_u = \omega + \text{dd}^c u$ and the space $\mathcal{H}_\omega$ of smooth strictly ω -plurisubharmonic functions are as in [Chapter 2](#).

For a Kähler form, the Monge–Ampère operator is the gradient of an energy: there is a functional on $\mathcal{H}_\omega$ whose derivative at u in every smooth real direction v is $\int_X v \omega_u^n$. For a Hermitian form, such a primitive exists exactly when ω is closed. Symmetry of its mixed second derivatives first forces $d(\omega_u^{n-1}) = 0$, and varying the potential then forces $d\omega = 0$; this is stronger than the mass invariance of [Chapter 2](#). For a nonclosed background, integrating the Monge–Ampère one-form along radial segments still defines a functional, and its first variation shows which torsion terms enter the corresponding Euler equation. A different energy is available for Hermitian symplectic forms on fourfolds: along potential variations, this completion energy changes by minus the change of the volume. It is therefore constant along potential variations exactly when the mass is invariant, although even then the Monge–Ampère one-form has no primitive unless ω is closed.

3.1 Primitives of the Monge–Ampère one-form

On $\mathcal{H}_\omega$ consider the *Monge–Ampère one-form*

$$\alpha_u(v) = \int_X v \omega_u^n, \quad v \in C^\infty(X, \mathbb{R}).$$

Let $U \subseteq \mathcal{H}_\omega$ be open in the C^2 topology on smooth functions. A *primitive* of α on U is a functional E on U such that, for every $u \in U$ and every smooth real direction v , the directional derivative

$$DE_u(v) = \left. \frac{d}{dt} \right|_{t=0} E(u + tv)$$

exists and equals $\alpha_u(v)$. Restrict E to the intersection of U with a finite-dimensional affine plane. Its first derivatives are values of α , which depend smoothly on the parameters, so its mixed second derivatives agree. The following integration-by-parts criterion identifies the differential condition imposed by this symmetry.

Lemma 3.1.1 *For a smooth real $(n-1, n-1)$ -form Ω , the pairing $B(v, w) = \int_X w dd^c v \wedge \Omega$ is symmetric on smooth real functions if and only if $d\Omega = 0$.*

Proof By Lemma 2.1.1, $B(v, w) = \int_X v dd^c(w\Omega)$. Since v is arbitrary, symmetry is therefore equivalent to the pointwise identity

$$dd^c(w\Omega) - dd^c w \wedge \Omega = w dd^c \Omega + dw \wedge d^c \Omega - d^c w \wedge d\Omega = 0$$

for every smooth real w . Taking $w = 1$ gives $dd^c \Omega = 0$. The remaining expression is linear in the first jet of w , so we may complexify the test functions. At a chosen point, take a holomorphic linear function multiplied by a cutoff function, so that $\partial w = \lambda$ is an arbitrary $(1, 0)$ -covector and $\bar{\partial} w = 0$ at that point. There the first-order expression equals

$$\frac{i}{2\pi} (\partial w \wedge \bar{\partial} \Omega - \bar{\partial} w \wedge \partial \Omega).$$

It follows that $\lambda \wedge \bar{\partial} \Omega = 0$ for every $(1, 0)$ -covector λ . Since the wedge pairing between $(1, 0)$ -covectors and forms of bidegree $(n-1, n)$ is nondegenerate, $\bar{\partial} \Omega = 0$, and $\partial \Omega = 0$ because Ω is real. Conversely, if $d\Omega = 0$, then $\partial \Omega = \bar{\partial} \Omega = 0$ by type, so $d^c \Omega = 0$, and the same product formula proves symmetry. $\square$

Lemma 3.1.2 *Let T be a form of type $(2, 1) + (1, 2)$ on a complex vector space of dimension $n \geq 2$. If $T \wedge A^{n-2} = 0$ for every real $(1, 1)$ -form A in an open neighborhood of a positive form, then $T = 0$.*

Proof For $n = 2$ the assertion is immediate. Otherwise the expression $T \wedge A^{n-2}$ is polynomial in the real coefficients of A , so it vanishes for every real $(1, 1)$ -form A . Polarization and then complexification give $T \wedge A_1 \wedge \cdots \wedge A_{n-2} = 0$ for arbitrary complex $(1, 1)$ -forms A_j , and such products span all forms of bidegree $(n-2, n-2)$.

Since these wedges preserve type, the identity holds separately for the two type components of T . Wedging the identity for $T^{2,1}$ with arbitrary $(0, 1)$ -covectors, we obtain test forms spanning bidegree $(n-2, n-1)$, which pairs perfectly with bidegree $(2, 1)$ into top degree. Thus $T^{2,1} = 0$. The component $T^{1,2}$ is treated in the same way with $(1, 0)$ -covectors. $\square$

Theorem 3.1.1 *For $n \geq 2$, the one-form α has a primitive on $\mathcal{H}_\omega$ if and only if $d\omega = 0$. In fact, a primitive on a C^2 -open neighborhood of 0 already forces $d\omega = 0$.*

Proof Suppose that a primitive E exists on such a neighborhood U . For $u \in U$ and smooth real directions v, w , the mixed second derivatives of $(s, t) \mapsto E(u + sv + tw)$ at the origin agree. After division by n , this equality reads

$$\int_X w \operatorname{dd}^c v \wedge \omega_u^{n-1} = \int_X v \operatorname{dd}^c w \wedge \omega_u^{n-1}. \quad (3.1)$$

By [Lemma 3.1.1](#),

$$0 = d(\omega_u^{n-1}) = (n-1)d\omega \wedge (\omega + \operatorname{dd}^c u)^{n-2}.$$

Fix a point x . A real quadratic polynomial in local coordinates, multiplied by a cutoff function equal to one near x , realizes any prescribed real $(1, 1)$ -form H as $\operatorname{dd}^c u(x)$. These functions can be chosen to depend linearly on H , with global C^2 norms bounded by a fixed constant times the coefficient norm of H . Thus every sufficiently small H is realized by a potential in U , and the preceding identity holds at x with $\omega(x) + H$ ranging over an open neighborhood of the positive form $\omega(x)$. Applying [Lemma 3.1.2](#) with $T = d\omega(x)$, we conclude that $d\omega(x) = 0$.

Since x was arbitrary, $d\omega = 0$. Conversely, [Proposition 3.2.1](#) below constructs a primitive for a closed background. $\square$

In dimension one every real $(1, 1)$ -form is closed, and [Proposition 3.2.1](#) always gives a primitive. For $n \geq 2$, the symmetry condition at a single potential u is $d(\omega_u^{n-1}) = 0$; the theorem uses it on an open set of potentials. Mass invariance alone does not suffice. Indeed, let X be a compact complex surface admitting no Kähler metric, and let ω be a Gauduchon form on X , that is, $\operatorname{dd}^c \omega = 0$ ([Definition 4.1.1](#)); such forms exist by [Theorem 4.1.1](#). The mass of ω is constant by [Corollary 2.2.1](#), but ω is not closed, so its Monge–Ampère one-form has no primitive.

3.2 Radial energy and closed backgrounds

Integrating the Monge–Ampère one-form along the segment from 0 to u defines a functional for an arbitrary background. Let θ be a smooth real $(1, 1)$ -form on X . For $u \in C^\infty(X, \mathbb{R})$, put $\theta_u = \theta + \operatorname{dd}^c u$ and define the *radial energy*

$$\begin{aligned} E_\theta(u) &= \int_0^1 \int_X u(\theta + t \operatorname{dd}^c u)^n dt \\ &= \frac{1}{n+1} \sum_{j=0}^n \int_X u \theta_u^j \wedge \theta^{n-j}. \end{aligned} \quad (3.2)$$

To obtain the second expression, write $\theta + t \operatorname{dd}^c u = (1-t)\theta + t\theta_u$, expand, and use

$$\binom{n}{j} \int_0^1 t^j (1-t)^{n-j} dt = \frac{1}{n+1}.$$

We write $DE_{\theta,u}(v)$ for the derivative of E_θ at u in the direction v . When θ is closed, integration by parts makes the derivatives of the mixed terms telescope.

Proposition 3.2.1 *If $d\theta = 0$, then $DE_{\theta,u}(v) = \int_X v\theta_u^n$ for every pair of smooth real functions u, v .*

Proof Differentiate the finite sum in (3.2). The term indexed by j contributes

$$\int_X v\theta_u^j \wedge \theta^{n-j} + j \int_X u d d^c v \wedge \theta_u^{j-1} \wedge \theta^{n-j},$$

the second summand being absent for $j = 0$. For $j \geq 1$, the form $\theta_u^{j-1} \wedge \theta^{n-j}$ is closed, so by Lemma 3.1.1 we may interchange u and v in the second summand. Using $dd^c u = \theta_u - \theta$, we can then write the contribution of the term with $j \geq 1$ as

$$(j+1) \int_X v\theta_u^j \wedge \theta^{n-j} - j \int_X v\theta_u^{j-1} \wedge \theta^{n-j+1}.$$

Together with the contribution $\int_X v\theta^n$ of the term $j = 0$, these expressions telescope to $(n+1) \int_X v\theta_u^n$. Dividing by $n+1$ completes the proof. $\square$

Thus, when $d\omega = 0$, the restriction of E_ω to $\mathcal{H}_\omega$ is the primitive required in Theorem 3.1.1.

3.3 First variation in a nonclosed background

For the Hermitian background $\theta = \omega$, the functional (3.2) integrates α along the segment from 0 to $u \in \mathcal{H}_\omega$. When ω is not closed, the derivative of E_ω differs from α by the terms produced when integration by parts differentiates the background powers. Computing this difference gives the Euler equation of E_ω even when no primitive exists.

Proposition 3.3.1 *For $u \in \mathcal{H}_\omega$ and $v \in C^\infty(X, \mathbb{R})$, put $\Omega_t = (\omega + tdd^c u)^{n-1}$ for $0 \leq t \leq 1$. Then*

$$DE_{\omega,u}(v) - \int_X v\omega_u^n = n \int_0^1 t \int_X v (u d d^c \Omega_t + du \wedge d^c \Omega_t - d^c u \wedge d \Omega_t) dt. \quad (3.3)$$

Proof Differentiating the radial integral in (3.2) in the direction v gives

$$DE_{\omega,u}(v) = \int_0^1 \left(\int_X v(\omega + tdd^c u)^n + nt \int_X u d d^c v \wedge \Omega_t \right) dt.$$

On the other hand,

$$\begin{aligned}
\int_X v \omega_u^n &= \int_0^1 \frac{d}{dt} \left(t \int_X v(\omega + t \operatorname{dd}^c u)^n \right) dt \\
&= \int_0^1 \left(\int_X v(\omega + t \operatorname{dd}^c u)^n + nt \int_X v \operatorname{dd}^c u \wedge \Omega_t \right) dt.
\end{aligned}$$

The terms without a factor nt cancel in the difference, leaving

$$\begin{aligned}
DE_{\omega,u}(v) - \int_X v \omega_u^n &= n \int_0^1 t \int_X (u \operatorname{dd}^c v - v \operatorname{dd}^c u) \wedge \Omega_t dt \\
&= n \int_0^1 t \int_X v (\operatorname{dd}^c(u \Omega_t) - \operatorname{dd}^c u \wedge \Omega_t) dt.
\end{aligned}$$

The second equality is [Lemma 2.1.1](#). Expanding the last parenthesis by the product rule in the proof of [Lemma 3.1.1](#) gives (3.3). When $n = 1$, one has $\Omega_t = 1$ and the right-hand side vanishes. $\square$

Proposition 3.3.2 *If $n = 2$, then every $u \in \mathcal{H}_\omega$ satisfies*

$$E_\omega(u) = \int_X u \omega^2 + \int_X u \omega \wedge \operatorname{dd}^c u + \frac{1}{3} \int_X u (\operatorname{dd}^c u)^2.$$

For every smooth real direction v , its differential satisfies

$$DE_{\omega,u}(v) - \int_X v \omega_u^2 = \int_X v (u \operatorname{dd}^c \omega + du \wedge \operatorname{d}^c \omega - \operatorname{d}^c u \wedge d\omega). \quad (3.4)$$

Proof Expanding the radial integral gives the first identity. For $n = 2$, one has $\Omega_t = \omega + t \operatorname{dd}^c u$, and since d and d^c annihilate $\operatorname{dd}^c u$, the derivatives $d\Omega_t$, $\operatorname{d}^c \Omega_t$ and $\operatorname{dd}^c \Omega_t$ are those of ω . Formula (3.3) and $2 \int_0^1 t dt = 1$ give the second identity. $\square$

Consequently, if $n = 2$ and μ is a fixed smooth real $(2, 2)$ -form on X , a critical point $u \in \mathcal{H}_\omega$ of the functional $E_\omega(u) - \int_X u \mu$ satisfies

$$\omega_u^2 + u \operatorname{dd}^c \omega + du \wedge \operatorname{d}^c \omega - \operatorname{d}^c u \wedge d\omega = \mu$$

rather than the Monge–Ampère equation $\omega_u^2 = \mu$. On a Gauduchon surface the term $u \operatorname{dd}^c \omega$ vanishes, but the first-order torsion terms can persist. The radial Euler equation can therefore differ from the Monge–Ampère equation even when the total mass is invariant.

3.4 Symplectic completions and potential variations

The radial energy is built from the Monge–Ampère one-form, and its first variation exhibits the torsion of the background. When a Hermitian form is the $(1, 1)$ -part of a closed real two-form, there is another natural energy: the squared L^2 norm of the

smallest $(2, 0)$ -part needed to close it. In complex dimension four, adding a complex Hessian to the form changes this energy by minus the change of the volume. Its potential variations are therefore governed by the volume, and not by a primitive of the Monge–Ampère one-form.

Throughout this section we assume $n = 4$. A Hermitian form ω is *Hermitian symplectic* if there is a smooth $(2, 0)$ -form ρ , called a *completion* of ω , such that

$$\partial\rho = 0, \quad \bar{\partial}\rho = -\partial\omega.$$

Equivalently, the real two-form $\omega + \rho + \bar{\rho}$ is closed. Applying $\bar{\partial}$ to the second equation shows that ω is pluriclosed, meaning $\text{dd}^c\omega = 0$. Two completions differ by a closed holomorphic $(2, 0)$ -form, so the completions of ω form an affine space over the finite-dimensional space of closed holomorphic $(2, 0)$ -forms. The quadratic norm

$$\|\rho\|_{L^2(\omega)}^2 = \frac{1}{2} \int_X \rho \wedge \bar{\rho} \wedge \omega^2$$

is positive definite on $(2, 0)$ -forms, and minimizing it over this affine space gives a unique *canonical completion* ρ_ω . It is characterized by being orthogonal to every closed holomorphic $(2, 0)$ -form. Define the *completion energy* and the volume of ω by

$$F(\omega) = \|\rho_\omega\|_{L^2(\omega)}^2, \quad V(\omega) = \frac{1}{4!} \int_X \omega^4.$$

The completion energy is nonnegative and vanishes exactly when ω is Kähler: a zero canonical completion forces $\partial\omega = 0$, while a closed ω has the zero completion.

Since ω is pluriclosed, it defines an Aeppli cohomology class, whose real $(1, 1)$ -representatives are the forms $\omega + \partial\bar{\tau} + \bar{\partial}\tau$, with τ a smooth $(1, 0)$ -form. We call a real form $\psi = \partial\bar{\tau} + \bar{\partial}\tau$ an *Aeppli variation*. If ρ completes ω and $\omega + t\psi$ is positive for a real t , then $\omega + t\psi$ has the completion $\rho + t\partial\tau$. In particular, the positive representatives $\omega + \partial\bar{\tau} + \bar{\partial}\tau > 0$ of the Aeppli class of ω are again Hermitian symplectic. Every positive potential variation $\omega + \text{dd}^c\varphi$ belongs to this class and has the same exterior derivative as ω . We write $DF_\omega(\psi)$ for the derivative of $t \mapsto F(\omega + t\psi)$ at $t = 0$.

Lemma 3.4.1 *Let ω be Hermitian symplectic, with canonical completion $\rho = \rho_\omega$. Every Aeppli variation $\psi = \partial\bar{\tau} + \bar{\partial}\tau$ satisfies*

$$DF_\omega(\psi) = \int_X \left(\text{Re}(\partial\tau \wedge \bar{\rho} \wedge \omega^2) + \rho \wedge \bar{\rho} \wedge \psi \wedge \omega \right). \quad (3.5)$$

Proof The canonical completion of $\omega + t\psi$ is $\rho + t\partial\tau - h(t)$, where $h(t)$ is a closed holomorphic $(2, 0)$ -form and $h(0) = 0$. In a fixed basis of these holomorphic forms, the orthogonal projection defining $h(t)$ solves a positive definite Gram system whose coefficients are smooth in t . Since ρ is orthogonal to closed holomorphic $(2, 0)$ -forms, the contribution of $h'(0)$ to the first derivative of the squared norm vanishes. We may therefore differentiate using the completion $\rho + t\partial\tau$. Differentiating its two factors and the factor $(\omega + t\psi)^2/2$ gives the formula. $\square$

Proposition 3.4.1 *Let ω be Hermitian symplectic. For every smooth real function φ with $\omega_\varphi = \omega + \text{dd}^c \varphi > 0$, one has $\rho_{\omega_\varphi} = \rho_\omega$ and*

$$F(\omega_\varphi) + V(\omega_\varphi) = F(\omega) + V(\omega). \quad (3.6)$$

Moreover, $DF_\omega(\text{dd}^c \varphi) = 0$ for every smooth real φ if and only if $\text{dd}^c(\omega^3) = 0$. Thus a critical point of F in its Aeppli class is Gauduchon.

Proof Fix any completion ζ of ω and put $\Theta_\zeta = \omega + \zeta + \bar{\zeta}$. Expansion by type gives

$$\frac{1}{4!} \int_X \Theta_\zeta^4 = V(\omega) + \frac{1}{2} \int_X \zeta \wedge \bar{\zeta} \wedge \omega^2 + \frac{1}{4} \int_X \zeta^2 \wedge \bar{\zeta}^2.$$

Since $\partial\omega_\varphi = \partial\omega$, the forms ω_φ and ω have the same completions. With ζ fixed, replacing ω by ω_φ changes the closed form Θ_ζ by an exact form, so the integral on the left is unchanged; so is the last integral on the right, which does not involve ω . Hence

$$\|\zeta\|_{L^2(\omega_\varphi)}^2 - \|\zeta\|_{L^2(\omega)}^2 = V(\omega) - V(\omega_\varphi).$$

This difference is independent of ζ , so the two norms have the same minimizer, which gives $\rho_{\omega_\varphi} = \rho_\omega$ and (3.6). Differentiating at $t = 0$ along $\omega + t\text{dd}^c \varphi$ and using Lemma 2.1.1, we obtain

$$DF_\omega(\text{dd}^c \varphi) = -\frac{1}{6} \int_X \varphi \text{dd}^c(\omega^3).$$

Since φ is arbitrary, this proves the remaining assertions. $\square$

The *positive index* of a real quadratic form on a real vector space is the supremum of the dimensions of the finite-dimensional subspaces on which it is positive definite; the *negative index* is defined in the same way. Thus the positive index is infinite when the form is positive definite on subspaces of arbitrarily large finite dimension.

Theorem 3.4.1 *Let ω be Hermitian symplectic, and let H_ω be the Hessian of F at ω along the affine space of real representatives of the Aeppli class of ω , so that $H_\omega(\psi, \psi)$ is the second derivative of $t \mapsto F(\omega + t\psi)$ at $t = 0$. If $\text{dd}^c(\omega^2) \neq 0$, the restriction of H_ω to potential directions $\psi = \text{dd}^c \varphi$ has infinite positive and negative index. If $\text{dd}^c(\omega^2) = 0$, then $F(\omega + \text{dd}^c \varphi) = F(\omega)$ whenever $\omega + \text{dd}^c \varphi > 0$. Consequently, every local minimum of F in an Aeppli class satisfies $\text{dd}^c(\omega^2) = 0$.*

Proof *Step 1: the Hessian formula.* Pluriclosedness and Stokes' theorem give $\int_X \omega \wedge (\text{dd}^c \varphi)^3 = \int_X (\text{dd}^c \varphi)^4 = 0$. Thus the volume and, by (3.6), the energy along a potential line $t \mapsto \omega + t\text{dd}^c \varphi$ are polynomials of degree at most two in t . Differentiating twice and integrating by parts, we obtain

$$\begin{aligned} H_\omega(\text{dd}^c \varphi, \text{dd}^c \varphi) &= -\frac{1}{2} \int_X \omega^2 \wedge (\text{dd}^c \varphi)^2 \\ &= \frac{1}{2} \int_X \text{dd}^c(\omega^2) \wedge d\varphi \wedge d^c \varphi. \end{aligned} \quad (3.7)$$

For the second equality, apply [Lemma 2.1.1](#) once and then use the identity $\text{dd}^c(\varphi^2/2) = \varphi \text{dd}^c \varphi + d\varphi \wedge d^c \varphi$ against the closed form $\text{dd}^c(\omega^2)$.

Step 2: both indices are infinite if $\text{dd}^c(\omega^2) \neq 0$. Put $\Psi = \text{dd}^c(\omega^2)$. At each point, $\xi \mapsto \Psi \wedge i\xi \wedge \bar{\xi}$, divided by a positive volume form, is a Hermitian quadratic form in the $(1, 0)$ -covector ξ , and these quadratic forms determine Ψ . Their traces with respect to ω are positive multiples of the density $\Psi \wedge \omega$, whose integral vanishes by Stokes' theorem and $\text{dd}^c \omega = 0$. If the quadratic forms took no strictly positive value, they would be negative semidefinite everywhere, with nonpositive traces of integral zero; the traces, and hence Ψ , would vanish identically. The same argument applies with the signs reversed. Therefore, if $\Psi \neq 0$, the quadratic forms take a strictly positive value somewhere and a strictly negative value somewhere.

Fix one of the two signs. Choose holomorphic coordinates on a ball such that, with $x = \text{Re } z_1$, the density $\Psi \wedge dx \wedge d^c x$ has that sign on the ball; this is possible because $dx \wedge d^c x$ is a positive multiple of $i dz_1 \wedge d\bar{z}_1$. For a nonzero real cutoff function a supported in the ball, set $\varphi_N = a \cos(Nx)$. Formula [\(3.7\)](#) gives

$$H_\omega(\text{dd}^c \varphi_N, \text{dd}^c \varphi_N) = \frac{N^2}{2} \int_X a^2 \sin^2(Nx) \Psi \wedge dx \wedge d^c x + O(N),$$

where the constant in $O(N)$ depends on Ψ , the chart and the cutoff, but not on N . By integration by parts in x , the integral tends to half the same integral without the factor $\sin^2(Nx)$. Hence the Hessian has the chosen sign for large N . For a positive integer k , apply this construction on k disjoint smaller balls in that region. By the local integral formula, the resulting nonzero directions are linearly independent and pairwise orthogonal for the Hessian, so their span is a k -dimensional subspace on which H_ω is definite of the chosen sign. Repeating the argument with the opposite sign proves that both indices are infinite. Each finite-dimensional span admits sufficiently small variations preserving positivity.

Step 3: flatness if $\text{dd}^c(\omega^2) = 0$. If $\Psi = 0$, [Lemma 2.1.2](#) and pluriclosedness give $\text{dd}^c(\omega^3) = 3\omega \wedge \Psi = 0$. Both derivatives at $t = 0$ of the quadratic polynomial $t \mapsto F(\omega + t \text{dd}^c \varphi)$ vanish, so it is constant on the interval of t for which $\omega + t \text{dd}^c \varphi > 0$. This interval contains 0 and 1 whenever $\omega + \text{dd}^c \varphi > 0$. Finally, a local minimum cannot have a potential direction along which the Hessian is negative, so it satisfies $\text{dd}^c(\omega^2) = 0$ by Step 2. $\square$

Corollary 3.4.1 *For a Hermitian symplectic form ω on X , the following conditions are equivalent:*

- (1) $F(\omega + \text{dd}^c \varphi)$ is independent of the smooth real function φ with $\omega + \text{dd}^c \varphi > 0$;
- (2) $\text{dd}^c(\omega^2) = 0$;
- (3) $\int_X (\omega + \text{dd}^c u)^4$ is independent of the bounded ω -plurisubharmonic function u .

The common mass in the third condition is $24V(\omega)$. Every local minimum of F in an Aeppli class has these properties.

Proof By (3.6), the energy is constant along smooth positive potential variations if and only if their volume is. Since $\text{dd}^c \omega = 0$, Lemma 2.1.2 and Theorem 2.2.2 show that this smooth mass invariance is equivalent to $\text{dd}^c(\omega^2) = 0$ and to mass invariance for bounded potentials. The zero potential gives the common mass. The last assertion follows from Theorem 3.4.1. $\square$

3.4.1 Completion energy on products of complex tori

Products of two complex two-tori give explicit Hermitian symplectic forms in both regimes of Theorem 3.4.1. Each factor carries a nonclosed form with an explicit completion. If both factors carry such a form, the product is critical for F under every Aeppli variation although its potential Hessian is indefinite. If only one factor does, the energy is constant along potential variations but varies in the Aeppli class.

Consider the square complex two-torus $S = \mathbb{C}^2 / (\mathbb{Z} + i\mathbb{Z})^2$. Let $z_j = x_j + iy_j$ be the coordinates on its cover and put $\eta = i \sum_{j=1}^2 dz_j \wedge d\bar{z}_j$. For $0 < s < 1$, the periodic forms

$$v_s = \frac{s}{\pi} e^{2\pi i x_1} dz_2, \quad \alpha_s = \eta + \partial \bar{v}_s + \bar{\partial} v_s$$

are well defined on S . The Hermitian matrix of α_s with respect to the forms $i dz_j \wedge d\bar{z}_k$ is

$$\begin{pmatrix} 1 & -se^{-2\pi i x_1} \\ -se^{2\pi i x_1} & 1 \end{pmatrix},$$

with eigenvalues $1 - s$ and $1 + s$, so α_s is a Hermitian form. It has the completion $\rho_s = \partial v_s = i s e^{2\pi i x_1} dz_1 \wedge dz_2$, and with $\mu_0 = \eta^2/2$,

$$\frac{\alpha_s^2}{2} = (1 - s^2)\mu_0, \quad \rho_s \wedge \bar{\rho}_s = s^2\mu_0.$$

Example 3.4.1 On $X = S \times S$, let ω be the sum of the pullbacks of $\alpha_{1/\sqrt{2}}$ from the two factors. This form is Hermitian symplectic but not Kähler, and it is critical for F under every Aeppli variation, including those with mixed factor components. If $V_0 = \int_S \mu_0$, then $F(\omega) = V_0^2/2 > 0$. The potential Hessian of F at ω has infinite positive and negative index, even though potential variations preserve $d\omega$.

Proof Denote the two factor forms by α_i, ρ_i , and put $\mu_i = \alpha_i^2/2$ and $v_i = \rho_i \wedge \bar{\rho}_i$; we suppress pullbacks from the notation. Every holomorphic form on a complex torus has

constant coefficients. On each factor, the L^2 pairing of $\rho_i = \partial v_i$ with a holomorphic two-form is a multiple of their wedge pairing, which vanishes by Stokes' theorem. On the product, pure and mixed two-forms are pointwise orthogonal, and the pairing with a pure-factor form is the vanishing pairing on that factor times the volume of the other factor. Thus $\rho = \rho_1 + \rho_2$ is the canonical completion of ω . Since $\mu_i = v_i$ is half the pullback of μ_0 , expansion gives $F(\omega) = \int_X (v_1 \wedge \mu_2 + \mu_1 \wedge v_2) = V_0^2/2$.

Put $\Theta_i = \alpha_i + \rho_i + \bar{\rho}_i$ and let $\Theta = \Theta_1 + \Theta_2$, which is closed. For an arbitrary real $(1, 1)$ -form ψ and $(2, 0)$ -form σ on X , expansion on the two factors gives

$$\operatorname{Re}(\sigma \wedge \bar{\rho} \wedge \omega^2) + \rho \wedge \bar{\rho} \wedge \psi \wedge \omega = \frac{1}{12}(\psi + \sigma + \bar{\sigma}) \wedge \Theta^3.$$

Indeed, the mixed components of ψ and σ have odd degree on both factors and contribute zero. The pure components on the left give $(\psi + \sigma + \bar{\sigma}) \wedge (\Theta_1 \wedge \mu_2 + \Theta_2 \wedge \mu_1)$, and since $\Theta_i^2 = 4\mu_i$, the cube on the right is twelve times the same complementary form. Apply [Lemma 3.4.1](#) with $\psi = \partial\bar{\tau} + \bar{\partial}\tau$ and $\sigma = \partial\tau$. The derivative is $\frac{1}{12} \int_X d(\tau + \bar{\tau}) \wedge \Theta^3 = 0$, since Θ is closed. This proves criticality under every Aeppli variation.

Each $\partial\alpha_i = -\bar{\partial}\rho_i$ is nonzero, so ω is not Kähler. In $\partial\omega \wedge \bar{\partial}\omega$, the terms coming from a single factor vanish for dimension reasons, while the two cross terms are nonzero and have different bidegrees on the factors, so they cannot cancel. Hence $d\omega \wedge d^c\omega \neq 0$, and since $dd^c\omega = 0$, [Lemma 2.1.2](#) gives $dd^c(\omega^2) \neq 0$. It remains to apply [Theorem 3.4.1](#). $\square$

If only one factor carries a nonclosed form, the energy becomes constant along potential variations, while the same explicit family shows that it still varies in the Aeppli class.

Example 3.4.2 For $0 < s < 1$, let $\widehat{\omega}_s$ on $X = S \times S$ be the sum of the pullbacks of α_s from the first factor and of η from the second, and set $V_0 = \int_S \mu_0$. Then $d\widehat{\omega}_s \neq 0$ and

$$F(\widehat{\omega}_s) = s^2 V_0^2, \quad V(\widehat{\omega}_s) = (1 - s^2) V_0^2.$$

The energy is constant on all positive smooth potential variations of $\widehat{\omega}_s$, and every bounded $\widehat{\omega}_s$ -plurisubharmonic function has mass $24(1 - s^2)V_0^2$. The form $\widehat{\omega}_s$ is not a critical point of F in its Aeppli class, and its Monge–Ampère one-form has no primitive on any C^2 -open neighborhood of zero.

Proof The pullback of ρ_s from the first factor is a completion of $\widehat{\omega}_s$. It is canonical: pure and mixed holomorphic two-forms are orthogonal for the product metric, and its pairing with pure-factor forms vanishes by the Stokes argument in the proof of [Example 3.4.1](#). The energy is therefore $\int_X \rho_s \wedge \bar{\rho}_s \wedge \eta^2/2 = s^2 V_0^2$. The volume is the product of the two surface volumes, which gives the second formula.

The exterior derivatives of $\widehat{\omega}_s$ come entirely from the first factor. Their wedge product $d\widehat{\omega}_s \wedge d^c\widehat{\omega}_s$ vanishes for degree reasons, while $dd^c\widehat{\omega}_s = 0$. Thus $dd^c(\widehat{\omega}_s^2) = 0$ by [Lemma 2.1.2](#), and [Corollary 3.4.1](#) gives the constancy of the energy and the common bounded mass.

The forms $\widehat{\omega}_{(1+t)s}$ are positive for small $|t|$ and lie in the Aeppli class of $\widehat{\omega}_s$, since $v_{(1+t)s} = (1+t)v_s$. The derivative of their energy at $t = 0$ is $2s^2V_0^2 > 0$, so $\widehat{\omega}_s$ is not a critical point in its Aeppli class. Finally, $\partial\alpha_s = -\bar{\partial}\rho_s \neq 0$. Hence $d\widehat{\omega}_s \neq 0$, and **Theorem 3.1.1** shows that no primitive exists. $\square$

Chapter 4

Gauduchon metrics and linear mass

Throughout this chapter, ω is a fixed Hermitian form on X , and $n \geq 2$ unless a section specifies another setting.

By [Chapter 2](#), the Monge–Ampère mass of a potential need not be determined by a nonclosed background. A linear quantity survives. If γ is a Gauduchon metric, that is, a Hermitian form with $\text{dd}^c(\gamma^{n-1}) = 0$, and if u is θ -plurisubharmonic for a smooth real $(1, 1)$ -form θ , then $\int_X (\theta + \text{dd}^c u) \wedge \gamma^{n-1}$ depends only on θ . Gauduchon’s theorem produces such metrics in every conformal class, and these pairings, the Gauduchon degrees of θ , take over the role of cohomological pairings. They bound the mass of positive currents, they decide whether θ admits a positive current $\theta + \text{dd}^c u$, and their normalized infimum is the largest lower curvature bound attainable in the background θ ; by weak compactness, this infimum is a minimum over Gauduchon currents. Applied to a perturbed form ω_u , the same conformal construction gives the probability measure that characterizes the range of the linearized Monge–Ampère operator.

Gauduchon degrees of holomorphic line bundles are defined in the same way, using the curvature of a Hermitian metric, and a positive degree excludes a metric with nonpositive curvature. Averaging the same argument over the fibers obstructs plurisubharmonic norms on vector bundles near a direct sum of line bundles of positive degree. On Hirzebruch surfaces this yields stable ample bundles that carry no strongly pseudoconvex Finsler metric of semipositive Kobayashi curvature, and it bounds the convexity of the complement of the zero section in their projective completions. The scalar Gauduchon equation also improves bundle metrics: a conformal change spreads directional curvature positivity from an open set to the whole manifold, which applies to the tangent bundles of nonflat Ricci-flat Kähler surfaces. Finally, on projective manifolds, Griffiths positivity admits a duality criterion analogous to the Lamari criterion, with a positive measure over the dual bundle in place of a Gauduchon current.

4.1 Conformal Gauduchon metrics

By [Proposition 2.2.1](#), the first variation of the mass at $u = 0$ vanishes exactly when $\text{dd}^c(\omega^{n-1}) = 0$. This condition can be achieved in every conformal class: finding a conformal factor amounts to finding a positive generator of the kernel of the adjoint of a scalar elliptic operator.

Definition 4.1.1 A Hermitian form γ is *Gauduchon*, or a *Gauduchon metric*, if

$$\text{dd}^c(\gamma^{n-1}) = 0.$$

It is *balanced* if $\text{d}(\gamma^{n-1}) = 0$, and *pluriclosed* if $\text{dd}^c\gamma = 0$.

Theorem 4.1.1 (Gauduchon's theorem) *Every Hermitian form η has a conformal Gauduchon representative. More precisely, there is a smooth strictly positive function ρ , unique up to multiplication by a positive constant, such that*

$$\text{dd}^c(\rho\eta^{n-1}) = 0.$$

The associated Gauduchon form is $\gamma = \rho^{1/(n-1)}\eta$.

Proof For a smooth real function v on X , define

$$Lv = n \frac{\text{dd}^c v \wedge \eta^{n-1}}{\eta^n}.$$

This real second-order operator has positive definite principal symbol and no zeroth-order term. By the maximum principle, its kernel consists of the constants. Its index is zero, since the linear path joining it to a Laplace operator consists of elliptic operators. Fredholm theory and elliptic regularity therefore show that the formal adjoint L^* of L with respect to η^n has a one-dimensional kernel, generated by a nonzero smooth real function ρ .

We first prove that $\int_X \rho \eta^n \neq 0$. Otherwise the constant function 1 would be orthogonal to the kernel of L^* , and the Fredholm alternative would solve $Lv = 1$, which is impossible at a maximum point of v . We may therefore rescale so that $\int_X \rho \eta^n = 1$.

Next we show that $\rho \geq 0$. Suppose instead that ρ is negative somewhere. Choose a nonzero smooth function $h \geq 0$ supported where $\rho < 0$, and put $c = \int_X h \rho \eta^n < 0$. The function $h - c$ is strictly positive and orthogonal to the kernel of L^* , so the Fredholm alternative would solve $Lv = h - c > 0$, which is again impossible at a maximum point of v .

In real local coordinates $(x_1, \dots, x_{2n})$, write $L^* = A^{ij} \partial_i \partial_j + B^i \partial_i + C$, where $\partial_i = \partial/\partial x_i$, the coefficients are smooth, and repeated indices are summed from 1 to $2n$. The leading symbol (A^{ij}) is positive definite. Since $\rho \geq 0$,

$$(L^* - \max(C, 0))\rho = -\max(C, 0)\rho \leq 0,$$

and the operator $L^* - \max(C, 0)$ has nonpositive zeroth-order term. By the strong minimum principle, a zero of ρ would force ρ to vanish identically on the connected manifold X . Hence $\rho > 0$.

Finally, integration by parts gives

$$\int_X \rho L v \eta^n = n \int_X v \operatorname{dd}^c(\rho \eta^{n-1}).$$

Thus the equation $L^* \rho = 0$ is precisely $\operatorname{dd}^c(\rho \eta^{n-1}) = 0$, and the one-dimensional adjoint kernel gives uniqueness up to positive scaling. Since $\gamma^{n-1} = \rho \eta^{n-1}$, the form γ is Gauduchon. $\square$

A Kähler form, that is, a closed Hermitian form, is both balanced and pluriclosed, and every balanced form is Gauduchon. On surfaces, balanced forms are Kähler, and the Gauduchon and pluriclosed conditions coincide.

4.2 Conservation of the trace mass

The power γ^{n-1} of a Gauduchon metric annihilates every complex Hessian under integration. It therefore assigns to a positive current $\theta + \operatorname{dd}^c u$ a mass depending only on its smooth background θ , also when the potential u is unbounded.

Proposition 4.2.1 *Let θ be a smooth real $(1, 1)$ -form, let u be a θ -plurisubharmonic function, and let γ be a Gauduchon metric. Then*

$$\int_X (\theta + \operatorname{dd}^c u) \wedge \gamma^{n-1} = \int_X \theta \wedge \gamma^{n-1}. \quad (4.1)$$

Proof Since $\operatorname{dd}^c(\gamma^{n-1}) = 0$, distributional integration by parts gives

$$\langle \operatorname{dd}^c u, \gamma^{n-1} \rangle = \langle u, \operatorname{dd}^c(\gamma^{n-1}) \rangle = 0.$$

The product on the left of (4.1) is a positive measure, whose total mass is therefore the finite number on the right. $\square$

We call $\int_X \theta \wedge \gamma^{n-1}$ the *Gauduchon degree* of θ with respect to γ . Here $\theta + \operatorname{dd}^c u$ is the full distributional current, including any mass carried by the pole set of u . The non-pluripolar Monge–Ampère measure of [Chapter 6](#) discards this mass; [Example 7.5.1](#) illustrates the difference on a curve.

Corollary 4.2.1 *There are constants $0 < a \leq b < +\infty$, depending only on ω and a chosen Gauduchon metric, such that every $u \in \operatorname{PSH}(X, \omega)$ satisfies*

$$a \leq \int_X (\omega + \operatorname{dd}^c u) \wedge \omega^{n-1} \leq b.$$

Proof Fix a Gauduchon form γ on X and choose positive constants c, C with $c\gamma^{n-1} \leq \omega^{n-1} \leq C\gamma^{n-1}$. Wedging these inequalities with the positive current $\omega + \text{dd}^c u$ and integrating, we obtain, by [Proposition 4.2.1](#), the bounds cA and CA , where $A = \int_X \omega \wedge \gamma^{n-1} > 0$. $\square$

The trace bound controls the mass of positive currents and hence their weak compactness. By itself it gives no bound for the Monge–Ampère mass, since a bound on the integral of a trace does not bound the integral of its n th power.

The pointwise arithmetic–geometric mean inequality relates the conserved trace to the density in a smooth Monge–Ampère equation. Fix a smooth positive volume form dV on X .

Proposition 4.2.2 *For any two Hermitian forms η, γ ,*

$$\eta \wedge \gamma^{n-1} \geq \left(\frac{\eta^n}{\gamma^n} \right)^{1/n} \gamma^n \quad (4.2)$$

pointwise. Consequently, let θ be a smooth real $(1, 1)$ -form and f a smooth strictly positive function. If $u \in C^\infty(X, \mathbb{R})$ and $c > 0$ satisfy $(\theta + \text{dd}^c u)^n = cf \, dV$ with $\theta + \text{dd}^c u > 0$, then

$$c^{1/n} \int_X \left(\frac{f \, dV}{\gamma^n} \right)^{1/n} \gamma^n \leq \int_X \theta \wedge \gamma^{n-1} \quad (4.3)$$

for every Gauduchon metric γ .

Proof In a frame where γ is the identity, let $\lambda_1, \dots, \lambda_n > 0$ be the eigenvalues of η . The ratios of the two sides of (4.2) to γ^n are $n^{-1} \sum_j \lambda_j$ and $(\prod_j \lambda_j)^{1/n}$, respectively, and their comparison is the arithmetic–geometric mean inequality.

For the second assertion, apply (4.2) with $\eta = \theta + \text{dd}^c u$, integrate, and use (4.1). $\square$

The corresponding density inequality for unbounded potentials in a Hermitian background is proved in [Lemma 6.4.2](#).

4.3 The Gauduchon criterion for positivity

The trace identity gives a necessary condition for $\text{PSH}(X, \theta)$ to be nonempty: every Gauduchon degree of θ must be nonnegative. The condition is also sufficient. A Hahn–Banach separation produces a positive current with the prescribed pairings, and a scalar elliptic equation shows that its difference from θ is dd^c -exact.

Theorem 4.3.1 (The generalized Lamari criterion) *For a smooth real $(1, 1)$ -form θ , the following conditions are equivalent:*

- (1) *There exists $u \in \text{PSH}(X, \theta)$.*
- (2) *$\int_X \theta \wedge \gamma^{n-1} \geq 0$ for every Gauduchon metric γ .*

To apply separation, we express the test in terms of smooth strictly positive dd^c -closed $(n-1, n-1)$ -forms Γ . Every strictly positive $(n-1, n-1)$ -form Γ has a unique strictly positive $(1, 1)$ -root γ , that is, $\Gamma = \gamma^{n-1}$. Indeed, in a frame in which Γ is diagonal, and with the same wedge normalization on both sides, the coefficients g_i of Γ are the products $\prod_{j \neq i} \lambda_j$ of the eigenvalues λ_j of γ . Hence

$$\lambda_i = \frac{(\prod_j g_j)^{1/(n-1)}}{g_i}.$$

This spectral formula uses only a positive determinant and a matrix inverse, so the root depends smoothly on the coefficients of Γ , also at repeated eigenvalues, and pointwise uniqueness makes the local roots agree on overlaps. Consequently, $\text{dd}^c \Gamma = 0$ says exactly that the root γ is Gauduchon.

Proof (of Theorem 4.3.1) Necessity is Proposition 4.2.1. For sufficiency, let F be the real vector space of smooth real $(n-1, n-1)$ -forms, and let

$$E = \{\Gamma \in F : \text{dd}^c \Gamma = 0\}, \quad \ell(\Gamma) = \int_X \theta \wedge \Gamma \quad (\Gamma \in E).$$

Fix a strictly positive $\Gamma_0 \in E$, which exists by Theorem 4.1.1. By the root calculation above, the hypothesis says that ℓ is nonnegative on the strictly positive elements of E . Adding $\epsilon \Gamma_0$ and letting $\epsilon \downarrow 0$, we see that ℓ is also nonnegative on the semipositive elements of E .

Step 1: a positive extension of ℓ . For $\Phi \in F$ put

$$p(\Phi) = \inf\{\ell(\Gamma) : \Gamma \in E, \Gamma \geq \Phi\}.$$

This is a finite sublinear function. To see finiteness, choose C with $-C\Gamma_0 \leq \Phi \leq C\Gamma_0$. The admissible element $C\Gamma_0$ gives an upper bound, while every admissible Γ satisfies $\Gamma + C\Gamma_0 \geq 0$ and hence $\ell(\Gamma) \geq -C\ell(\Gamma_0)$. Sublinearity follows by adding and rescaling competitors. For $\Phi \in E$, the nonnegativity of $\ell(\Gamma - \Phi)$ for admissible Γ shows that $p(\Phi) = \ell(\Phi)$.

The Hahn–Banach theorem gives a real linear extension T of ℓ to F with $T(\Phi) \leq p(\Phi)$ for all $\Phi \in F$. If $\Phi \geq 0$, the zero form is admissible for $p(-\Phi)$, so $T(-\Phi) \leq 0$, that is, $T(\Phi) \geq 0$. Moreover, the bounds by $C\Gamma_0$ show that T is continuous for the uniform norm. It is therefore a positive $(1, 1)$ -current, and the current $S = T - \theta$ annihilates E .

Step 2: S is dd^c -exact. To recover a potential from S , consider the scalar operator

$$Dv = \frac{\text{dd}^c(v\Gamma_0)}{dV},$$

where dV is the smooth positive volume form fixed above. Since $\text{dd}^c \Gamma_0 = 0$, this is an elliptic scalar operator with no zeroth-order term. Its kernel consists of the constants and its index is zero, while Stokes' theorem gives $\int_X Dv dV = 0$. Consequently its range is exactly the space of smooth functions of integral zero, and by elliptic

estimates its inverse on functions normalized by $\int_X v \, dV = 0$ is continuous in the smooth topology.

For a smooth top-degree form ζ with $\int_X \zeta = 0$, solve $Dv = \zeta/dV$ with this normalization and set $R\zeta = v\Gamma_0$. Then $\text{dd}^c R\zeta = \zeta$, and R is continuous. Define a distribution u on such top-degree forms by

$$\langle u, \zeta \rangle = S(R\zeta),$$

and extend it to all top-degree forms by assigning an arbitrary value on one fixed volume form of integral one. For every $\Phi \in F$, the form $\Phi - R(\text{dd}^c \Phi)$ belongs to E , and S annihilates it. It follows that

$$\langle \text{dd}^c u, \Phi \rangle = S(R(\text{dd}^c \Phi)) = S(\Phi).$$

Thus $\theta + \text{dd}^c u = T \geq 0$, and **Proposition 1.1.1** gives a representative of u in $\text{PSH}(X, \theta)$. $\square$

Applying the criterion to $\theta - a\omega$, for $a \in \mathbb{R}$, determines the largest lower curvature bound attainable in the background θ .

Corollary 4.3.1 *For a smooth real $(1, 1)$ -form θ , set*

$$\kappa_\omega(\theta) = \inf_{\gamma \text{ Gauduchon}} \frac{\int_X \theta \wedge \gamma^{n-1}}{\int_X \omega \wedge \gamma^{n-1}}.$$

This is a finite real number, and it is the largest real a for which there is a quasi-plurisubharmonic function u satisfying

$$\theta + \text{dd}^c u \geq a\omega.$$

*In particular, this largest value is attained, and θ is big, in the sense of **Section 1.19**, precisely when $\kappa_\omega(\theta) > 0$.*

Proof Since θ is smooth, $-C\omega \leq \theta \leq C\omega$ for some C , so the infimum lies in $[-C, C]$. If $\theta + \text{dd}^c u \geq a\omega$, the trace identity applied to the background $\theta - a\omega$ shows that a is at most each of the ratios in the definition, hence $a \leq \kappa_\omega(\theta)$. Conversely, for $a = \kappa_\omega(\theta)$, all Gauduchon degrees of $\theta - a\omega$ are nonnegative, and **Theorem 4.3.1** applied to this smooth form gives the required u . The last assertion follows, since bigness means the existence of a θ -plurisubharmonic u with $\theta + \text{dd}^c u \geq \delta\omega$ for some $\delta > 0$. $\square$

Whether the infimum defining $\kappa_\omega(\theta)$ is attained by a smooth Gauduchon metric is decided by a rigidity property of the trace: a positive current $\theta + \text{dd}^c u$ with vanishing Gauduchon degree is zero.

Lemma 4.3.1 *Let θ be a smooth real $(1, 1)$ -form with $\text{PSH}(X, \theta) \neq \emptyset$. If*

$$\int_X \theta \wedge \gamma^{n-1} = 0$$

for one Gauduchon metric γ , then $\theta = \text{dd}^c f$ for a smooth real function f . Conversely, a form $\text{dd}^c f$ with f smooth has zero degree with respect to every Gauduchon metric. The same conclusions hold for $n = 1$, with $\gamma^{n-1} = 1$.

Proof Choose $u \in \text{PSH}(X, \theta)$ and put $S = \theta + \text{dd}^c u \geq 0$. By Proposition 4.2.1, $\int_X S \wedge \gamma^{n-1} = 0$. Since the trace measure $S \wedge \gamma^{n-1}$ of the positive current S controls all its coefficient measures, $S = 0$. Taking the trace of the equation $\text{dd}^c u = -\theta$ with respect to ω gives an elliptic equation with smooth right-hand side, so u is smooth by elliptic regularity, and $f = -u$ has the required property. The converse is Stokes' theorem. For $n = 1$, the trace measure is S itself and the same argument applies. $\square$

For a smooth real $(1, 1)$ -form θ , put $a = \kappa_\omega(\theta)$. By Corollary 4.3.1, the form $\theta - a\omega$ admits a positive current $\theta - a\omega + \text{dd}^c u$. A Gauduchon metric γ attains the infimum defining $\kappa_\omega(\theta)$ precisely when the Gauduchon degree of $\theta - a\omega$ with respect to γ vanishes. Hence Lemma 4.3.1 shows that the infimum is attained by a smooth Gauduchon metric if and only if

$$\theta - a\omega = \text{dd}^c f \quad \text{for some } f \in C^\infty(X, \mathbb{R}),$$

and in that case every Gauduchon metric attains it. Thus a positive current at the threshold always exists, whereas a smooth minimizing Gauduchon metric exists only in this exceptional situation.

4.4 Compactness and duality of Gauduchon currents

When no smooth Gauduchon metric attains the threshold, a minimizer can still be found among weak limits of normalized Gauduchon forms. The normalization bounds the coefficient measures and hence gives compactness. Let $\mathcal{G}_\omega$ be the set of positive $(n-1, n-1)$ -currents T on X satisfying

$$\text{dd}^c T = 0, \quad \int_X \omega \wedge T = 1.$$

We call them *normalized Gauduchon currents*. Let $\mathcal{C}_\omega$ be the weak closure of the set of smooth strictly positive members of $\mathcal{G}_\omega$. By the root calculation preceding the proof of Theorem 4.3.1, these smooth members are exactly the normalized powers $\gamma^{n-1} / \int_X \omega \wedge \gamma^{n-1}$ of Gauduchon metrics γ .

Proposition 4.4.1 *The sets $\mathcal{G}_\omega$ and $\mathcal{C}_\omega$ are nonempty, compact and convex. For every smooth real $(1, 1)$ -form θ ,*

$$\kappa_\omega(\theta) = \min_{T \in \mathcal{C}_\omega} \int_X \theta \wedge T. \quad (4.4)$$

Moreover, a current $T \in \mathcal{G}_\omega$ belongs to $\mathcal{C}_\omega$ if and only if

$$\int_X \theta \wedge T \geq 0 \quad \text{for every smooth real } \theta \text{ with } \text{PSH}(X, \theta) \neq \emptyset. \quad (4.5)$$

Proof Gauduchon's theorem gives a smooth strictly positive member of $\mathcal{G}_\omega$ after normalization. The fixed trace mass bounds the total variation of all coefficient measures in finitely many local frames, so weak compactness of finite measures gives compactness of the family of positive currents with this trace. Positivity, the trace normalization and the equation $\text{dd}^c T = 0$ pass to weak limits. On this bounded set, testing against smooth forms or against forms with continuous coefficients gives the same topology, by uniform approximation, and this topology is metrizable since the space of continuous test forms is separable. Thus the compactness can also be used sequentially. The defining conditions of $\mathcal{G}_\omega$ are convex. Its smooth strictly positive members form a convex set, so their closure $\mathcal{C}_\omega$ is compact and convex as well.

Pairing with a fixed smooth θ is weakly continuous. Its minimum on the closure of the smooth members is therefore their infimum, which proves (4.4). The Lamari criterion shows that (4.5) holds for every smooth strictly positive member, and hence for every member of their weak closure.

Conversely, suppose that $T \in \mathcal{G}_\omega$ does not belong to $\mathcal{C}_\omega$, and separate this point from the compact convex set $\mathcal{C}_\omega$ in the space of currents with the weak topology. A continuous linear functional for that topology is evaluation against a smooth form. After changing its sign if necessary, we obtain a smooth real $(1, 1)$ -form β such that

$$\int_X \beta \wedge T < \min_{R \in \mathcal{C}_\omega} \int_X \beta \wedge R = \kappa_\omega(\beta).$$

By Corollary 4.3.1, the smooth form $\beta - \kappa_\omega(\beta)\omega$ admits a positive current. Its pairing with T is negative, because $\int_X \omega \wedge T = 1$. This contradicts (4.5) and proves the converse. $\square$

Corollary 4.4.1 *The function κ_ω is concave, positively homogeneous and invariant under the addition of $\text{dd}^c f$ for $f \in C^\infty(X, \mathbb{R})$. Let θ and η be smooth real $(1, 1)$ -forms and let $\varepsilon \geq 0$. If $-\varepsilon\omega \leq \theta - \eta \leq \varepsilon\omega$, then*

$$|\kappa_\omega(\theta) - \kappa_\omega(\eta)| \leq \varepsilon.$$

If smooth real $(1, 1)$ -forms θ_j converge uniformly to a smooth form θ and $T_j \in \mathcal{C}_\omega$ minimize their pairings, every weak cluster point of (T_j) minimizes the pairing with θ .

Proof By (4.4), κ_ω is an infimum of linear functionals, which proves concavity and positive homogeneity. Invariance under the addition of $\text{dd}^c f$ follows from $\text{dd}^c T = 0$. The normalization of the trace gives

$$\left| \int_X (\theta - \eta) \wedge T \right| \leq \varepsilon \quad (T \in \mathcal{C}_\omega),$$

and taking infima proves the estimate. For the last assertion, pass to a subsequence $T_j \rightharpoonup T \in \mathcal{C}_\omega$. The estimate and the uniform convergence of the backgrounds give

$$\int_X \theta \wedge T = \lim_j \int_X \theta_j \wedge T_j = \lim_j \kappa_\omega(\theta_j) = \kappa_\omega(\theta).$$

Thus T is a minimizer. $\square$

In general, the closure $\mathcal{C}_\omega$ cannot be replaced by all of $\mathcal{G}_\omega$: the exceptional-curve example in [Example 27.8.1](#) separates the two sets by a smooth closed form. Testing against all of $\mathcal{G}_\omega$ instead detects smooth positivity and nefness, as shown in [Theorem 25.19.1](#).

4.5 Convex norms and Gauduchon degrees

For holomorphic line bundles, the trace identity of [Proposition 4.2.1](#) becomes a statement about curvature. Let F be a holomorphic line bundle on X and k a smooth Hermitian metric on F . In a local holomorphic frame e of F we identify k with the positive function $|e|_k^2$, and the curvature form of k is $R_k = -dd^c \log k$. Let Θ be a smooth strictly positive real $(n-1, n-1)$ -form with $dd^c \Theta = 0$; by the root calculation preceding the proof of [Theorem 4.3.1](#), $\Theta = \gamma^{n-1}$ for a unique Gauduchon metric γ . The *degree* of F with respect to Θ is

$$\deg_\Theta F = \int_X R_k \wedge \Theta.$$

Two metrics on F differ by a factor e^{-u} with u smooth, which adds $dd^c u$ to the curvature, so the degree is independent of k by [Lemma 2.1.1](#). It is the Gauduchon degree of the curvature form with respect to γ ; the form Θ need not be d -closed.

The squared norm $v \mapsto |v|_k^2$ is plurisubharmonic on the total space of F off the zero section exactly when $\log k$ is plurisubharmonic, that is, when $R_k \leq 0$; this follows from the Levi form computation in the proof of [Lemma 4.5.6](#) below. A line bundle of positive degree therefore admits no metric with plurisubharmonic squared norm. This section extends the obstruction to direct sums of line bundles of positive degree, to all holomorphic structures sufficiently close to such a direct sum, and to norms that need not be Hermitian. The mechanism is again integration against Θ : averaging the horizontal complex Hessians of a norm near the line summands produces a negative multiple of the degrees, and this negativity is stable under small changes of the holomorphic structure.

For a smooth complex vector bundle F , a *smooth complex norm* is a continuous function $p : F \rightarrow [0, +\infty)$, positive away from the zero section and smooth there, such that

$$p(\lambda v) = |\lambda|p(v), \quad p(v+w) \leq p(v) + p(w)$$

for $\lambda \in \mathbb{C}$ and vectors v, w in the same fiber. Its square $G = p^2$ satisfies $G(\lambda v) = |\lambda|^2 G(v)$. Near each line summand of a direct sum, the triangle inequality controls the fiber derivatives of G , and these estimates control the averaged horizontal complex Hessians.

Lemma 4.5.1 *Fix a smooth positive volume form μ on X . Every holomorphic line bundle F has a Hermitian metric k satisfying*

$$R_k \wedge \Theta = \lambda \mu, \quad \lambda = \frac{\deg_{\Theta} F}{\int_X \mu}.$$

Proof Start with any metric k^0 , and put $\mathcal{L}u = (\mathrm{dd}^c u \wedge \Theta)/\mu$. This scalar operator is uniformly elliptic, has no zeroth-order term, and its kernel consists of the constants by the maximum principle. On Hölder spaces, the homotopy to a Laplace operator used in the proof of [Theorem 4.1.1](#) shows that its index is zero, so its cokernel is one-dimensional. Since $\mathrm{dd}^c \Theta = 0$, integration by parts gives $\int_X \mathcal{L}u \mu = 0$, and therefore its image consists exactly of the smooth functions of zero μ -mean. Hence we can solve

$$\mathrm{dd}^c u \wedge \Theta = \lambda \mu - R_{k^0} \wedge \Theta,$$

whose right-hand side has integral zero, and elliptic regularity makes u smooth. Then $k = k^0 e^{-u}$ has the required curvature. $\square$

Let $F_0 = \bigoplus_{s=1}^r F_s$ be a direct sum of holomorphic line bundles, with $r \geq 2$. Choose Hermitian metrics k_s on F_s and write $k = \bigoplus_s k_s$. Let P_s be the orthogonal projection onto F_s , and let

$$\Sigma = \{v \in F_0 : |v|_k = 1\}$$

be the unit sphere bundle, with fibers Σ_x . On each fiber sphere Σ_x we use the rotation-invariant probability measure $d\sigma_x$. Fix a nonnegative smooth function χ supported in $(-1, 1)$ and positive near zero. For $0 < \varepsilon < 1/2$, define weights ρ_s on Σ by

$$\rho_s(v) = c_{\varepsilon} \chi \left(\frac{|(I - P_s)v|_k^2}{\varepsilon^2} \right), \quad \int_{\Sigma_x} \rho_s d\sigma_x = 1.$$

In unitary frames respecting the splitting, these weights and the normalizing constant c_{ε} are independent of the base point and of the index s . Independent phase rotations of the summands preserve them, so they are globally defined. The support of ρ_s lies within distance ε of the unit circle of F_s .

Lemma 4.5.2 *For a smooth complex norm on F_0 with square G , put*

$$a_s(x) = G(e_s), \quad N(x) = \sum_s a_s(x), \quad D_j G(v) = d_v G(P_j v),$$

where e_s is any k_s -unit vector in the fiber of F_s at x ; complex homogeneity makes a_s well defined. Then

$$G(v) \leq N|v|_k^2, \quad |d_v G(w)| \leq 2N|v|_k|w|_k.$$

On the support of ρ_s ,

$$|D_j G| \leq 2\varepsilon N \quad (j \neq s), \quad |D_s G - 2a_s| \leq 10\varepsilon N.$$

Proof The triangle inequality and the Cauchy–Schwarz inequality give $p(v) \leq \sum_s |v_s|_k \sqrt{a_s} \leq \sqrt{N}|v|_k$. Differentiating $|p(v + tw) - p(v)| \leq |t|p(w)$ in the real variable t gives $|d_v p(w)| \leq p(w)$, and both global bounds follow.

For v in the support of ρ_s , set $w = (I - P_s)v$ and $e_s = P_s v / |P_s v|_k$. Then $|w|_k < \varepsilon$ and $|v - e_s|_k \leq |w|_k + 1 - |P_s v|_k < 2\varepsilon$. The segment from e_s to v stays in the unit ball and avoids zero, so integrating the derivative bound along it gives $|G(v) - a_s| \leq 4\varepsilon N$. For $j \neq s$, we have $|P_j v|_k < \varepsilon$, which gives the first axis bound. Euler’s identity $d_v G(v) = 2G(v)$ yields

$$D_s G - 2a_s = 2(G(v) - a_s) - \sum_{j \neq s} D_j G.$$

The sum on the right is $d_v G(w)$, whose absolute value is at most $2\varepsilon N$. This proves the second axis bound. $\square$

Write $\pi : F_0 \rightarrow X$ for the bundle projection. For $v \in F_0$ with $\pi(v) = x$, let $H_{0,v} : T_x X \rightarrow T_v F_0$ be the horizontal lift for the Chern connection of k . It is complex linear, and at unit vectors it is tangent to Σ , since the Chern connection preserves k . For a smooth real function G on $F_0 \setminus \{0\}$, define a $(1, 1)$ -form $\beta_s(G)$ and functions U_s, V_{sj} on X by

$$\begin{aligned} \beta_s(G) &= \int_{\Sigma_x} \rho_s H_{0,v}^* (\mathrm{dd}^c G) \, d\sigma_x, \\ U_s &= \int_{\Sigma_x} G \rho_s \, d\sigma_x, \\ V_{sj} &= \int_{\Sigma_x} D_j G \rho_s \, d\sigma_x. \end{aligned}$$

Lemma 4.5.3 *With R_j the curvature of k_j ,*

$$\beta_s(G) = \mathrm{dd}^c U_s - \frac{1}{2} \sum_j R_j V_{sj}.$$

Proof At a fixed base point, choose holomorphic frames of the line bundles with $k_j = e^{-\varphi_j}$ and $d\varphi_j = 0$ at that point. There the horizontal lift has zero vertical component. Write the smooth unitary fiber coordinates as $\zeta_j = e^{-\varphi_j/2} v_j$ and $G(z, v) = g(z, \zeta)$. At the base point, the first base derivatives of ζ_j vanish, and its mixed second base derivatives are $-\frac{1}{2}(\varphi_j)_{\alpha\bar{\beta}} \zeta_j$ and their conjugates. The chain rule therefore gives

$$G_{\alpha\bar{\beta}} = g_{\alpha\bar{\beta}} - \frac{1}{2} \sum_j (\varphi_j)_{\alpha\bar{\beta}} (\zeta_j g_{\zeta_j} + \bar{\zeta}_j g_{\bar{\zeta}_j}).$$

The expression in parentheses is $D_j G$. Both the spherical measure and ρ_s are independent of z in unitary coordinates, so averaging the identity gives the result, since $R_j = \mathrm{dd}^c \varphi_j$. $\square$

Theorem 4.5.1 *Suppose that for each s there is a smooth strictly positive real $(n-1, n-1)$ -form Θ_s satisfying*

$$\mathrm{dd}^c \Theta_s = 0, \quad \deg_{\Theta_s} F_s > 0.$$

Then there is a C^4 neighborhood of the split Dolbeault operator on the underlying smooth bundle of F_0 such that no integrable Dolbeault operator in this neighborhood admits a smooth complex norm whose square is plurisubharmonic off the zero section.

Proof *Step 1: the split structure.* Fix μ and use [Lemma 4.5.1](#) to choose k_s with $R_s \wedge \Theta_s = \lambda_s \mu$, where $\lambda_s > 0$. Put

$$\lambda_* = \min_s \lambda_s, \quad C = 5 \sum_s \lambda_s + \sum_s \sum_{j \neq s} \sup_X \left| \frac{R_j \wedge \Theta_s}{\mu} \right|.$$

For a squared norm G , define $I_0(G) = \sum_s \int_X \beta_s(G) \wedge \Theta_s$. By [Lemma 4.5.3](#), the term $\mathrm{dd}^c U_s$ integrates to zero against Θ_s , and the axis estimates of [Lemma 4.5.2](#) then give

$$I_0(G) = -\frac{1}{2} \sum_{s,j} \int_X V_{sj} R_j \wedge \Theta_s \leq -(\lambda_* - \varepsilon C) \int_X N \mu.$$

Choose ε so that $\varepsilon C < \lambda_*/2$, and keep all weights fixed.

Step 2: nearby holomorphic structures. Write a nearby operator as $\bar{\partial}_A = \bar{\partial}_0 + A$, with $\bar{\partial}_A^2 = 0$. Its Chern connection for k is $D_A = D_0 + A - A^{*k}$, where the adjoint changes the type from $(0, 1)$ to $(1, 0)$. Let J_A be the corresponding complex structure on the total space and $H_{A,v}$ the horizontal lift of D_A . These depend smoothly on A , and $H_{A,v}$ is complex linear and tangent to the fixed sphere bundle Σ .

For $g \in C^\infty(\Sigma, \mathbb{R})$, define its homogeneous extension by

$$(\mathcal{E}g)(v) = |v|_k^2 g(v/|v|_k),$$

and define a real differential operator on Σ by

$$(\mathcal{P}_A g)(v) = \sum_s \rho_s(v) \frac{H_{A,v}^* (\mathrm{dd}_{J_A}^c \mathcal{E}g)_v \wedge \Theta_s(x)}{\mu(x)}, \quad x = \pi(v).$$

It has order at most two. By the identity $\mathrm{d}_J^c f = -(4\pi)^{-1} \mathrm{d}f \circ J$, its coefficients depend on A and its first derivatives, as well as on the fixed smooth data. Consequently they converge in C^2 as $A \rightarrow 0$ in C^4 .

Step 3: the adjoint operator. Take the formal adjoint $\mathcal{P}_A^*$ for the fixed density $\mathrm{d}v = \mathrm{d}\sigma_x \mu(x)$ on the compact sphere bundle, and put $b_A = \mathcal{P}_A^* 1$. Locally, if $\mathrm{d}v = m(y) \mathrm{d}y$ and $\mathcal{P}_A = \sum_{|\alpha| \leq 2} c_{\alpha,A} \partial^\alpha$, then

$$b_A = m^{-1} \sum_{|\alpha| \leq 2} (-1)^{|\alpha|} \partial^\alpha (m c_{\alpha,A}).$$

Thus $\|b_A - b_0\|_{C^0} \rightarrow 0$ as $A \rightarrow 0$ in C^4 . For $g = G|_\Sigma$, homogeneity gives $\mathcal{E}g = G$ and

$$I_A(G) := \int_\Sigma \mathcal{P}_A g \, d\nu = \int_\Sigma g b_A \, d\nu.$$

Since $0 < g \leq N \circ \pi$ and the spherical measures have mass one,

$$|I_A(G) - I_0(G)| \leq \|b_A - b_0\|_{C^0} \int_X N \mu.$$

Choose the neighborhood so that $\|b_A - b_0\|_{C^0} < \lambda_*/4$ in it. Then $I_A(G) \leq -\frac{1}{4}\lambda_* \int_X N \mu < 0$ for every smooth squared complex norm G . If G were plurisubharmonic for J_A , all horizontal pullbacks of $\text{dd}_{J_A}^c G$ would be semipositive, and their pairings with Θ_s , weighted by $\rho_s \geq 0$, would give $I_A(G) \geq 0$, a contradiction. $\square$

The neighborhood depends on the bundle and on the test forms Θ_s , and different line summands may require different tests. Its size is independent of all derivatives of the candidate norms: integration over the fixed sphere bundle transfers those derivatives to the coefficients of the adjoint operator.

The rest of this section develops consequences of [Theorem 4.5.1](#). Norms produced by duality, such as polar norms of Finsler metrics and support functions of neighborhoods of the zero section, are in general only continuous; [Sections 4.5.1](#) and [4.5.2](#) extend the obstruction to continuous norms with strict convexity margins. Polar duality then shows that, near such a split bundle, the dual of an ample bundle carries no Finsler metric with semipositive Kobayashi curvature ([Section 4.5.3](#)). Hirzebruch surfaces provide split bundles with positive Gauduchon degrees that are limits of stable ample bundles ([Sections 4.5.4](#) to [4.5.6](#)), and a single Stein hypersurface detects the failure of positivity for all Finsler metrics on such a bundle ([Section 4.5.7](#)). Finally, a sufficiently concave neighborhood of the zero section would give a dual support norm, so the obstruction also bounds the convexity of the complement of the zero section in a projective completion; positive curvature gives bounds in the opposite direction ([Sections 4.5.8](#) to [4.5.11](#)).

4.5.1 Homogeneous convex regularization

[Theorem 4.5.1](#) concerns smooth norms, whereas the norms produced by duality later in this section are in general only continuous. We show that a continuous homogeneous function with strict positivity margins can be approximated by smooth ones with the same margins, so the obstruction applies to it as well. The local step is Wu's convolution in projective coordinates, written as an average of holomorphic linear shears; the local approximations are glued by the argument of Greene and Wu. We give both steps in order to keep track of strict plurisubharmonicity and of strong convexity in the fibers; see [Section 33.3](#) for attribution.

Let $\pi : F \rightarrow X$ be a holomorphic vector bundle, and write $F^\times$ for the complement of its zero section. A continuous real function Q on F is *complex homogeneous of*

degree two if

$$Q(\lambda v) = |\lambda|^2 Q(v) \quad (\lambda \in \mathbb{C}).$$

We call Q *locally strongly convex in the fibers* if, in a local bundle frame and near every point of $F^\times$, there is a constant $c > 0$ such that $Q(z, v) - c|v|^2$ is convex on sufficiently small real fiber balls. For continuous functions, strict plurisubharmonicity means that subtracting a sufficiently small positive multiple of the Euclidean squared norm in local coordinates of the total space leaves a plurisubharmonic function. Both conditions are local, and on compact subsets of $F^\times$ they hold with uniform positive margins.

Lemma 4.5.4 *Let M be a compact smooth manifold and let $\mathcal{S}$ be a sheaf of germs of continuous real functions on M , whose elements we call sections. Suppose that $\mathcal{S}$ is closed under maxima and has the following two properties.*

Stability: if f is a section near a compact set K , then $f + u$ is a section near K whenever u is smooth and sufficiently small in the C^∞ topology on a neighborhood of K .

Local approximation: every point has a neighborhood U such that, for every compact $K \Subset U$, a section near K can be approximated uniformly on K by smooth sections near K , with arbitrarily small errors in any prescribed finite collection of derivative norms on compact subsets where the section is already smooth.

Then every global section can be approximated uniformly on M by smooth global sections.

Proof We first describe a gluing step. Let f be a global section that is smooth near a compact set L_1 , and let L_2 be a compact subset of one of the neighborhoods U in the statement. Choose relatively compact open sets W_3, W_4 with $L_1 \subset W_3$, f smooth near $\overline{W}_3$, and $L_2 \subset W_4 \Subset U$. Choose a smooth function $0 \leq \rho \leq 1$ equal to one near $\overline{W}_3$, with compact support in the region where f is smooth. Put $V = W_3 \cup W_4$, and choose a smooth function $-1 \leq \psi \leq 1$ equal to one near $L_1 \cup L_2$ and equal to minus one near $M \setminus V$.

By stability, for sufficiently small $\xi > 0$ the function $f_\xi = f + \xi\psi$ is still a global section. Approximate f_ξ on $\overline{W}_4$ by a smooth section g , with uniform error less than $\delta < \xi/2$, and with arbitrarily small derivative errors near the compact set $\overline{W}_4 \cap \text{supp } \rho$, where f_ξ is smooth. On V define

$$h = f_\xi \quad \text{on } W_3, \quad h = \rho f_\xi + (1 - \rho)g \quad \text{on } W_4.$$

These definitions agree on the overlap, and h is smooth. Where ρ vanishes, h is the section g . Where ρ can be nonzero, $h - f_\xi = (1 - \rho)(g - f_\xi)$, and stability applied to the smooth section f_ξ makes h a section if the derivative errors of $g - f_\xi$ are sufficiently small. Moreover, $|h - f_\xi| < \delta$.

Define $f_1 = \max\{f, h\}$ on V and $f_1 = f$ outside V . Near $L_1 \cup L_2$ we have $h > f$, and near the boundary of V we have $h < f$. Thus f_1 is continuous, it is a section because $\mathcal{S}$ is closed under maxima, and it is smooth near $L_1 \cup L_2$. Also $\|f_1 - f\|_{C^0} < \xi + \delta$. Near L_1 it equals $f + \xi$, so the previous smoothness is preserved.

Now cover M by finitely many compact sets L_2 of this kind and repeat the step, starting with L_1 empty and then taking for L_1 the union of the previously treated compact sets. At every step choose ξ and δ so small that the sum of the finitely many uniform errors is below the prescribed tolerance. The final section is smooth everywhere and has the required uniform error. $\square$

Lemma 4.5.5 *In a holomorphic bundle chart, write $v = (v', v_r)$ and use the affine projective coordinate $w = v'/v_r$ on the cone $v_r \neq 0$. Suppose that a positive continuous complex homogeneous function Q of degree two is strictly plurisubharmonic and locally strongly convex in the fibers on this cone, and put $q(z, w) = Q(z, (w, 1))$. For a nonnegative smooth approximate identity $\eta_\delta(s, t)$ of integral one, define*

$$q_\delta(z, w) = \int q(z - s, w - t) \eta_\delta(s, t) \, ds \, dt, \quad Q_\delta(z, v) = |v_r|^2 q_\delta(z, v'/v_r).$$

On every relatively compact projective subchart, for sufficiently small δ , Q_δ is a smooth positive complex homogeneous function of degree two that is strictly plurisubharmonic and locally strongly convex in the fibers. As $\delta \rightarrow 0$, it converges to Q uniformly on compact subsets of the cone consisting of vectors of norm one, and in every finite derivative norm wherever Q is already smooth.

Proof Complex homogeneity gives the identity

$$Q_\delta(z, v) = \int Q(z - s, T_t v) \eta_\delta(s, t) \, ds \, dt, \quad T_t(v', v_r) = (v' - v_r t, v_r).$$

For fixed (s, t) , the map $(z, v) \mapsto (z - s, T_t v)$ is holomorphic and invertible, and its restriction to each fiber is linear. On a compact subset of the cone consisting of vectors of norm one, all these maps with (s, t) sufficiently small stay in a fixed compact subset of the original cone, and their differentials and inverses are uniformly bounded there. A positive local lower bound for the Levi form of Q , interpreted through quadratic barriers, therefore gives a positive lower bound for every pullback and for their average. The same argument with real quadratic barriers in the fibers preserves local strong convexity. Only fiber segments contained in the local cone neighborhood are used here.

Ordinary convolution makes q_δ smooth, and the formula for Q_δ makes it smooth on the cone and complex homogeneous. Uniform convergence, derivative convergence on compact regions where Q is smooth, and positivity for small δ follow from the corresponding properties of convolution and from the positive minimum of Q on compact sets of vectors of norm one. $\square$

Theorem 4.5.2 *Let $Q : F \rightarrow [0, +\infty)$ be continuous, positive on $F^\times$, complex homogeneous of degree two, strictly plurisubharmonic on $F^\times$, and locally strongly convex in the fibers. Then there are continuous complex homogeneous functions Q_j of degree two, smooth on $F^\times$, strictly plurisubharmonic there and locally strongly convex in the fibers, which converge to Q uniformly on the unit sphere bundle of any fixed smooth Hermitian metric. Each $p_j = \sqrt{Q_j}$ is a smooth complex norm.*

Proof Fix a smooth Hermitian squared norm G on F , and let $M = \mathbb{P}(F)$ be the bundle of complex lines in F . The quotient $m = Q/G$ is a positive continuous function on the compact manifold M . Define a sheaf $\mathcal{S}$ on M by requiring that the corresponding function Gm on the cone be positive, strictly plurisubharmonic, and locally strongly convex in the fibers.

This sheaf is closed under maxima. Indeed, multiplication by $G > 0$ commutes with maxima. Near a point of the cone, subtract a common positive quadratic barrier from both functions; their maximum remains plurisubharmonic, and on sufficiently small fiber balls it remains convex. Positivity is also preserved.

For stability on a compact subset K of M , restrict to vectors of norm one lying over K , and to a fixed compact annulus around them. Finitely many bundle charts provide positive common lower bounds for both barriers. If u is a smooth function on M that is sufficiently small in C^2 near K , the Levi form and the real fiber Hessian of Gu are smaller than half these bounds on that annulus. The perturbed function is therefore still positive and has both strict margins. Homogeneity transports the local conditions to the rest of the cone over K . This proves the stability required in [Lemma 4.5.4](#).

On a sufficiently small projective coordinate chart, [Lemma 4.5.5](#) gives local approximation, including derivative control on compact subsets where m is smooth; dividing its regularizations by G gives local smooth sections of $\mathcal{S}$. By [Lemma 4.5.4](#), there are smooth positive global sections $m_j \rightarrow m$ uniformly. Put $Q_j = Gm_j$ off the zero section and $Q_j = 0$ on the zero section. Homogeneity gives continuity at zero, uniformly over the compact base, as well as the asserted convergence on a fixed unit sphere bundle.

It remains to see that p_j is a norm. Local convexity in the fibers away from zero implies convexity on the whole fiber. Indeed, the restriction of Q_j to a real line avoiding zero is locally convex and hence convex, while on a real line through zero, homogeneity gives $Q_j(tv) = t^2 Q_j(v)$ for real t , which is convex including at zero. Thus the set $B_x = \{v : Q_j(v) \leq 1\}$ is convex, balanced and absorbing, and its gauge is $\sqrt{Q_j}$. If v, w are nonzero, convexity applied to $v/p_j(v)$ and $w/p_j(w)$, with weights proportional to $p_j(v)$ and $p_j(w)$, gives the triangle inequality; the cases with a zero vector follow directly. Positivity, smoothness off zero and complex homogeneity give the remaining properties of a smooth complex norm. $\square$

Proposition 4.5.1 *Suppose that F admits a smooth positive complex homogeneous function H of degree two that is strictly plurisubharmonic on $F^\times$. If a positive continuous complex homogeneous function Q of degree two is plurisubharmonic on $F^\times$ and locally strongly convex in the fibers, then F admits a smooth complex norm with strictly plurisubharmonic square on $F^\times$.*

Proof For $\tau > 0$, set $Q_\tau = Q + \tau H$; it is positive, complex homogeneous and strictly plurisubharmonic. On a compact annulus of vectors of norm close to one, local strong convexity of Q in the fibers gives a positive uniform margin in finitely many frames, while the real fiber Hessian of H is uniformly bounded there. Choose τ so small that the possible negative part of τ times this Hessian consumes less than half the margin. Homogeneity then gives local strong convexity of Q_τ in the fibers everywhere off

zero. Apply [Theorem 4.5.2](#) to Q_τ and take one of its smooth regularizations; its square root is the required smooth complex norm. $\square$

Corollary 4.5.1 *For every holomorphic structure in the neighborhood of [Theorem 4.5.1](#), there is no positive continuous complex homogeneous function of degree two that is both strictly plurisubharmonic off zero and locally strongly convex in the fibers. If that structure admits a function H as in [Proposition 4.5.1](#), there is also no positive continuous complex homogeneous function of degree two that is plurisubharmonic off zero and locally strongly convex in the fibers.*

Proof For the first assertion, [Theorem 4.5.2](#) would produce a smooth complex norm with plurisubharmonic square, contrary to [Theorem 4.5.1](#). For the second, use [Proposition 4.5.1](#) and the same obstruction. $\square$

The second assertion requires the strictly plurisubharmonic homogeneous function H , which need not exist for an arbitrary holomorphic bundle; [Section 4.5.2](#) shows that it exists when the dual bundle is ample. Without a strong convexity margin in the fibers, the regularization gives no obstruction for continuous fiber norms.

4.5.2 Strict positivity from the tautological metric

The second part of [Corollary 4.5.1](#) requires a smooth strictly plurisubharmonic function on $F^\times$ that is complex homogeneous of degree two. Such a function is the squared norm of a vector, viewed as a point of the tautological line it spans, for a suitable metric on the tautological line bundle. Its Levi form is strictly positive exactly when the dual tautological metric is positively curved, so the function exists when F^* is ample.

Let $F \rightarrow X$ be a holomorphic vector bundle of positive rank. In this subsection, $\mathbb{P}(F)$ parametrizes complex lines in F , $\mathcal{O}_{\mathbb{P}(F)}(-1)$ is the tautological line bundle whose fiber over a line is that line, and

$$L = \mathcal{O}_{\mathbb{P}(F)}(1) = \mathcal{O}_{\mathbb{P}(F)}(-1)^*.$$

The map $v \mapsto ([v], v)$ identifies $F^\times$ holomorphically with the complement of the zero section in $\mathcal{O}_{\mathbb{P}(F)}(-1)$. We use the curvature convention $R_h = -\text{dd}^c \log h$ of [Section 4.5](#).

Lemma 4.5.6 *A smooth Hermitian metric h on L determines a positive smooth complex homogeneous function H of degree two on $F^\times$: the squared norm of v in the dual metric on the tautological line $\mathcal{O}_{\mathbb{P}(F)}(-1)_{[v]}$. The function H is strictly plurisubharmonic if and only if R_h is strictly positive on $\mathbb{P}(F)$.*

Proof Take local holomorphic coordinates y on $\mathbb{P}(F)$ and a holomorphic frame e of the tautological line bundle, and write the metric of the dual frame as $h = e^{-\varphi}$. The dual metric gives

$$H(y, \lambda e) = |\lambda|^2 e^{\varphi(y)}, \quad R_h = \text{dd}^c \varphi.$$

Let $\mathcal{L}$ denote the complex Hessian, without the factor $i/(2\pi)$ of the curvature normalization. Differentiating at a point with $\lambda \neq 0$ gives

$$\mathcal{L}H(u, t) = H\left(\mathcal{L}\varphi(u) + \left|\frac{t}{\lambda} + \partial\varphi(u)\right|^2\right), \quad (u, t) \in T_y^{1,0}\mathbb{P}(F) \oplus \mathbb{C}.$$

If $\mathcal{L}\varphi$ is positive definite, the right-hand side is positive for every nonzero (u, t) : the first term detects $u \neq 0$, and the second detects $t \neq 0$ when $u = 0$. Conversely, for $u \neq 0$, set $t = -\lambda\partial\varphi(u)$; strict positivity of $\mathcal{L}H$ then forces $\mathcal{L}\varphi(u) > 0$. This is exactly positivity of R_h . The squared tautological norm is independent of the chosen frame and is complex homogeneous, so the local functions define the asserted global function H . $\square$

A line bundle is very ample when its complete linear system defines a holomorphic embedding, and ample when some positive tensor power is very ample. With the convention above, a vector bundle F^* is called ample when L is ample.

Proposition 4.5.2 *If F^* is ample, there is a positive complex homogeneous function H of degree two on $F^\times$ that is smooth and strictly plurisubharmonic there and, after extension by zero, continuous on F .*

Proof Choose $m \geq 1$ such that L^m is very ample. Its complete linear system gives an embedding $\iota : \mathbb{P}(F) \rightarrow \mathbb{P}^N$ with $L^m = \iota^* \mathcal{O}_{\mathbb{P}^N}(1)$. Pull back the Fubini–Study metric to a metric k on L^m , and take its positive m th root h on L : in a local frame $h = k^{1/m}$, and the transformation law for L^m makes these local roots a metric on L . Its curvature is

$$R_h = \frac{1}{m} \iota^* \omega_{\text{FS}} > 0,$$

because the differential of the embedding is injective. Apply [Lemma 4.5.6](#). Since the base is compact, the resulting H is bounded on the unit sphere bundle of a fixed Hermitian metric. Homogeneity then gives $0 < H(v) \leq C|v|^2$ off zero, which proves continuity of the extension by zero. $\square$

Corollary 4.5.2 *Let F carry a holomorphic structure in the neighborhood of [Theorem 4.5.1](#). If F^* is ample, there is no positive continuous complex homogeneous function of degree two on F that is plurisubharmonic off zero and locally strongly convex in the fibers.*

Proof By [Proposition 4.5.2](#), ampleness of F^* gives the function H required in [Proposition 4.5.1](#). A function Q as in the statement would therefore give a smooth complex norm on F with strictly plurisubharmonic square, contradicting [Theorem 4.5.1](#). $\square$

The function H is not the square of a Hermitian norm in general, since the metric on the tautological line may vary with the line. It provides the strict plurisubharmonicity on the total space needed for regularization, whereas local strong convexity in the fibers remains a separate hypothesis in the continuous obstruction.

4.5.3 Polar norms of semipositive Finsler metrics

For a holomorphic vector bundle that is not assumed to carry a positively curved Hermitian metric, positivity can be measured by Finsler metrics and their Kobayashi curvature. Polar duality converts a Finsler metric on E with semipositive Kobayashi curvature into a continuous norm on E^* whose square is plurisubharmonic and uniformly convex in the fibers. With the regularization of [Section 4.5.1, Theorem 4.5.1](#) therefore excludes such Finsler metrics on an ample bundle whose dual is close to a split bundle with positive Gauduchon degrees.

Let $E \rightarrow X$ be a holomorphic vector bundle of positive rank; in this subsection $n \geq 1$. Write $E^\times$ for the complement of its zero section. A *squared Finsler metric* on E is a positive smooth function G on $E^\times$ with

$$G(x, tv) = |t|^2 G(x, v), \quad t \in \mathbb{C} \setminus \{0\},$$

extended continuously by zero to the zero section. It is *strongly pseudoconvex* if its vertical complex Hessian $(G_{i\bar{j}})$ is positive definite; this does not require convexity in the real fiber variables.

In local holomorphic base and fiber coordinates (z, v) , with Greek indices for base coordinates, Latin indices for fiber coordinates and summation over repeated indices, put

$$\begin{aligned} S_{\alpha\bar{\beta}} &= G_{\alpha\bar{\beta}} - G_{\alpha\bar{j}} G^{\bar{j}i} G_{i\bar{\beta}}, \\ \mathcal{K}_G &= -\frac{i}{2\pi G} S_{\alpha\bar{\beta}} dz^\alpha \wedge d\bar{z}^\beta, \end{aligned}$$

where $(G^{\bar{j}i})$ is the inverse of the vertical Hessian. We use this convention for the *Kobayashi curvature* $\mathcal{K}_G$, a horizontal $(1, 1)$ -form at each point of $E^\times$. Thus $\mathcal{K}_G \geq 0$ means $S \leq 0$, and $\mathcal{K}_G > 0$ means that S is negative definite.

Lemma 4.5.7 *Let G be a strongly pseudoconvex squared Finsler metric. If $\mathcal{K}_G > 0$, then for every $v_0 \in E_{x_0}^\times$ there is a local holomorphic section σ with $\sigma(x_0) = v_0$ and*

$$G(z, \sigma(z)) \leq G(x_0, v_0)$$

near x_0 . Moreover, without any curvature assumption, on a coordinate ball, for $\varphi = |z|^2$ and $\varepsilon > 0$, the metric $G_\varepsilon = e^{-\varepsilon\varphi} G$ is strongly pseudoconvex and satisfies

$$\mathcal{K}_{G_\varepsilon} = \mathcal{K}_G + \varepsilon dd^c \varphi.$$

Proof Since the vertical Hessian is positive, the Levi-orthogonal complement $H_{G,v}$ of the vertical tangent space at v projects isomorphically onto the base tangent space. The Levi form of G on $H_{G,v}$ is the Schur complement S , which is negative definite when $\mathcal{K}_G > 0$. For the vertical radial vector $R = v_i \partial_{v_i}$, complex homogeneity gives

$$\partial G(R) = G, \quad \mathcal{L}_G(a, \bar{R}) = \partial G(a)$$

for every tangent vector a , where $\mathcal{L}_G$ is the Levi form. Since R is vertical, the second identity implies $\partial G|_{H_{G,v}} = 0$.

Choose a holomorphic section σ_0 through v_0 whose tangent space at x_0 is H_{G,v_0} . In coordinates centered at x_0 , the function $G \circ \sigma_0$ has zero first derivative and Taylor expansion

$$G(x_0, v_0) + P(z) + \overline{P(\bar{z})} + S_{\alpha\bar{\beta}} z^\alpha \bar{z}^\beta + O(|z|^3),$$

where P is a homogeneous holomorphic quadratic polynomial. The identity $\partial_v G(v_0)(v_0) = G(v_0) > 0$ gives a vertical vector b with $\partial_v G(v_0)(b) = 1$. Set $\sigma = \sigma_0 - bP$ in the local frame. This changes only the pure quadratic terms and cancels $P + \bar{P}$. The remaining quadratic form is negative definite, and therefore dominates the cubic remainder on a sufficiently small ball. The section stays nonzero there and satisfies the asserted inequality.

For the last assertion, differentiate $e^{-\varepsilon\varphi} G$ in the Schur complement. Euler's identities give $G_{i\bar{j}} = v_i G_{i\bar{j}}$ and $G_\alpha = G_{\alpha\bar{j}} \bar{v}_j$. Hence the terms containing $\partial\varphi$, including its square, cancel between the base Hessian and the mixed block product, leaving

$$S(G_\varepsilon) = e^{-\varepsilon\varphi} (S(G) - \varepsilon G(\varphi_{\alpha\bar{\beta}})).$$

Dividing by G_ε gives the curvature formula. The vertical Hessian of G_ε is the positive multiple $e^{-\varepsilon\varphi} (G_{i\bar{j}})$, so G_ε is again strongly pseudoconvex. $\square$

Proposition 4.5.3 *Let G be a strongly pseudoconvex squared Finsler metric with $\mathcal{K}_G \geq 0$. Its polar square*

$$Q(x, \xi) = \max_{[v] \in \mathbb{P}(E_x)} \frac{|\xi(v)|^2}{G(x, v)}, \quad \xi \in E_x^*,$$

is continuous and plurisubharmonic on the total space of E^ , positive off the zero section and complex homogeneous of degree two. The function $\log Q$ is plurisubharmonic off the zero section, and $\sqrt{Q}$ is a complex norm on each fiber.*

Proof The ratio is invariant under complex rescaling of v , so the maximum can be taken over the compact unit sphere in a local frame, which proves continuity. Positive upper and lower bounds for G on that sphere compare Q with a Hermitian squared dual norm; this gives positivity off zero and continuity at zero, and complex homogeneity is clear. Moreover,

$$\sqrt{Q(x, \xi)} = \sup_{v \neq 0} \frac{|\xi(v)|}{\sqrt{G(x, v)}}.$$

Each term satisfies the triangle inequality in ξ , and so does their supremum.

On a coordinate ball, set $G_\varepsilon = e^{-\varepsilon|z|^2} G$. By [Lemma 4.5.7](#), its Kobayashi curvature is strictly positive, and its polar square is $Q_\varepsilon = e^{\varepsilon|z|^2} Q$. At a point (x_0, ξ_0) with $\xi_0 \neq 0$, choose a maximizing line and a vector v_0 on it. The lemma, applied to G_ε , gives a holomorphic section σ such that

$$\log Q_\varepsilon(z, \xi) \geq \log |\xi(\sigma(z))|^2 - \log G_\varepsilon(x_0, v_0),$$

with equality at (x_0, ξ_0) . The pairing $\xi(\sigma(z))$ is nonzero near that point, so the right-hand side is pluriharmonic there. Restriction to sufficiently small holomorphic disks centered at the point therefore gives the submean inequality for $\log Q_\varepsilon$. This argument applies at every point off the zero section, and together with continuity it shows that $\log Q_\varepsilon$ is plurisubharmonic there.

As $\varepsilon \downarrow 0$, the functions $\log Q_\varepsilon = \log Q + \varepsilon|z|^2$ converge locally uniformly off the zero section. Passing to the limit in the submean inequalities on disks proves that $\log Q$ is plurisubharmonic off the zero section. Since the exponential is increasing and convex, Jensen's inequality shows that $Q = \exp(\log Q)$ is plurisubharmonic there. At a point of the zero section, $Q = 0$ and $Q \geq 0$, so every centered disk satisfies the submean inequality there. Together with continuity and the submean inequalities at nonzero points, this proves plurisubharmonicity on the whole total space of E^* . $\square$

Lemma 4.5.8 *Let k be a smooth Hermitian metric on E , and let G be a positive smooth complex homogeneous function of degree two on $E^\times$, extended by zero. Then its polar square Q , defined as in [Proposition 4.5.3](#), has a constant $c > 0$ such that*

$$Q(x, \xi) - c|\xi|_{k^*}^2$$

is real convex on every dual fiber. Neither strong pseudoconvexity nor real convexity of G is required here.

Proof The real fiber Hessian of G is bounded above by $2L$ times k on the compact unit sphere bundle of k , for some $L > 0$, and homogeneity extends this bound to every nonzero vector. Also, G is C^1 at zero with derivative zero, since its value is $O(|v|^2)$ and its first fiber derivative is $O(|v|)$, uniformly over the base. Integrating the Hessian estimate along a segment gives

$$G(v + w) \leq G(v) + d_v G(w) + L|w|_k^2; \quad (4.6)$$

a segment passing through zero is handled by splitting it there and using the continuity of the first derivative.

Complex homogeneity and completing the square on each complex line give the identity

$$Q(x, \xi) = \max_{v \in E_x} \{2 \operatorname{Re} \xi(v) - G(x, v)\}. \quad (4.7)$$

The maximum exists because $G(v) \geq a|v|_k^2$ for a uniform constant $a > 0$. Fix a maximizer v_0 for ξ_0 . Differentiation, including the case $\xi_0 = v_0 = 0$, gives $dG(v_0) = 2 \operatorname{Re} \xi_0$. Evaluate the expression in (4.7) for $\xi_0 + \zeta$ at $v_0 + w$ and apply (4.6). The terms involving $\xi_0(w)$ cancel, and we obtain

$$Q(\xi_0 + \zeta) \geq Q(\xi_0) + 2 \operatorname{Re} \zeta(v_0) + 2 \operatorname{Re} \zeta(w) - L|w|_k^2.$$

Taking the supremum over w yields

$$Q(\xi_0 + \zeta) \geq Q(\xi_0) + 2 \operatorname{Re} \zeta(v_0) + L^{-1} |\zeta|_{k^*}^2.$$

Set $c = L^{-1}$ and $\Phi = Q - c|\cdot|_{k^*}^2$. After subtracting the square, this inequality gives a real affine function on the whole dual fiber that lies below Φ and equals Φ at ξ_0 . Hence Φ is the supremum of such affine functions, and therefore convex. Neither uniqueness of the maximizer nor real convexity of G has been used. $\square$

Corollary 4.5.3 *If E is ample and has a strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature, then E^* admits a smooth complex norm whose square is strictly plurisubharmonic off zero and locally strongly convex in the real fibers.*

Proof By [Proposition 4.5.3](#), the polar square is a positive continuous plurisubharmonic complex homogeneous function of degree two, and by [Lemma 4.5.8](#) it has the strong convexity in the fibers required in [Proposition 4.5.1](#). Applying [Proposition 4.5.2](#) to $F = E^*$, whose dual $F^* = E$ is ample, gives the positive smooth strictly plurisubharmonic homogeneous function H on E^* . Hence [Proposition 4.5.1](#) applies. Its proof uses [Theorem 4.5.2](#), which preserves strong convexity in the fibers, and the square root of the resulting function is the asserted smooth norm. $\square$

Corollary 4.5.4 *Let F be the underlying smooth bundle of F_0 in [Theorem 4.5.1](#), with a holomorphic structure in the neighborhood given there. If F^* is ample, then F^* admits no strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature.*

Proof Apply [Corollary 4.5.3](#) to $E = F^*$. Such a metric would produce a smooth complex norm on F with plurisubharmonic square, contrary to [Theorem 4.5.1](#). $\square$

The corollary applies only near a split bundle whose line summands have positive Gauduchon degrees, and it is not vacuous only if such a neighborhood contains holomorphic structures with ample dual. On Hirzebruch surfaces, [Theorem 4.5.3](#) gives stable ample bundles whose duals lie in this neighborhood. Since the polar square need not be smooth, the regularization of [Section 4.5.1](#) is an essential step of the argument.

4.5.4 Ample comparison quotients on Hirzebruch surfaces

To apply [Corollary 4.5.4](#), we need ample vector bundles whose duals are close to a split bundle $F_1 \oplus F_2$ with $\deg_{\Theta_s} F_s > 0$ for suitable test forms Θ_s . The split bundle $F_1^* \oplus F_2^*$ is not ample itself: otherwise its quotient line bundles F_s^* would be ample, hence carry positively curved metrics, and each F_s would have negative degree for every test form. The ample bundles must therefore be obtained by deformation. On a Hirzebruch surface we choose a split bundle $E_0 = L_1 \oplus L_2$ whose dual summands have positive degree for suitable Kähler forms, and we construct an ample bundle

E_{amp} with the same Chern classes as a quotient of a trivial bundle. Both bundles belong to the family of bundles with these Chern classes that are prioritary for the ruling. This family is irreducible, which will allow us to find ample bundles in every neighborhood of E_0 .

Let $e \geq 0$ be an integer, and let

$$X = \mathbb{F}_e = \mathbb{P}_{\mathbb{P}^1}(O \oplus O(e)), \quad \pi : X \longrightarrow \mathbb{P}^1,$$

be the Hirzebruch surface, where the projective bundle parametrizes lines. Write S for the section defined by the subbundle $O(e)$ and f for a fiber of π , called a ruling fiber; we identify line bundles with divisor classes and write $O_X(aS + bf)$. The normal bundle of S is $O(-e)$, so

$$S^2 = -e, \quad S \cdot f = 1, \quad f^2 = 0.$$

The dual of the tautological line bundle is $O_X(S)$. A line bundle of degree zero on the ruling fibers is pulled back from $\mathbb{P}^1$: its direct image has rank one, and the evaluation map from the pullback of the direct image is an isomorphism on each fiber. Consequently $\text{Pic}(X) = \mathbb{Z}S \oplus \mathbb{Z}f$.

Lemma 4.5.9 *For integers $a \geq 0$ and b ,*

$$\pi_* O_X(aS + bf) = \bigoplus_{i=0}^a O_{\mathbb{P}^1}(b - ie), \quad R^1 \pi_* O_X(aS + bf) = 0.$$

A class $aS + bf$ is effective exactly when $a, b \geq 0$. If $a \geq 1$ and $b > ae$, its line bundle is very ample. In particular,

$$H = S + (3e + 1)f, \quad H^2 = 5e + 2, \quad h^0(X, O_X(H)) = 5e + 4.$$

The canonical class is $K_X = -2S - (e + 2)f$.

Proof Over a trivializing chart of the base, sections of $O_X(aS)$ are homogeneous polynomials of degree a in the fiber coordinates. Their transition law gives

$$\pi_* O_X(aS) = \text{Sym}^a(O \oplus O(-e)),$$

and twisting by the base gives the formula. The first cohomology of $O_{\mathbb{P}^1}(a)$ on each fiber vanishes, which gives the assertion on the higher direct image. If $a < 0$, restriction to a general ruling fiber excludes a nonzero section. For $a \geq 0$, the direct-image formula gives a nonzero section exactly when $b \geq 0$.

Suppose that $a \geq 1$ and $b > ae$. All line bundles in the direct image then have degree at least one. Fiber polynomials of degree a separate points and tangent directions within a fiber. To separate points over different base points, choose a fiber monomial that is nonzero at the first point and a coefficient section vanishing at the second base point but not at the first. At any point, choose such a nonzero monomial and a coefficient section with a simple zero at its base point; the resulting global

section vanishes there, has nonzero derivative in a prescribed base direction and has zero vertical derivative. The complete linear system therefore separates points and first jets, so it defines an embedding. The formulas for H^2 and $h^0(H)$ follow from the intersection numbers and from the direct image $\mathcal{O}(3e+1) \oplus \mathcal{O}(2e+1)$. Finally, the relative Euler sequence gives $K_{X/\mathbb{P}^1} = -2S - ef$, and adding the pullback of the canonical class of $\mathbb{P}^1$ proves the last identity. $\square$

Put

$$L_1 = \mathcal{O}_X(5S - f), \quad L_2 = \mathcal{O}_X(-S + (12e + 5)f), \quad E_0 = L_1 \oplus L_2.$$

Their Chern classes satisfy

$$c_1(E_0) = 4H, \quad c_2(E_0) = 65e + 26 = 13H^2.$$

An ample bundle with these Chern classes can be constructed as a quotient of a trivial bundle. The main point of the proof is to make the fibers of the associated map to projective space finite, which requires excluding common curves of the defining sections uniformly over the projective parameter.

Proposition 4.5.4 *There exist linearly independent sections $a_0, \dots, a_3$ of $\mathcal{O}_X(H)$ with no common zero. For any such quadruple and a general quadruple $b_0, \dots, b_3$ of sections of $\mathcal{O}_X(3H)$, the sequence*

$$0 \longrightarrow \mathcal{O}_X(-H) \oplus \mathcal{O}_X(-3H) \xrightarrow{(a,b)} \mathcal{O}_X^{\oplus 4} \longrightarrow E_{\text{amp}} \longrightarrow 0$$

has a locally free ample cokernel E_{amp} of rank two, with $c_1(E_{\text{amp}}) = 4H$ and $c_2(E_{\text{amp}}) = 13H^2$. Here general means outside a proper Zariski-closed subset of the space of quadruples.

Proof *Step 1: the quadruple a .* Since $\mathcal{O}_X(H)$ is globally generated, a common zero at a fixed point imposes four independent linear conditions on a quadruple a . The incidence variety of quadruples with a common zero at some point of the surface therefore has codimension at least two in the space of quadruples, and its image there is closed by properness. Linear independence is also a nonempty open condition, because $h^0(H) \geq 4$, and the two open conditions intersect. Fix such an a and write

$$V = H^0(X, \mathcal{O}_X(3H))^{\oplus 4}, \quad N = \dim V.$$

Step 2: local freeness. At a fixed point x , the map (a, b) drops rank exactly when $b(x)$ is proportional to the nonzero vector $a(x)$. Since evaluation on V is surjective, this is a condition of codimension three. Its incidence over X has dimension at most $N - 1$, and its image in V is closed. Outside that image the cokernel is locally free of rank two.

Step 3: the map to projective space. Dualizing the sequence identifies E_{amp}^* with a subbundle of $(\mathbb{C}^4)^* \otimes \mathcal{O}_X$. This inclusion defines a proper morphism

$$q_b : \mathbb{P}(E_{\text{amp}}^*) \longrightarrow \mathbb{P}((\mathbb{C}^4)^*), \quad \mathcal{O}_{\mathbb{P}(E_{\text{amp}}^*)}(1) = q_b^* \mathcal{O}_{\mathbb{P}^3}(1).$$

For $w = [w_0 : \cdots : w_3]$, its fiber is the common zero scheme of

$$s_w = \sum_i w_i a_i \in H^0(X, \mathcal{O}_X(H)), \quad t_w = \sum_i w_i b_i \in H^0(X, \mathcal{O}_X(3H)).$$

Linear independence of a gives $s_w \neq 0$ for every w .

Step 4: no common curves. A nonzero effective subdivisor D of $\text{div}(s_w)$ has class $uS + v f$, where

$$u \in \{0, 1\}, \quad 0 \leq v \leq 3e + 1, \quad (u, v) \neq (0, 0).$$

Write $|D| = \mathbb{P}H^0(X, \mathcal{O}_X(D))$ for the complete linear system. For each of these finitely many classes D_0 , let T_{D_0} parametrize the triples $(w, [\sigma], [\tau])$ with

$$[\sigma] \in |D_0|, \quad [\tau] \in |H - D_0|, \quad [s_w] = [\sigma\tau].$$

Since products of nonzero sections are nonzero, this is a closed projective parameter scheme. Its fiber over w consists of the finitely many effective subdivisors of the fixed divisor $\text{div}(s_w)$, counted with their possible multiplicities. Thus $\dim T_{D_0} \leq 3$.

Vanishing on a nonzero effective divisor D imposes at least four independent conditions on $H^0(X, \mathcal{O}_X(3H))$. Indeed, choose an integral curve C in its support. Very ampleness gives sections r_0, r_1 of $\mathcal{O}_X(H)$ with nonconstant ratio on C . The four cubic monomials in their restrictions are linearly independent, since a linear relation would make the nonconstant ratio algebraic over $\mathbb{C}$, hence constant.

For fixed $(w, [\sigma], [\tau])$, the map $V \rightarrow H^0(X, \mathcal{O}_X(3H))$, $b \mapsto t_w$, is surjective. The condition that t_w vanish on $D = \text{div}(\sigma)$ therefore has codimension at least four in V . This condition is closed in families: the universal multiplication map

$$H^0(X, \mathcal{O}_X(3H - D_0)) \otimes \mathcal{O}_{|D_0|}(-1) \longrightarrow H^0(X, \mathcal{O}_X(3H)) \otimes \mathcal{O}_{|D_0|}$$

is injective on fibers, so its image is a subbundle, and the condition is the vanishing of the image of t_w in the quotient bundle. Its incidence over T_{D_0} has dimension at most $N - 1$, and its image in V is closed.

Step 5: conclusion. Choose b outside these finitely many proper closed images and outside the image of Step 2. Then s_w and t_w have no common curve for any w , so every fiber of q_b is finite. A proper morphism with finite fibers is finite, and the pullback of $\mathcal{O}_{\mathbb{P}^3}(1)$ by a finite morphism is ample; hence E_{amp} is ample. Finally, the Whitney formula gives

$$c(E_{\text{amp}}) = \frac{1}{(1-H)(1-3H)} = 1 + 4H + 13H^2.$$

A vector bundle E on X is called *prioritary for the ruling* if $\text{Ext}_X^2(E, E(-f)) = 0$. Since all ruling fibers are linearly equivalent, this condition does not depend on the chosen fiber, and by Serre duality it is equivalent to

$$\text{Hom}_X(E, E(K_X + f)) = 0.$$

Prioritary bundles of fixed rank and Chern classes form an irreducible family, by the theorem of Walter recalled in [Section 4.5.6](#).

Lemma 4.5.10 *Both E_0 and E_{amp} are prioritary for the ruling.*

Proof Write $D = K_X + f = -2S - (e + 1)f$. The summands of $\text{End}(E_0)(D)$ have classes

$$D, \quad D, \quad 4S - (13e + 7)f, \quad -8S + (11e + 5)f.$$

Each has a negative coefficient in the basis S, f , so by [Lemma 4.5.9](#) none of them has a nonzero section. This proves the required vanishing of Hom for E_0 .

Precomposition with the surjection $\mathcal{O}_X^4 \rightarrow E_{\text{amp}}$ gives an injection

$$\text{Hom}(E_{\text{amp}}, E_{\text{amp}}(D)) \hookrightarrow H^0(X, E_{\text{amp}}(D))^4.$$

Twist the defining sequence by D . Its middle term has no sections. For $j = 1, 3$, Serre duality and the formula of [Lemma 4.5.9](#) give

$$H^1(X, \mathcal{O}_X(D - jH)) = H^1(X, \mathcal{O}_X(jH - f))^*,$$

$$\pi_* \mathcal{O}_X(jH - f) = \bigoplus_{i=0}^j \mathcal{O}_{\mathbb{P}^1}(j(3e + 1) - 1 - ie).$$

The higher direct image vanishes, and every degree in this sum is at least $j(2e + 1) - 1 \geq 0$. Hence all these first cohomology groups vanish, and the long exact sequence of the twisted sequence gives $H^0(X, E_{\text{amp}}(D)) = 0$. This proves the vanishing of Hom for E_{amp} . $\square$

Proposition 4.5.5 *For $F_s = L_s^*$, $s = 1, 2$, there are Kähler forms η_s with $\deg_{\eta_s} F_s = 1$. Consequently, the split bundle $E_0^* = F_1 \oplus F_2$ satisfies the hypotheses of [Theorem 4.5.1](#).*

Proof The integral classes

$$A_1 = 6S + (6e + 1)f, \quad A_2 = S + (13e + 6)f$$

are very ample by [Lemma 4.5.9](#). Pullbacks of normalized Fubini–Study forms under the corresponding embeddings give Kähler forms η_s representing $c_1(\mathcal{O}_X(A_s))$. A direct computation of intersection numbers gives

$$c_1(L_1) \cdot A_1 = -1, \quad c_1(L_2) \cdot A_2 = -1,$$

so the degrees of the duals are equal to one. Since $n = 2$, the closed positive $(1, 1)$ -forms η_s are admissible test forms Θ_s in [Theorem 4.5.1](#). $\square$

4.5.5 Stable extensions approaching the split comparison bundle

The bundles near E_0 that we construct will also be slope-stable for a fixed polarization. The split bundle E_0 is unstable, and the ample bundle E_{amp} need not be stable. Nonsplit extensions of L_2 by L_1 have the same Chern classes as E_0 , are stable, and converge to E_0 as the extension class tends to zero; they are not ample, however. The next subsection combines them with E_{amp} .

Keep the Hirzebruch surface $X = \mathbb{F}_e$, its ruling and the line bundles of [Section 4.5.4](#). Thus

$$L_1 = \mathcal{O}_X(5S - f), \quad L_2 = \mathcal{O}_X(-S + (12e + 5)f), \quad E_0 = L_1 \oplus L_2.$$

We use the very ample polarization $P = 4H - f = 4S + (12e + 3)f$. For a torsion-free coherent sheaf E of positive rank on X , put

$$\deg_P E = c_1(E) \cdot P, \quad \mu_P(E) = \frac{\deg_P E}{\text{rank } E}.$$

A vector bundle V is μ_P -stable if $\mu_P(M) < \mu_P(V)$ for every coherent subsheaf $M \subset V$ with $0 < \text{rank } M < \text{rank } V$. Since $\mu_P(L_2) > \mu_P(E_0)$ by the computation below, the split bundle E_0 is not μ_P -stable.

Proposition 4.5.6 *The extension space has dimension*

$$\dim \text{Ext}_X^1(L_2, L_1) = 105e + 35.$$

Every nonsplit extension

$$0 \longrightarrow L_1 \longrightarrow V \xrightarrow{q} L_2 \longrightarrow 0$$

is a locally free, μ_P -stable bundle with $c_1(V) = 4H$ and $c_2(V) = 13H^2$.

Proof Extensions of line bundles are locally free: the quotient is free on a small trivializing neighborhood, so the sequence splits there. Their classes form

$$\text{Ext}_X^1(L_2, L_1) = H^1(X, \mathcal{O}_X(6S - (12e + 6)f)).$$

By [Lemma 4.5.9](#), the higher direct image of this line bundle vanishes and its direct image is the sum of the seven line bundles $\mathcal{O}_{\mathbb{P}^1}(-12e - 6 - ie)$, $0 \leq i \leq 6$. Their first cohomology groups have total dimension

$$\sum_{i=0}^6 (12e + 5 + ie) = 105e + 35 > 0.$$

The Chern classes follow from the extension sequence. Direct computations of intersection numbers give

$$\mu_P(L_1) = 40e + 11, \quad \mu_P(V) = 40e + 14, \quad \mu_P(L_2) = 40e + 17.$$

It suffices to test line-bundle subsheaves $M \hookrightarrow V$. Indeed, a rank-one torsion-free subsheaf on a smooth surface has a line bundle as its double dual, and its inclusion extends across the finitely many missing points by Hartogs extension in local bundle frames. The extended map remains injective and has the same first Chern class. This argument does not require the quotient to be locally free.

If the composite $M \rightarrow L_2$ is zero, then M maps nontrivially into L_1 , so $\deg_P M \leq \mu_P(L_1) < \mu_P(V)$. Otherwise its zero divisor D is effective and $M = L_2(-D)$. If $D = 0$, the composite is an isomorphism and its inverse splits q , contrary to the hypothesis. Hence $D \neq 0$, and

$$\deg_P M = \mu_P(V) + 3 - D \cdot P.$$

Every effective class is $aS + bf$ with $a, b \geq 0$, and

$$S \cdot P = 8e + 3, \quad f \cdot P = 4.$$

For $e \geq 1$, every nonzero effective divisor has P -degree at least four, which proves the strict slope inequality.

For $e = 0$, the only nonzero effective class of P -degree at most three is S . A lift of multiplication by a nonzero section $s \in H^0(X, \mathcal{O}_X(S))$ from $L_2(-S)$ to V would make the pullback of the nonzero extension class vanish. That pullback is the image of the class under the map

$$H^1(X, \mathcal{O}_X(6S - 6f)) \xrightarrow{\cdot s} H^1(X, \mathcal{O}_X(7S - 6f)).$$

On $X = \mathbb{P}^1 \times \mathbb{P}^1$, order the factors so that $\mathcal{O}_X(S) = \mathcal{O}(1, 0)$ and $\mathcal{O}_X(f) = \mathcal{O}(0, 1)$. The Künneth formula identifies this map with

$$[H^0(\mathbb{P}^1, \mathcal{O}(6)) \xrightarrow{\cdot s} H^0(\mathbb{P}^1, \mathcal{O}(7))] \otimes \text{Id}_{H^1(\mathbb{P}^1, \mathcal{O}(-6))}.$$

Multiplication by a nonzero section is injective on global sections, and tensoring with a vector space preserves injectivity. Thus the nonzero extension class cannot pull back to zero. This excludes the possible equality of slopes and proves stability also for $e = 0$. $\square$

Proposition 4.5.7 *Every extension of L_2 by L_1 , including the split extension, is prioritary for the ruling and is not ample. Its restriction to every ruling fiber is $\mathcal{O}_{\mathbb{P}^1}(5) \oplus \mathcal{O}_{\mathbb{P}^1}(-1)$.*

Proof Put $D = K_X + f = -2S - (e + 1)f$. The four line bundles $L_i^* \otimes L_j(D)$ have classes

$$D, \quad D, \quad 4S - (13e + 7)f, \quad -8S + (11e + 5)f.$$

Each has a negative coefficient in the basis S, f , and hence no nonzero section. Applying $\text{Hom}_X(L_i, \cdot)$ to the extension twisted by D gives $\text{Hom}_X(L_i, V(D)) = 0$ for $i = 1, 2$. Applying $\text{Hom}_X(\cdot, V(D))$ to the original extension then gives $\text{Hom}_X(V, V(D)) = 0$. By Serre duality this is the prioritary condition $\text{Ext}_X^2(V, V(-f)) = 0$.

Restriction to a ruling fiber is exact, because the quotient is locally free. The restricted line bundles have degrees five and minus one, and the restricted extension splits, since $\text{Ext}_{\mathbb{P}^1}^1(\mathcal{O}(-1), \mathcal{O}(5)) = H^1(\mathbb{P}^1, \mathcal{O}(6)) = 0$. The quotient of negative degree on this curve excludes ampleness. $\square$

Proposition 4.5.8 *On the smooth bundle underlying E_0 there is a holomorphic one-parameter family of Dolbeault operators $\bar{\partial}_t = \bar{\partial}_0 + tA$, $t \in \mathbb{C}$, such that for $t \neq 0$ the holomorphic bundle defined by $\bar{\partial}_t$ is μ_P -stable and prioritary, but not ample. As $t \rightarrow 0$, these operators converge to $\bar{\partial}_0$ in the C^m norm for every integer $m \geq 0$.*

Proof Choose a nonzero extension class and a smooth Dolbeault representative $\eta \in \Omega^{0,1}(X, L_2^* \otimes L_1)$ of it, so that $\bar{\partial}\eta = 0$. On the smooth direct sum, set

$$A = \begin{pmatrix} 0 & \eta \\ 0 & 0 \end{pmatrix}.$$

The covariant Dolbeault derivative of A is zero and $A \wedge A = 0$, so $\bar{\partial}_t^2 = 0$. Adding the Dolbeault operator of the base $\mathbb{C}$ of the parameter t also gives an integrable operator on $X \times \mathbb{C}$, because the family depends holomorphically on t . This defines a holomorphic family of bundles whose extension class is $t[\eta]$. It is nonsplit for $t \neq 0$, so the two preceding propositions apply. For a fixed smooth background connection and fixed metrics,

$$\|\bar{\partial}_t - \bar{\partial}_0\|_{C^m} = |t| \|A\|_{C^m} \rightarrow 0,$$

and the norm $\|A\|_{C^m}$ is finite for every m because X is compact. $\square$

Thus stability and ampleness have been realized separately in the prioritary family of E_0 : the nonsplit extensions are stable but not ample, while E_{amp} is ample. The deformation argument of [Theorem 4.5.3](#) joins the stable locus to the ample one and provides stable ample bundles arbitrarily close to E_0 .

4.5.6 Deforming to stable ample bundles

We keep the Hirzebruch surface $X = \mathbb{F}_e$ and the data H, P, L_1, L_2, E_0 of [Sections 4.5.4](#) and [4.5.5](#). The ample quotient E_{amp} and a nonsplit extension are two prioritary bundles with the same Chern classes as E_0 ; the former is ample and the latter is stable. Prioritary bundles with these invariants form an irreducible family in which ampleness and stability are open conditions, so bundles with both properties are dense in the family, and in particular they accumulate at E_0 . We first prove the required openness assertions for algebraic families.

Throughout this subsection, T denotes a smooth complex algebraic variety. A *flat family* is a coherent sheaf $\mathcal{E}$ on $X \times T$ that is flat over T , and its fiber $\mathcal{E}_t$ at $t \in T$ is its restriction to $X \times \{t\}$.

Lemma 4.5.11 *If a flat family $\mathcal{E}$ has a locally free fiber at $t_0 \in T$, then $\mathcal{E}$ is a vector bundle on $X \times T'$ for some Zariski-open neighborhood T' of t_0 .*

Proof At a point of $X \times \{t_0\}$, lift a local basis of the fiber to $\mathcal{E}$. By Nakayama's lemma, the resulting map from a free module of finite rank is surjective near that point. Tensor its kernel sequence with the residue field of t_0 . Flatness over T makes the first Tor term zero, so the kernel restricts to the kernel of the chosen isomorphism on the fiber, namely zero, and Nakayama's lemma shows that the kernel vanishes near that point. Thus $\mathcal{E}$ is locally free near every point of the central fiber. The locus where $\mathcal{E}$ is not locally free is closed. Since the projection $X \times T \rightarrow T$ is proper, the image of that locus is closed and misses t_0 , and we remove this image. $\square$

Lemma 4.5.12 *For a vector bundle $\mathcal{E}$ on $X \times T$, the parameters t for which $\mathcal{E}_t$ is ample form a Zariski-open subset of T .*

Proof Put $Y = \mathbb{P}_{X \times T}(\mathcal{E}^*)$, with the line convention, and let $p : Y \rightarrow T$ be the projection, a projective flat morphism. Write $\mathcal{L} = \mathcal{O}_Y(1)$. If $\mathcal{E}_{t_0}$ is ample, then $\mathcal{L}_{t_0}$ is ample. Choose k so that its k th power is very ample and has vanishing higher cohomology. By Serre vanishing, semicontinuity, and cohomology and base change, after shrinking T around t_0 the sheaf $\mathcal{V} = p_* \mathcal{L}^k$ is locally free and commutes with restriction to fibers. After a further shrinking, the evaluation map $p^* \mathcal{V} \rightarrow \mathcal{L}^k$ is surjective: its cokernel vanishes on the central fiber, and the image of its support under the proper map p is closed and misses t_0 .

Evaluation gives a proper morphism

$$g : Y \longrightarrow \mathbb{P}_T(\mathcal{V}^*), \quad g^* \mathcal{O}(1) = \mathcal{L}^k,$$

whose restriction to the central fiber is a closed immersion. The locus where g is quasi-finite is open; its complement has closed image in T by properness and misses t_0 , so after a further shrinking g is proper and quasi-finite, hence finite. For a finite morphism, pushforward commutes with base change. The cokernel of

$$\mathcal{O}_{\mathbb{P}_T(\mathcal{V}^*)} \longrightarrow g_* \mathcal{O}_Y$$

therefore vanishes on the central fiber, and its support projects to a closed subset of T missing t_0 . After removing that subset, the map is surjective, so g is a closed immersion. Consequently $\mathcal{L}^k$ is very ample on every fiber, and $\mathcal{E}_t$ is ample there. $\square$

Lemma 4.5.13 *For a family $\mathcal{E}$ of rank-two vector bundles on $X \times T$ whose fibers have a fixed first Chern class, the parameters t for which $\mathcal{E}_t$ is μ_P -stable form a Zariski-open subset of T .*

Proof Fix a stable fiber at t_0 and put $\nu = c_1(\mathcal{E}_{t_0}) \cdot P/2$, which is independent of t . Choose $k \geq 1$ such that $\mathcal{E}_{t_0}^*(kP)$ is globally generated and has vanishing higher cohomology. The argument with Serre vanishing, base change and evaluation used in the previous proof gives, over a neighborhood of t_0 , maps

$$\mathcal{E}_t \longrightarrow \mathcal{O}_X(kP)^{\oplus N}$$

that are injective on every fiber. By the double-dual argument for rank-one subsheaves in the proof of [Proposition 4.5.6](#), a destabilizing subsheaf of $\mathcal{E}_t$ yields a nonzero map from a line bundle $M = \mathcal{O}_X(aS + bf)$ with $\deg_P M \geq \nu$. At least one component of its composite with the injection above is nonzero, and since effective classes have nonnegative coefficients,

$$a \leq 4k, \quad b \leq (12e + 3)k.$$

Since $\deg_P M = (8e + 3)a + 4b$, the inequality $\deg_P M \geq \nu$ also gives

$$a \geq \frac{\nu - 4(12e + 3)k}{8e + 3}, \quad b \geq \frac{\nu - 4k(8e + 3)}{4}.$$

Only finitely many integral pairs (a, b) satisfy these four bounds. For each such pair with $\deg_P M \geq \nu$, semicontinuity makes the set

$$\{t : H^0(X, \mathcal{E}_t \otimes M^*) \neq 0\}$$

closed, and it does not contain t_0 . Conversely, a nonzero map from such an M is injective as a map of sheaves and violates stability. Thus the set of parameters with unstable fibers is, on this neighborhood, exactly the finite union of these closed subsets, and removing the union proves the claim. $\square$

Lemma 4.5.14 *Let T be smooth and irreducible, let $U \subset T$ be a nonempty Zariski-open subset, and let $\mathcal{E}$ be a vector bundle on $X \times T$. For every $t_0 \in T$, there are points $t_j \in U$ tending to t_0 in the analytic topology, together with smooth complex-linear identifications of the bundles underlying $\mathcal{E}_{t_j}$ and $\mathcal{E}_{t_0}$, under which the Dolbeault operators of the fibers converge in the C^m norm for every integer $m \geq 0$. The dual operators converge in the same sense.*

Proof The proper algebraic closed subset $T \setminus U$ has empty interior in the analytic topology. In an analytic coordinate ball B around t_0 , choose $t_j \in U \cap B$ with $t_j \rightarrow t_0$. Choose a smooth complex connection on $\mathcal{E}|_{X \times B}$. Parallel transport along radial paths in B , keeping $x \in X$ fixed, gives identifications

$$\Phi_t : \mathcal{E}_{t_0}^{\text{sm}} \longrightarrow \mathcal{E}_t^{\text{sm}}, \quad \Phi_{t_0} = \text{id},$$

depending smoothly on (x, t) , where the superscript sm denotes the underlying smooth complex bundle. These identifications need not be holomorphic. Transport the Dolbeault operators by these maps and write

$$\bar{\partial}_t = \Phi_t^{-1} \bar{\partial}_{\mathcal{E}_t} \Phi_t, \quad A_t = \bar{\partial}_t - \bar{\partial}_{\mathcal{E}_{t_0}}.$$

Since both operators satisfy the same Leibniz rule, A_t is an endomorphism-valued $(0, 1)$ -form. Its coefficients are smooth in (x, t) , and $A_{t_0} = 0$. Fix background metrics

and a smooth connection on the central bundle. Compactness of X and continuity of every finite collection of derivatives give

$$\|A_{t_j}\|_{C^m(X)} \longrightarrow 0 \quad \text{for every integer } m \geq 0.$$

The dual identifications are $(\Phi_t^{-1})^*$. In transported dual frames the perturbation is $-A_t^\top$, so the same convergence holds for the dual Dolbeault operators. $\square$

We use Walter's theorem on prioritary stacks: on a birationally ruled surface, a nonempty stack of prioritary torsion-free sheaves with fixed rank $r \geq 2$ and fixed numerical Chern classes is smooth and irreducible. Here prioritary means that $\text{Ext}^2(E, E(-f)) = 0$ for every ruling fiber f ; on X all ruling fibers are linearly equivalent. The theorem concerns the full prioritary stack and has no semistability hypothesis.

Theorem 4.5.3 *For every $e \geq 0$, there are integrable Dolbeault operators on the smooth bundle underlying E_0 that converge to its split operator in every C^m norm, $m \geq 0$, and define ample μ_P -stable bundles of rank two with $c_1 = 4H$ and $c_2 = 13H^2$. The induced dual operators converge to the split dual operator in every C^m norm.*

Proof Let $\mathcal{P}$ be the prioritary stack with invariants $(2, 4H, 13H^2)$. It contains E_0 by Proposition 4.5.7, and Walter's theorem makes it smooth and irreducible. Let $\mathcal{A}$ and $\mathcal{S}$ be the loci of ample and of μ_P -stable vector bundles in $\mathcal{P}$. They are open by the three preceding family lemmas, which apply on smooth local charts of $\mathcal{P}$; the first lemma allows restriction to locally free families near a point given by a vector bundle. The ample bundle of Proposition 4.5.4 is prioritary by Lemma 4.5.10, so $\mathcal{A}$ is nonempty. A nonsplit extension is stable and prioritary by Propositions 4.5.6 and 4.5.7, so $\mathcal{S}$ is nonempty. By irreducibility, $\mathcal{U} = \mathcal{A} \cap \mathcal{S}$ is nonempty and dense.

Choose a smooth local chart $q : T \rightarrow \mathcal{P}$ of finite type over $\mathbb{C}$, with a point t_0 representing E_0 , and let $\mathcal{E}$ be the corresponding flat family on $X \times T$. Fix an identification $\mathcal{E}_{t_0} \simeq E_0$. The variety T is smooth because the stack and the chart are smooth. Shrink T to an irreducible neighborhood of t_0 and use Lemma 4.5.11 to make $\mathcal{E}$ a vector bundle on the whole product. The inverse image $q^{-1}(\mathcal{U})$ is dense: every nonempty open $T' \subset T$ has nonempty open image $q(T')$ under the smooth map q , and this image meets $\mathcal{U}$. Apply Lemma 4.5.14 to this dense open set. Each transported operator defines a bundle isomorphic to the corresponding ample stable fiber. The fixed invariants of the stack give its Chern classes, and the lemma also gives the convergence of the dual operators. $\square$

Corollary 4.5.5 *For every $e \geq 0$, there is an ample μ_P -stable bundle E of rank two on X with $c_1(E) = 4H$ and $c_2(E) = 13H^2$ that admits no smooth strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature.*

Proof By Proposition 4.5.5, the two line summands of E_0^* have positive degrees with respect to suitable test forms. The preceding theorem gives an ample stable bundle E whose dual Dolbeault operator is as close to the split dual operator in C^4 as required. Apply Corollary 4.5.4 to $F = E^*$. $\square$

4.5.7 A fixed Stein hypersurface for all Finsler metrics

Corollary 4.5.5 shows that no Finsler metric on E has semipositive Kobayashi curvature, but it does not locate the failure. For a single metric, a point where the curvature is not semipositive gives a local hypersurface through that point on which the metric has a nondegenerate critical point with many positive Levi directions. Holomorphic approximation on a Stein manifold allows one hypersurface to serve for all metrics at once.

In this subsection, X is a connected smooth projective variety of dimension $n \geq 1$, and $E \rightarrow X$ is an algebraic vector bundle of rank $r \geq 2$, viewed as a holomorphic bundle. We use the squared Finsler metrics and the convention for Kobayashi curvature of [Section 4.5.3](#). A compact subset K of a Stein manifold Y is *holomorphically convex* if it coincides with its holomorphic hull $\{y \in Y : |f(y)| \leq \sup_K |f| \text{ for all } f \in \mathcal{O}(Y)\}$. We use the classical Oka–Weil theorem in the following form: a function holomorphic near a holomorphically convex compact subset of a Stein manifold can be approximated uniformly there by global holomorphic functions. We also use polynomial Runge approximation in one variable on a union of two disjoint closed disks.

Lemma 4.5.15 *Let K, L be holomorphically convex compact subsets of a Stein manifold Y . If a global holomorphic function maps them into disjoint closed disks in $\mathbb{C}$, then $K \cup L$ is holomorphically convex.*

Proof Write h for the function and Δ_K, Δ_L for the disks. Their union is polynomially convex, so testing with polynomials in h shows that h maps the holomorphic hull of $K \cup L$ into $\Delta_K \cup \Delta_L$. Suppose that $p \notin K \cup L$ and $h(p) \in \Delta_K$. Holomorphic convexity of K gives $a \in \mathcal{O}(Y)$ with $|a(p)| > \sup_K |a|$. Choose polynomials tending uniformly to one on Δ_K and to zero on Δ_L . Their compositions with h , multiplied by a , converge to a at p and on K , and to zero on L . A sufficiently good approximation therefore separates p from $K \cup L$. The case $h(p) \in \Delta_L$ is identical, with K and L interchanged. Thus no point outside $K \cup L$ belongs to its hull. $\square$

Lemma 4.5.16 *Let U be a connected smooth affine variety and let $q \geq 0$ be an integer. Put $B = U \times \mathbb{C}^* \times \mathbb{C}^q$, with coordinates (x, t, s) , and for $\lambda \in \mathbb{C}^*$ let $d_\lambda(x, t, s) = (x, \lambda t, \lambda s)$. For each $j \geq 1$, let $C_j \subset B$ be a holomorphically convex compact set, let g_j be holomorphic near C_j , and let $\delta_j > 0$. Suppose that $t(C_j)$ lies in the disk $|t - t_j| \leq |t_j|/4$ for some $t_j \neq 0$. Then there are $\lambda_j \in \mathbb{C}^*$ and $f \in \mathcal{O}(B)$ such that*

$$\sup_{d_{\lambda_j}(C_j)} |f - \lambda_j g_j \circ d_{\lambda_j}^{-1}| < |\lambda_j| \delta_j \quad (j \geq 1).$$

Proof Choose an exhaustion $(L_j)_{j \geq 0}$ of the affine, hence Stein, manifold B by holomorphically convex compact sets with $L_j \subset \text{int } L_{j+1}$. We construct $f_j \in \mathcal{O}(B)$ and compact sets K_j inductively, starting with $f_0 = 0$ and $K_0 = L_0$.

At stage $j \geq 1$, choose $M > 0$ with $t(K_{j-1}) \subset \{|t| \leq M\}$, and choose $R > 4M/3$. Dilation by $\lambda_j = R/t_j$ moves the t -projection of C_j into the disk $|t - R| \leq R/4$, which is disjoint from $|t| \leq M$. For the rest of the induction we replace C_j, g_j and

δ_j by the dilated compact set $d_{\lambda_j}(C_j)$, the function $\lambda_j g_j \circ d_{\lambda_j}^{-1}$ and the tolerance $|\lambda_j| \delta_j$, keeping the same notation. **Lemma 4.5.15**, applied with the function t , makes $K_{j-1} \cup C_j$ holomorphically convex.

On disjoint neighborhoods of K_{j-1} and C_j , prescribe f_{j-1} and g_j , respectively. Oka–Weil approximation gives $f_j \in O(B)$ with

$$\sup_{K_{j-1}} |f_j - f_{j-1}| < \epsilon_j, \quad \sup_{C_j} |f_j - g_j| < \epsilon_j, \quad \epsilon_j = 2^{-j-2} \min(1, \delta_1, \dots, \delta_j).$$

Let K_j be a member of the fixed exhaustion containing $K_{j-1} \cup C_j \cup L_j$ in its interior. The interiors of the sets K_j exhaust B , and the summable errors make f_j converge locally uniformly to some $f \in O(B)$. For a fixed j , every later approximation controls its error on C_j , since $C_j \subset K_{m-1}$ for $m > j$. Consequently

$$\sup_{C_j} |f - g_j| \leq \sum_{m \geq j} \epsilon_m \leq 2^{-j-1} \delta_j < \delta_j.$$

Returning to the original notation gives the stated tolerances. $\square$

Theorem 4.5.4 *Suppose that E admits no smooth strongly pseudoconvex squared Finsler metric with semipositive Kobayashi curvature. Then there is a connected smooth Stein hypersurface $S \subset E^\times$, locally closed in the analytic topology, with the following property: for every smooth strongly pseudoconvex squared Finsler metric G on E , the restriction $G|_S$ has a nondegenerate critical point with at least r positive Levi eigenvalues, and hence with at most $n - 1$ negative ones.*

Proof *Step 1: coordinates.* An algebraic frame trivializes E over a nonempty affine open subset $U \subset X$. Since X is smooth and connected, it is irreducible, so U is dense and connected. Write the fiber coordinates as $(w, t, s) \in \mathbb{C} \times \mathbb{C} \times \mathbb{C}^{r-2}$, and put $B = U \times \mathbb{C}^* \times \mathbb{C}^{r-2}$. We seek S as a graph $w = f(x, t, s)$ over B ; such a graph avoids the zero section because $t \neq 0$.

Step 2: a local test for one metric. Fix a candidate metric G . Since its Kobayashi curvature is not semipositive, its horizontal Schur complement has a positive direction somewhere. This condition is open, so it holds at a point $v_0 = (x_0, w_0, t_0, s_0)$ with $x_0 \in U$, $t_0 \neq 0$ and $G_w(v_0) \neq 0$. Indeed, the first two conditions define a dense open set, and the zero set of G_w has empty interior, since vanishing of G_w on an open set would give $G_{w\bar{w}} = 0$ there, contradicting the positivity of the vertical Hessian.

Let H be the Levi-orthogonal complement of the vertical tangent space V at v_0 . The Euler identities in the proof of **Lemma 4.5.7** give

$$K := \ker \partial G(v_0) = H \oplus (V \cap K), \quad \dim_{\mathbb{C}}(V \cap K) = r - 1.$$

Indeed, ∂G vanishes on H , and its value on the vertical radial vector is $G(v_0) > 0$. The two summands are Levi orthogonal, the vertical summand is positive definite, and the horizontal summand has a positive direction. Thus the Levi form of G restricted to K has at least r positive eigenvalues.

Since $G_w(v_0) \neq 0$, the space K is the graph of a linear map defined on $T_{b_0}^{1,0}B$, where $b_0 = (x_0, t_0, s_0)$. Choose a local holomorphic function g near b_0 with $g(b_0) = w_0$ whose graph has tangent space K at v_0 . Then $F = G \circ \text{Graph}(g)$ has a critical point at b_0 , and its Levi form there is the restriction of the Levi form of G to K . Keep this first jet of g fixed and vary its quadratic jet. The mixed second derivatives of F do not change, while in local coordinates z on B the pure second derivatives satisfy

$$F_{\alpha\beta}(b_0) = A_{\alpha\beta} + G_w(v_0)g_{\alpha\beta}(b_0),$$

where A is fixed. Since $G_w(v_0) \neq 0$, we can prescribe the pure quadratic part of F to be $\tau \operatorname{Re} \sum_{\alpha} z_{\alpha}^2$, whose real Hessian has eigenvalues $\pm 2\tau$. If τ is larger than half the operator norm of the real Hessian of the fixed mixed part, the full real Hessian is invertible by the Neumann-series criterion. The critical point is then nondegenerate, with the same Levi form.

Step 3: stability of the test. Choose compact neighborhoods $C' \subset \operatorname{int} C$ of b_0 on which g is defined, with C holomorphically convex and $t(C) \subset \{|t - t_0| \leq |t_0|/4\}$. A small closed Euclidean ball in a closed affine embedding of B is such a set C , since linear functions separate points outside the ball from the ball. Fix a smooth Hermitian background metric on E and its compact unit sphere bundle Σ . By homogeneity, the C^2 distance between metrics on Σ controls their C^2 distance on each fixed compact subset of $E^\times$. Persistence of nondegenerate critical points and openness of the conditions on the Levi eigenvalues therefore give a neighborhood $\mathcal{V}_G$ of $G|_{\Sigma}$ for the C^2 topology and a number $\delta_G > 0$ with the following property: for every metric whose restriction to Σ lies in $\mathcal{V}_G$ and every holomorphic function within δ_G of g uniformly on C , the restriction of the metric to the graph of the function still has a nondegenerate critical point over C' with at least r positive Levi eigenvalues. Here the Cauchy estimates on C' turn uniform closeness on C into C^2 closeness on C' .

Step 4: one hypersurface for all metrics. The restrictions of the candidate metrics to Σ form a subspace of the separable metrizable space $C^2(\Sigma)$. This subspace is second countable, hence Lindelöf, so the cover by the neighborhoods $\mathcal{V}_G$ has a countable subcover $(\mathcal{V}_j)_{j \geq 1}$, with associated data C_j, g_j, δ_j . For $D_{\lambda}(x, w, t, s) = (x, \lambda w, \lambda t, \lambda s)$,

$$G \circ D_{\lambda} = |\lambda|^2 G.$$

Dilation therefore preserves critical points of restrictions to graphs, their real nondegeneracy and their Levi inertia, for every candidate metric. It maps the graph of a function g over C to the graph of $\lambda g \circ d_{\lambda}^{-1}$ over $d_{\lambda}(C)$, with d_{λ} as in [Lemma 4.5.16](#). A function within $|\lambda|\delta_j$ of $\lambda g_j \circ d_{\lambda}^{-1}$ on $d_{\lambda}(C_j)$ pulls back under the dilation to a function within δ_j of g_j on C_j . In particular, the metric neighborhood $\mathcal{V}_j$ needs no change.

Applying [Lemma 4.5.16](#), we obtain one function $f \in \mathcal{O}(B)$ that satisfies all the dilated tests. Its graph $\mathcal{S}$ is biholomorphic to the connected affine Stein manifold B , and it is smooth and closed in the open subset $\{x \in U, t \neq 0\}$ of $E^\times$. Every candidate metric belongs to some $\mathcal{V}_j$, so its restriction to $\mathcal{S}$ has the required nondegenerate critical point. Since $\dim_{\mathbb{C}} \mathcal{S} = n + r - 1$, at least r positive Levi eigenvalues leave at most $n - 1$ negative ones. $\square$

Corollary 4.5.6 *For each $e \geq 0$, the bundle E of [Corollary 4.5.5](#) can be chosen so that $E^\times$ contains a connected smooth Stein hypersurface on which the restriction of every smooth strongly pseudoconvex squared Finsler metric on E has a nondegenerate critical point with at least two positive Levi eigenvalues and at most one negative Levi eigenvalue.*

Proof The bundle constructed in the proof of [Theorem 4.5.3](#) is a fiber of an algebraic family on a chart of the prioritary stack, so it is algebraic. Apply [Theorem 4.5.4](#) with $n = r = 2$, using the curvature obstruction of [Corollary 4.5.5](#). $\square$

4.5.8 Concave neighborhoods and dual norms

A relatively compact neighborhood Ω of the zero section of a vector bundle E determines a norm on E^* , the support function $\xi \mapsto \max_{v \in \bar{\Omega} \cap E_x} |\xi(v)|$ of its fibers. If the boundary of Ω is sufficiently concave in the horizontal directions, holomorphic sections touching the boundary from inside show that this support norm has plurisubharmonic square, and supporting balls give it uniform convexity in the fibers. Consequently, when the dual norms are obstructed as in [Theorem 4.5.1](#), such neighborhoods cannot exist. In terms of exhaustion functions, this bounds the convexity of the complement of the zero section in the projective completion of E .

In this subsection, $E \rightarrow X$ is a holomorphic vector bundle of rank $r \geq 1$, and $n \geq 1$. Fix a smooth Hermitian metric k on E , with real inner product $k_{\mathbb{R}} = \operatorname{Re} k$ and dual norm $|\cdot|_{k^*}$. For a smooth real function f , write $\mathcal{L}_f$ for its complex Hessian. Let Ω be an open set with smooth boundary, defined near $\partial\Omega$ by $f < 0$ with $df \neq 0$ on $\partial\Omega$. We say that $\partial\Omega$ has *at least n negative Levi directions* if, at every boundary point, $\mathcal{L}_f$ has at least n negative eigenvalues on $\ker \partial f$.

Lemma 4.5.17 *Fix $\delta, B > 0$. On a finite-dimensional Hermitian vector space, put*

$$s_c(\xi) = |\xi(c)| + \delta|\xi|$$

for covectors ξ and vectors c with $|c| \leq B$. There is $\gamma > 0$, depending only on δ and B , such that $s_c^2 - \gamma|\xi|^2$ is real convex for every such c .

Proof For $0 < \tau \leq 1$, replace s_c by the norm

$$s_{c,\tau}(\xi) = \sqrt{|\xi(c)|^2 + \tau|\xi|^2} + \delta|\xi|,$$

which is smooth off zero. Its Lipschitz constant is at most $L = \sqrt{B^2 + 1} + \delta$, uniformly in c and τ . All derivatives below are real derivatives on the dual space. At $\xi \neq 0$, set $u = \xi/|\xi|$ and decompose a vector as $w = \alpha u + b$ with b orthogonal to u for the real inner product. Write $s = s_{c,\tau}$ and $A = ds_\xi(w)$. Since the first summand of s is convex and $s \geq \delta|\xi|$,

$$D^2 s(w, w) \geq \delta \frac{|b|^2}{|\xi|}, \quad D^2(s^2)(w, w) \geq 2A^2 + 2\delta^2|b|^2.$$

Homogeneity gives $ds_\xi(u) = s(\xi)/|\xi| \geq \delta$. Since $|ds_\xi(b)| \leq L|b|$, we have

$$|w|^2 \leq \frac{2A^2}{\delta^2} + \left(1 + \frac{2L^2}{\delta^2}\right) |b|^2.$$

Take $\gamma = \delta^4/(\delta^2 + 2L^2)$. Then $\gamma \leq \delta^2/2$ and $\gamma(1 + 2L^2/\delta^2) = \delta^2$, so $D^2(s^2)(w, w) \geq 2\gamma|w|^2$.

The homogeneous function $s^2 - \gamma|\xi|^2$ of degree two extends as a C^1 function at zero with differential zero. Its restriction to every real line is convex, including at zero, because its second derivative is nonnegative away from zero and its first derivatives match there. Thus it is convex on the whole space. Finally,

$$0 \leq s_{c,\tau}(\xi) - s_c(\xi) \leq \sqrt{\tau} |\xi|,$$

and the locally uniform limit as $\tau \downarrow 0$ proves the assertion with the same γ . $\square$

Theorem 4.5.5 *Suppose that a relatively compact neighborhood $\Omega \Subset E$ of the zero section has smooth boundary with at least n negative Levi directions. Then*

$$p(x, \xi) = \max_{v \in \overline{\Omega} \cap E_x} |\xi(v)|$$

is a continuous complex norm on E^ whose square $Q = p^2$ is plurisubharmonic on the total space of E^* . For some $\gamma > 0$, each function $Q(x, \cdot) - \gamma|\cdot|_{k^*}^2$ is real convex. If E is ample, E^* also admits a smooth complex norm with strictly plurisubharmonic square off the zero section.*

Proof *Step 1: basic bounds.* Put $A_x = \overline{\Omega} \cap E_x$. By compactness of X there are $0 < a_0 < b_0$ such that, in every fiber, the closed k -ball of radius a_0 is contained in Ω and $\overline{\Omega}$ lies in the open ball of radius b_0 . The maximum defining p is attained, and

$$a_0|\xi|_{k^*} \leq p(x, \xi) \leq b_0|\xi|_{k^*}.$$

As a supremum of absolute values of linear functionals, p is complex homogeneous and satisfies the triangle inequality.

Step 2: support points. Fix $\xi_0 \neq 0$ and a maximizing point $v_0 \in A_{x_0}$. It lies on $\partial\Omega$, since at an interior point a small vertical displacement would increase $|\xi_0(v)|$. Multiply ξ_0 by a complex number of modulus one to obtain η with $\eta(v_0) = p(x_0, \xi_0) = a > 0$. Then $\ell = \operatorname{Re} \eta$ satisfies $\ell \leq a$ on A_{x_0} . Choose a smooth defining function f near the boundary, with $\Omega = \{f < 0\}$ and $df \neq 0$ there.

Let $V = T_{v_0}^{1,0} E_{x_0}$ be the vertical tangent space and $T = \ker \partial f(v_0)$. Choose an n -dimensional complex subspace $W \subset T$ on which $\mathcal{L}_f$ is negative definite. We first show that the vertical differential $d_v f(v_0)$ is nonzero. Otherwise $V \subset T$, and counting dimensions gives $W \cap V \neq \{0\}$. A vector in this intersection has negative vertical Levi form, and the two corresponding real directions show that the real vertical Hessian of f has a negative direction. Its negative cone is open, hence contains a direction w

with $\ell(w) > 0$. Since the vertical first derivative vanishes, Taylor expansion gives $f(v_0 + tw) < 0$ for small $t > 0$, contradicting $\ell \leq a$ on A_{x_0} .

The boundary of A_{x_0} is therefore smooth at v_0 . Since the supporting functional ℓ attains its maximum on A_{x_0} there,

$$d_v f(v_0) = c d\ell, \quad c > 0;$$

the sign follows because an inward direction along which ℓ increases would contradict the maximality. On the affine hyperplane $\{\ell = a\}$ of the fiber, the restriction of f has a local minimum zero at v_0 : a point there with $f < 0$ would allow an additional displacement increasing ℓ within Ω . The real vertical Hessian of f is thus nonnegative on $\ker d\ell$. Consequently $\mathcal{L}_f$ is nonnegative on the complex space $V \cap T$, of dimension $r - 1$. Hence $W \cap V = \{0\}$, and the projection $W \rightarrow T_{x_0}^{1,0} X$ is an isomorphism.

Step 3: plurisubharmonicity. In local coordinates z centered at x_0 , choose a holomorphic section σ_0 through v_0 with tangent space W . The function $f \circ \sigma_0$ has zero first derivative and negative definite mixed Hessian. Its quadratic expansion is

$$f(\sigma_0(z)) = \sum H_{\alpha\bar{\beta}} z_\alpha \bar{z}_\beta + 2 \operatorname{Re} P(z) + O(|z|^3),$$

where P is a holomorphic quadratic polynomial. Choose a vertical vector b with $\partial_v f(b) = 1$, and replace σ_0 by $\sigma = \sigma_0 - bP$. This preserves the first jet and cancels the pure quadratic part. Thus, after shrinking the chart,

$$f(\sigma(z)) \leq -\epsilon |z|^2, \quad \sigma(0) = v_0,$$

for some $\epsilon > 0$. In particular $\sigma(z) \in A_z$ throughout the chart.

Compactness of $\bar{\Omega}$ makes p upper semicontinuous: for convergent covectors, the corresponding maximizing vectors have a subsequence whose limit lies in the limiting fiber of $\bar{\Omega}$. The supporting section gives the opposite inequality $p(z, \xi) \geq |\xi(\sigma(z))|$, with equality at (x_0, ξ_0) . Therefore p is continuous off the zero section, and its upper bound gives continuity at zero. The holomorphic pairing $\xi(\sigma(z))$ is nonzero near the contact point, and its logarithmic absolute value is a pluriharmonic function lying below $\log p$ and equal to it at (x_0, ξ_0) . The mean-value property on small holomorphic disks therefore gives the submean inequality for $\log p$ at every point off the zero section. Thus $\log p$, and then $Q = \exp(2 \log p)$ by Jensen's inequality, are plurisubharmonic there. At the zero section the continuous nonnegative function Q vanishes, so its submean inequality on disks also holds there.

Step 4: uniform convexity in the fibers. Consider all maximizing triples (x, ξ, v) with $|\xi|_{k^*} = 1$. They form a compact set, since p is continuous, and by Step 2 the vertical differential $d_v f$ does not vanish at these support points. Thus there are uniform constants $m > 0$, $\rho > 0$ and $C \geq 1$ such that, for vertical vectors w ,

$$|d_v f| \geq m, \quad f(v + w) \leq d_v f(w) + C|w|_k^2 \quad (|w|_k \leq \rho).$$

Choose $0 < \delta < \min\{a_0/2, \rho/2, m/(2C)\}$. At a support point, write N for the outward real vertical unit normal and set $c = v - \delta N$. If $|w + \delta N|_k \leq \delta$, then

$$k_{\mathbb{R}}(w, N) \leq -\frac{|w|_k^2}{2\delta}, \quad f(v+w) \leq -\left(\frac{m}{2\delta} - C\right)|w|_k^2 \leq 0.$$

All these points lie in the neighborhood where f is defined, so the closed ball $\overline{B}_k(c, \delta)$ is contained in A_x .

The support function of this ball is $s_c(\xi) = |\xi(c)| + \delta|\xi|_{k^*} \leq p(x, \xi)$. For a maximizing covector of unit norm, with its phase normalized as in Step 2, the real part $\operatorname{Re} \eta$ has real dual norm one and its metric dual vector is N . Hence $\operatorname{Re} \eta(N) = 1$, and since $|\eta(N)| \leq 1$, also $\eta(N) = 1$. We obtain $\eta(c) = a - \delta > 0$, and therefore $s_c(\xi) = a$. Homogeneity now gives

$$Q(x, \xi) = \sup_c s_c(\xi)^2,$$

where c ranges over the centers of the supporting balls in the fiber. Every such center satisfies $|c|_k \leq b_0 + \delta$, so by [Lemma 4.5.17](#) all the functions $s_c^2 - \gamma|\xi|_{k^*}^2$ are convex for the same $\gamma > 0$. Their supremum is finite, and it proves the asserted strong convexity of Q .

Step 5: smoothing. Finally, if E is ample, [Proposition 4.5.2](#) gives the smooth strictly plurisubharmonic homogeneous function on E^* required in [Proposition 4.5.1](#), and applying that proposition to Q gives the smooth norm. $\square$

For a complex manifold of dimension N and an integer $1 \leq q \leq N$, we say that the manifold is q -convex if it has a smooth real exhaustion function with at least $N - q + 1$ positive Levi eigenvalues outside a compact set; here an exhaustion function is one whose sublevel sets are compact. A q -convex manifold is also q' -convex for $q \leq q' \leq N$. We call such integers q the *smooth convexity indices* of the manifold, and the smallest of them, when one exists, its *least smooth convexity index*.

Lemma 4.5.18 *Let Y be a complex manifold of dimension N , and let $Z \subset Y$ be a closed complex submanifold of dimension $D \geq 1$. If the least smooth convexity index of Z is $\kappa \leq D$, then every smooth convexity index of Y is at least κ .*

Proof Suppose that Y is p -convex for an integer $1 \leq p < \kappa$. Then a smooth exhaustion function ψ has at least $N - p + 1$ positive Levi eigenvalues outside a compact set $K \subset Y$. Its restriction to the closed submanifold Z is an exhaustion function, since its sublevel sets are closed subsets of the compact sublevel sets of ψ , and $K \cap Z$ is compact.

At a point of $Z \setminus K$, choose a complex subspace $P \subset T^{1,0}Y$ of dimension $N - p + 1$ on which the Levi form of ψ is positive definite. Then

$$\dim_{\mathbb{C}}(P \cap T^{1,0}Z) \geq (N - p + 1) + D - N = D - p + 1.$$

The Levi form of $\psi|_Z$ is the restriction of the Levi form of ψ , since the inclusion is holomorphic, so it has at least $D - p + 1$ positive eigenvalues. Since $p < \kappa \leq D$, this shows that Z is p -convex, which contradicts the definition of κ . $\square$

In the following results, projectivizations parametrize complex lines.

Corollary 4.5.7 *Suppose that E is ample and that E^* admits no smooth complex norm with plurisubharmonic square off the zero section. Then the complement*

$$Z \setminus Y, \quad Z = \mathbb{P}(O_X \oplus E), \quad Y = \mathbb{P}(O_X),$$

is not r -convex.

Proof The chart of Z where the O_X -coordinate is nonzero is identified with the total space of E , and Y is its zero section. Suppose that $Z \setminus Y$ is r -convex. Since $\dim Z = n + r$, a smooth exhaustion function ψ then has at least $n + 1$ positive Levi eigenvalues outside a compact set K . Choose a relatively compact disk-bundle neighborhood $D \Subset E$ of Y . The set $Z \setminus D$ is compact and disjoint from Y . Choose a regular value c of ψ greater than its maximum on $Z \setminus D$ and on K .

Since $\{\psi \leq c\}$ is compact in $Z \setminus Y$, the set $\Omega = \{\psi > c\} \cup Y$ is an open neighborhood of Y . Its closure is a compact subset of D , and its boundary is the regular level set $\{\psi = c\}$. The defining function $f = c - \psi$ has at least $n + 1$ negative Levi eigenvalues there. Restriction to the complex tangent hyperplane removes at most one negative direction, leaving at least n . Since E is ample, [Theorem 4.5.5](#) produces a smooth complex norm on E^* with plurisubharmonic square, a contradiction. $\square$

Corollary 4.5.8 *For every $e \geq 0$, there is an ample rank-two bundle E on the Hirzebruch surface $X = \mathbb{F}_e$ such that $\mathbb{P}(O_X \oplus E) \setminus \mathbb{P}(O_X)$ is not 2-convex. The bundle may be chosen with the slope-stability and Chern classes of [Theorem 4.5.3](#).*

Proof Use [Theorem 4.5.3](#) to choose E whose dual Dolbeault operator lies in the C^4 neighborhood of [Theorem 4.5.1](#); the split dual bundle satisfies the hypotheses of that theorem by [Proposition 4.5.5](#). Thus E^* admits no smooth complex norm with plurisubharmonic square, and [Corollary 4.5.7](#) with $r = 2$ gives the assertion. $\square$

4.5.9 Curvature and projective complement exhaustions

[Corollary 4.5.7](#) excludes r -convexity of the complement of the zero section in the projective completion, but it does not decide which larger indices occur. Upper bounds come from curvature. The reciprocal of the squared norm of a Hermitian metric is an exhaustion near the removed zero section, and every positive direction of the curvature, evaluated at a fiber vector, contributes a positive Levi eigenvalue. For a stable bundle of positive Gauduchon degree, the Hermitian–Einstein metric provides such a direction at every fiber vector.

In this subsection, $E \rightarrow X$ is a holomorphic vector bundle of rank $r \geq 1$, $n \geq 1$, and h is a smooth Hermitian metric on E . In a holomorphic frame, write the matrix of h as M , using column vectors and an inner product linear in its first argument, so that $h(v, v) = v^* M v$. Put

$$F_h = \bar{\partial}(M^{-1} \partial M) = \sum_{\alpha, \beta} F_{\alpha \bar{\beta}} dz_\alpha \wedge d\bar{z}_\beta, \quad R_h(u, \bar{u}) = \sum_{\alpha, \beta} F_{\alpha \bar{\beta}} u_\alpha \bar{u}_\beta.$$

For $v \in E_x$, the real $(1, 1)$ -form $\alpha_{h,v} = i h(F_h v, v)$ has the Hermitian coefficient form $u \mapsto h(R_h(u, \bar{u})v, v)$. For a Hermitian form ω on X , the *mean curvature* of h is the h -Hermitian endomorphism $K_{\omega,h} = \Lambda_\omega(iF_h)$, where Λ_ω denotes contraction with ω , so that $\Lambda_\omega(\beta) \omega^n = n\beta \wedge \omega^{n-1}$ for $(1, 1)$ -forms β . The curvature F_h is unscaled: for a line bundle, the curvature $-\text{dd}^c \log h$ of [Section 4.5](#) is $iF_h/(2\pi)$.

Use the line convention for projectivization and put

$$U_E = \mathbb{P}(O_X \oplus E) \setminus \mathbb{P}(O_X).$$

The chart $[1 : v]$ identifies the total space of E with an open subset of $\mathbb{P}(O_X \oplus E)$, in which $\mathbb{P}(O_X)$ is the zero section; thus U_E contains $E^\times$. Its complex dimension is $n + r$. Convexity is understood in the sense of the smooth exhaustions of [Section 4.5.8](#).

Lemma 4.5.19 *Put $G(v) = h(v, v)$ and $\rho = G^{-1}$ on $E^\times$. In a holomorphic frame that is unitary and Chern-normal at x , meaning that $M(x)$ is the identity and the first derivatives of M vanish at x , the complex Hessian of ρ at (x, v) is*

$$\mathcal{L}_\rho(u, w) = \frac{h(R_h(u, \bar{u})v, v)}{G^2} - \frac{|w|_h^2}{G^2} + \frac{2|h(w, v)|^2}{G^3}, \quad u \in T_x^{1,0}X, \quad w \in E_x,$$

where (u, w) are the horizontal and vertical components of a tangent vector. There are no mixed horizontal–vertical terms, and the vertical block has exactly one positive and $r - 1$ negative eigenvalues.

Proof Such a frame is obtained by a constant change of frame making it unitary at x , followed by a holomorphic change of frame, linear in the coordinates, that cancels ∂M . Then $F_{\alpha\bar{\beta}} = -\partial_\alpha \partial_{\bar{\beta}} M$ at x . The horizontal first derivatives of G and its mixed horizontal–vertical second derivatives vanish. The horizontal complex Hessian of G is $-h(R_h(u, \bar{u})v, v)$, its vertical complex Hessian is $|w|_h^2$, and its vertical first derivative in the direction w is $h(w, v)$. Apply

$$\partial \bar{\partial}(G^{-1}) = 2G^{-3} \partial G \wedge \bar{\partial} G - G^{-2} \partial \bar{\partial} G.$$

The vertical block equals $G^{-1} > 0$ at $w = v$ and equals $-|w|_h^2/G^2$ when $w \perp_h v$. These two subspaces are orthogonal for the vertical block, which proves the statement about its eigenvalues. $\square$

Theorem 4.5.6 *Let s be an integer with $0 \leq s \leq n$. Suppose that for every $x \in X$ and every $0 \neq v \in E_x$, the coefficient form of $\alpha_{h,v}$ has at least s positive eigenvalues. Then U_E is $(n + r - s)$ -convex.*

Proof By [Lemma 4.5.19](#), the horizontal block of $\mathcal{L}_\rho$ has at least s positive eigenvalues and the vertical block has one. Their direct sum thus has at least $s + 1$ positive eigenvalues at every point of $E^\times$.

Choose $\epsilon > 0$ and a smooth function $\chi : [0, +\infty) \rightarrow [0, 1]$ equal to one on $[0, \epsilon]$ and to zero on $[2\epsilon, +\infty)$. Define

$$\psi([1 : v]) = \frac{\chi(G(v))}{G(v)} \quad (v \neq 0),$$

and extend ψ by zero on the divisor at infinity $\mathbb{P}(E)$. This extension is smooth. Indeed, near a point $[0 : v]$ with $v \neq 0$, use a local representative $[u : v]$ in a projective chart. On its intersection with the affine chart, $G(v/u) = h(v, v)/|u|^2$ tends to infinity as $u \rightarrow 0$, so $\chi(G)$ vanishes in a neighborhood of the point.

The function ψ tends to infinity near the removed zero section. Since the ambient projective bundle is compact, every sublevel set of ψ is compact in U_E : it is closed there and cannot accumulate on the removed section. Put $D = \{G < \epsilon\} \subset E$, including the zero section, and $K = \mathbb{P}(\mathcal{O}_X \oplus E) \setminus D$. Then K is a compact subset of U_E , and $\psi = \rho$ on $U_E \setminus K$. Thus the exhaustion ψ has at least $s + 1$ positive Levi eigenvalues outside a compact set. In dimension $n + r$, this is $(n + r - s)$ -convexity. $\square$

Taking $s = 0$ gives $(n + r)$ -convexity for every bundle. For $s = 1$, the curvature hypothesis is precisely RC-positivity of the metric, as in [Definition 4.9.1](#). A positive definite mean curvature provides such a direction by taking a trace.

To apply this to stable bundles, we extend the degree of line bundles of [Section 4.5](#) to vector bundles through their determinants.

Definition 4.5.1 For a Gauduchon form ω on X , define

$$\deg_{\omega} E = \deg_{\omega^{n-1}} \det E = \int_X \frac{i \operatorname{tr} F_h}{2\pi} \wedge \omega^{n-1}, \quad \mu_{\omega}(E) = \frac{\deg_{\omega} E}{r}.$$

For a nonzero torsion-free coherent sheaf $\mathcal{F}$, use the determinant line bundle $\det \mathcal{F} = (\wedge^{\operatorname{rank} \mathcal{F}} \mathcal{F})^{**}$ to define its degree and slope. The bundle E is ω -slope-stable if $\mu_{\omega}(\mathcal{F}) < \mu_{\omega}(E)$ for every coherent subsheaf $\mathcal{F} \subset E$ with $0 < \operatorname{rank} \mathcal{F} < r$ and torsion-free quotient.

If $\det h' = e^f \det h$, the two curvature representatives differ by $-\operatorname{dd}^c f$, whose integral against ω^{n-1} vanishes by [Lemma 2.1.1](#). Thus the degree depends only on the Bott–Chern class $c_1^{\text{BC}}(E)$ of the closed form $i \operatorname{tr} F_h / (2\pi)$, and it is the pairing of this class with ω^{n-1} . The Hopf example in [Example 4.5.1](#) shows that the de Rham first Chern class of E does not determine the degree.

Corollary 4.5.9 *If $K_{\omega, h}$ is positive definite for a Hermitian form ω on X , then U_E is $(n + r - 1)$ -convex. This holds, in particular, when ω is Gauduchon, E is ω -slope-stable, and $\deg_{\omega} E > 0$.*

Proof For $v \neq 0$, the trace of $\alpha_{h, v}$ with respect to ω is $h(K_{\omega, h} v, v) > 0$, and a Hermitian form with positive trace has a positive eigenvalue. Apply [Theorem 4.5.6](#) with $s = 1$.

Under the Gauduchon and stability hypotheses, the classical existence theorem for Hermitian–Einstein metrics on stable bundles gives a metric h with $K_{\omega, h} = \lambda \operatorname{Id}_E$, where λ is a constant. Taking the trace and integrating the contraction identity gives

$$r\lambda \int_X \omega^n = n \int_X \operatorname{tr}(iF_h) \wedge \omega^{n-1} = 2\pi n \deg_{\omega} E > 0.$$

Here $\text{tr } F_h = \bar{\partial} \partial \log \det M$, so $i \text{tr } F_h / (2\pi)$ represents $c_1^{\text{BC}}(E)$. Thus $\lambda > 0$, and the first assertion applies. $\square$

Corollary 4.5.10 *For every $e \geq 0$, there is a stable ample rank-two bundle E on $X = \mathbb{F}_e$ as in [Corollary 4.5.8](#) for which U_E is 3-convex but not 2-convex. Its least smooth convexity index is three.*

Proof Use the ruling section S and fiber f of [Lemma 4.5.9](#), and put $H = S + (3e+1)f$ and $P = 4H - f$. Choose E as in [Corollary 4.5.8](#), μ_P -stable and with $c_1(E) = 4H$. The intersection numbers of [Lemma 4.5.9](#) give

$$c_1(E) \cdot P = 4H \cdot (4H - f) = 80e + 28 > 0.$$

By the same lemma, $P = 4S + (12e+3)f$ is very ample. Take for ω the pulled-back Fubini–Study Kähler form representing $c_1(\mathcal{O}_X(P))$. Degrees with respect to ω are intersection numbers with P , so E is ω -slope-stable with $\deg_\omega E > 0$, and [Corollary 4.5.9](#) gives 3-convexity, since $n = r = 2$. By the choice of E , the complement is not 2-convex. Finally, 1-convexity would imply 2-convexity, so the least index is three. $\square$

4.5.10 External tensor products and complement convexity

On a product of k manifolds, the external tensor product of bundles with positive mean curvature has, at every nonzero fiber vector, a positive curvature direction tangent to each factor. Indeed, the curvature of the tensor product metric has no components mixing different factors, so this count applies to every fiber vector, including vectors that are not decomposable tensors. [Theorem 4.5.6](#) then improves the convexity bound by k .

Let $k \geq 2$. For $1 \leq i \leq k$, let X_i be a connected compact complex manifold of dimension $n_i \geq 1$, let $E_i \rightarrow X_i$ be a holomorphic vector bundle of rank $r_i \geq 1$, and choose a smooth Hermitian metric h_i on E_i and a Hermitian form ω_i on X_i . With $p_i : X = \prod_i X_i \rightarrow X_i$ the projections, put

$$E = \bigotimes_{i=1}^k p_i^* E_i, \quad h = \bigotimes_{i=1}^k p_i^* h_i, \quad n = \sum_i n_i, \quad r = \prod_i r_i.$$

For an endomorphism A_i of E_i , write $\widehat{A}_i$ for its action on the i th tensor factor, with the identity on every other factor. We use the Chern curvature, the forms $\alpha_{h,v}$ and the mean curvatures of [Section 4.5.9](#).

Lemma 4.5.20 *The curvature of h is*

$$F_h = \sum_i \widehat{p_i^* F_{h_i}}.$$

For every $v \in E_x$, the coefficient form of $\alpha_{h,v}$ is block diagonal with respect to the decomposition $T_x^{1,0} X = \bigoplus_i T_{x_i}^{1,0} X_i$, and

$$\mathrm{tr}_{\omega_i}(\alpha_{h,v}|_{T_{x_i} X_i}) = h(\widehat{K_i} v, v), \quad K_i = K_{\omega_i, h_i}.$$

Proof In product holomorphic frames, the matrix of the metric is $M = \bigotimes_i M_i$, and its connection matrix is

$$M^{-1} \partial M = \sum_i \widehat{M_i^{-1} \partial M_i}.$$

Each summand depends only on the coordinates of X_i . Applying $\bar{\partial}$ gives the curvature formula and shows that all components mixing different factors vanish. Pairing with v gives the block diagonal form. Contracting the i th block with ω_i commutes with the identity actions on the other tensor factors, which gives the trace identity. $\square$

Theorem 4.5.7 *If every K_i is positive definite, then*

$$\mathbb{P}(O_X \oplus E) \setminus \mathbb{P}(O_X)$$

is $(n + r - k)$ -convex.

Proof At each point, choose an h_i -orthonormal eigenbasis of K_i . The resulting product basis is h -orthonormal, and $\widehat{K_i}$ has the positive eigenvalues of K_i , repeated according to the dimensions of the other tensor factors. Hence $h(\widehat{K_i} v, v) > 0$ for every nonzero v , whether or not v is decomposable.

By Lemma 4.5.20, each diagonal block of $\alpha_{h,v}$ has positive trace and therefore a positive eigenvalue, so the block diagonal form has at least k positive eigenvalues. Since $k \leq n$, Theorem 4.5.6 with $s = k$ gives the assertion. $\square$

Corollary 4.5.11 *Suppose that each ω_i is Gauduchon, that E_i is ω_i -slope-stable as in Definition 4.5.1, and that $\deg_{\omega_i} E_i > 0$. Then the complement $\mathbb{P}(O_X \oplus E) \setminus \mathbb{P}(O_X)$ is $(n + r - k)$ -convex. For k stable ample Hirzebruch examples as in Corollary 4.5.10, with their polarizations, this gives $(2^k + k)$ -convexity.*

Proof As in the proof of Corollary 4.5.9, choose a Hermitian–Einstein metric on each E_i . Its mean curvature is $\lambda_i \mathrm{Id}_{E_i}$, with $\lambda_i > 0$ by the positivity of the degree and the integrated trace identity. Apply Theorem 4.5.7. For the Hirzebruch factors, $n_i = r_i = 2$, so $n + r - k = 2k + 2^k - k = 2^k + k$. $\square$

4.5.11 Homogeneous plurisubharmonic functions and Hopf complements

Curvature gives upper bounds for the least convexity index of a projective complement. Lower bounds come from plurisubharmonic functions: a smooth positive plurisubharmonic function on the punctured bundle that is homogeneous of degree two excludes every improvement of the trivial bound, and closed submanifolds transfer such lower bounds by [Lemma 4.5.18](#). On Hopf manifolds these tools determine the least index for line bundles whose de Rham first Chern class vanishes. The answer depends on the sign of their Gauduchon degree, which therefore detects information invisible to de Rham cohomology.

Let $F \rightarrow B$ be a holomorphic vector bundle of rank $r \geq 1$ over a connected compact complex manifold B of dimension $n \geq 1$. Write $F^\times$ for the complement of its zero section, and put $N = n + r$ and

$$U_F = \mathbb{P}(O_B \oplus F) \setminus \mathbb{P}(O_B).$$

The reciprocal-norm exhaustion in [Theorem 4.5.6](#) with $s = 0$ shows that U_F is N -convex.

Proposition 4.5.9 *Suppose that $F^\times$ admits a smooth positive plurisubharmonic function G satisfying $G(cv) = |c|^2 G(v)$ for every $c \in \mathbb{C}^*$ and $v \in F^\times$. Then the least smooth convexity index of U_F is N .*

Proof Since every smaller convexity index would imply it, it suffices to exclude $(N - 1)$ -convexity. Suppose that a smooth exhaustion function ψ of U_F has at least two positive Levi eigenvalues outside a compact set $K \subset U_F$.

Fix a reference Hermitian norm on F . On its compact unit sphere bundle, G has a positive minimum and a finite maximum, so by homogeneity G is comparable to the squared reference norm uniformly on $F^\times$. Thus the level sets

$$\Sigma_t = \{G = t^2\}, \quad t > 0,$$

are compact, and multiplication by t maps Σ_1 onto Σ_t . They are smooth hypersurfaces by the Euler identity: if $R_v = v$ is the real radial vector at v , then $dG(R_v) = 2G(v) > 0$. Since K stays away from the removed zero section, there is $\epsilon > 0$ such that Σ_t is disjoint from K for $0 < t < \epsilon$.

Put

$$M(t) = \max_{v \in \Sigma_1} \psi([1 : tv]), \quad 0 < t < \epsilon.$$

On any closed interval in $(0, \epsilon)$, the radial derivatives of the smooth function under the maximum are uniformly bounded over the compact level set, so M is locally Lipschitz. Since ψ is an exhaustion, $M(t) \rightarrow +\infty$ as $t \rightarrow 0$: otherwise maximizing points along a sequence $t \rightarrow 0$ would lie in one compact sublevel set while accumulating on the removed section. Choose $0 < t_0 < t_1 < \epsilon$ with $M(t_0) > M(t_1)$. Since a Lipschitz function is absolutely continuous and is the integral of its derivative, there is a point $t \in (t_0, t_1)$ at which M is differentiable with $M'(t) < 0$.

Choose $v \in \Sigma_1$ attaining $M(t)$, and set $p = tv$. For both signs of h , the inequality

$$M(t+h) \geq \psi([1 : (t+h)v])$$

is an equality at $h = 0$, so differentiability of M gives $\frac{d}{dt}\psi([1 : tv]) = M'(t)$. Since ψ restricted to Σ_t attains its maximum at p and $dG \neq 0$, there is a real number λ with $d\psi = \lambda dG$ at p . Evaluating on the radial direction gives

$$\lambda = \frac{M'(t)}{2t} < 0.$$

The function $\psi - \lambda G$ has zero differential at p and nonpositive real Hessian on $T_p \Sigma_t$. Indeed, its restriction to Σ_t is ψ minus a constant, which has a maximum at p , and since its differential vanishes at p , its second derivative along a curve in Σ_t is the Hessian evaluated on the tangent vector. On the complex tangent hyperplane $H = T_p \Sigma_t \cap iT_p \Sigma_t$, this implies

$$\mathcal{L}_\psi|_H \leq \lambda \mathcal{L}_G|_H \leq 0.$$

The first inequality follows by adding the real Hessian inequalities for a tangent vector and its complex rotation; the second uses plurisubharmonicity of G and $\lambda < 0$. A two-dimensional complex subspace on which $\mathcal{L}_\psi$ is positive definite would meet the hyperplane H nontrivially, so ψ has at most one positive Levi eigenvalue at $p \notin K$. This contradiction excludes $(N-1)$ -convexity. Together with [Theorem 4.5.6](#) for $s = 0$, it proves the proposition. $\square$

Corollary 4.5.12 *If F admits a smooth Hermitian metric h with*

$$h(R_h(u, \bar{u})v, v) \leq 0 \quad \text{for every } x \in B, u \in T_x^{1,0}B, v \in F_x,$$

then the least smooth convexity index of U_F is $n+r$.

Proof Put $G(v) = h(v, v)$. At $x \in B$, take a holomorphic frame that is unitary and Chern-normal at x , and write a tangent vector to F at $v \in F_x$ as (u, w) , with $u \in T_x^{1,0}B$ and $w \in F_x$. The calculation in the proof of [Lemma 4.5.19](#) gives

$$\mathcal{L}_G(u, w) = -h(R_h(u, \bar{u})v, v) + |w|_h^2 \geq 0,$$

with zero mixed block. Thus G is smooth, plurisubharmonic and positive off the zero section, and it satisfies $G(cv) = |c|^2 G(v)$. Apply [Proposition 4.5.9](#). $\square$

Corollary 4.5.13 *If F admits a Hermitian metric with flat Chern connection, then the least smooth convexity index of U_F is $n + r$.*

Proof In parallel holomorphic unitary frames, the squared norm is $G(v) = \sum_j |v_j|^2$, which is plurisubharmonic on the total space. Since the transition matrices are constant and unitary, G is globally defined; it is smooth, positive on $F^\times$ and homogeneous of degree two under complex scalars. Apply [Proposition 4.5.9](#). $\square$

Fix $n \geq 2$, a real number $0 < q < 1$ and a complex number $a \neq 0$. On the scalar Hopf manifold

$$X_q = (\mathbb{C}^n \setminus \{0\}) / \langle z \mapsto qz \rangle,$$

let E_a be the holomorphic line bundle obtained as the quotient of $(\mathbb{C}^n \setminus \{0\}) \times \mathbb{C}$ by $(z, v) \sim (qz, av)$. Put

$$b = -\frac{\log |a|}{\log q}, \quad G(z, v) = |z|^{2b} |v|^2.$$

Since $q^{2b} |a|^2 = 1$, the function G descends to the squared norm of a Hermitian metric on E_a .

Example 4.5.1 The least smooth convexity index of U_{E_a} is two when $0 < |a| < 1$, and $n + 1$ when $|a| \geq 1$. For every Gauduchon form γ on X_q , the degree of E_a with respect to γ^{n-1} is positive, zero or negative according as $|a| < 1$, $|a| = 1$ or $|a| > 1$. The de Rham first Chern class of E_a vanishes in all cases.

Proof Let α be the form on X_q induced by $\text{dd}^c \log |z|^2$; it descends because the contraction changes $\log |z|^2$ by a constant. For $u \in T_z^{1,0}(\mathbb{C}^n \setminus \{0\})$, its coefficient form is, up to the positive factor $1/(2\pi)$,

$$\frac{|u|^2}{|z|^2} - \frac{|\langle u, z \rangle|^2}{|z|^4},$$

where $\langle \cdot, \cdot \rangle$ is the Euclidean Hermitian inner product. By the Cauchy–Schwarz inequality, it is positive semidefinite with kernel $\mathbb{C}z$, hence of rank $n - 1$. The curvature $-\text{dd}^c \log |z|^{2b}$ of the metric G is $-b\alpha$. The integral of $\alpha \wedge \gamma^{n-1}$ is strictly positive, so the degree has the sign of $-b$, which gives the three stated cases. The map $z \mapsto (z/|z|, \log |z|)$ identifies the covering space with $S^{2n-1} \times \mathbb{R}$, and the contraction translates the second coordinate by $\log q$. Hence X_q is diffeomorphic to $S^{2n-1} \times S^1$, and $H_{\text{dR}}^2(X_q, \mathbb{R}) = 0$ since $n \geq 2$.

If $|a| < 1$, then $b < 0$, so every nonzero fiber vector gives $n - 1$ positive curvature directions. Applying [Theorem 4.5.6](#) with $r = 1$ and $s = n - 1$, we obtain 2-convexity. For the lower bound, consider the map $X_q \rightarrow \mathbb{P}^{n-1}$, $[z] \mapsto [z]$, whose fibers are compact embedded elliptic curves $C \simeq \mathbb{C}^*/q^{\mathbb{Z}}$. On a lifted fiber $z = \zeta z_0$, the logarithm of the metric coefficient is $b \log |\zeta|^2 + b \log |z_0|^2$, which is pluriharmonic in ζ . Thus $E_a|_C$ has flat Chern connection. The complement $U_{E_a|_C}$ is a closed complex submanifold of U_{E_a} . A 1-convex exhaustion function of U_{E_a} would restrict to an exhaustion function of this submanifold that is strictly plurisubharmonic outside a

compact set. This contradicts [Corollary 4.5.13](#), since the restricted bundle has base dimension one and rank one. The phase of a affects the gluing but not these metric and curvature calculations.

If $|a| \geq 1$, then $b \geq 0$. On the covering space of $E_a^\times$, the function

$$\log G = b \log |z|^2 + \log |v|^2$$

is plurisubharmonic: the first summand has semipositive Levi form and the second is pluriharmonic for $v \neq 0$. Consequently

$$\mathcal{L}_G = G(\mathcal{L}_{\log G} + \partial \log G \otimes \overline{\partial \log G}) \geq 0.$$

The descended function G is smooth, positive and homogeneous of degree two under complex scalars. Apply [Proposition 4.5.9](#) with rank one and total dimension $n + 1$. $\square$

On the same scalar Hopf manifold X_q , consider a direct sum of rank $r \geq 1$ with complex parameters $a_1, \dots, a_r \neq 0$:

$$F = \bigoplus_{j=1}^r E_{a_j}, \quad b_j = -\frac{\log |a_j|}{\log q}, \quad G(z, v) = \sum_{j=1}^r |z|^{2b_j} |v_j|^2.$$

Here E_{a_j} is defined by the rule $(z, v_j) \sim (qz, a_j v_j)$. Since $q^{2b_j} |a_j|^2 = 1$, the function G descends to the squared norm of the direct sum metric on F .

Proposition 4.5.10 *The least smooth convexity index of U_F is $r + 1$ if every $|a_j| < 1$, and $n + r$ if every $|a_j| \geq 1$.*

Proof Let α be the form induced by $\mathrm{dd}^c \log |z|^2$. By the calculation in [Example 4.5.1](#), it is semipositive of rank $n - 1$, with radial kernel. The direct sum metric has diagonal curvature, and the normalized curvature evaluated at v is

$$\frac{i}{2\pi} h(F_h v, v) = \left(\sum_{j=1}^r (-b_j) |z|^{2b_j} |v_j|^2 \right) \alpha.$$

If every $|a_j| < 1$, then every $b_j < 0$. The coefficient is then strictly positive for $v \neq 0$, so [Theorem 4.5.6](#) with $s = n - 1$ shows that U_F is $(r + 1)$ -convex. On any embedded elliptic fiber C of $X_q \rightarrow \mathbb{P}^{n-1}$, each line metric has flat Chern connection by the logarithmic calculation in [Example 4.5.1](#), and so does their direct sum. Hence [Corollary 4.5.13](#) gives least index $r + 1$ for $U_{F|_C}$. This is a closed complex submanifold of U_F , being its inverse image over C , and [Lemma 4.5.18](#) gives the lower bound.

If every $|a_j| \geq 1$, then every $b_j \geq 0$. For $v_j \neq 0$, the function $|z|^{2b_j} |v_j|^2$ is plurisubharmonic by the calculation with the logarithm and the exponential in [Example 4.5.1](#). It is also smooth at $v_j = 0$, because $z \neq 0$, and by continuity its complex Hessian is nonnegative there as well. The sum G is therefore plurisubharmonic on the covering space of the total space and descends to F . It is positive on $F^\times$ and homogeneous of degree two under complex scalars, so [Proposition 4.5.9](#) applies. $\square$

For a mixed sum, let $t = \#\{j : |a_j| \geq 1\}$ and assume $0 < t < r$. If $\kappa(F)$ denotes the least smooth convexity index of U_F , then

$$\max\{r + 1, n + t\} \leq \kappa(F) \leq n + r.$$

Indeed, the same flat restriction to elliptic fibers gives the lower bound $r + 1$. The direct sum of the t summands with $|a_j| \geq 1$ is a holomorphic subbundle $F_0 \subset F$, and U_{F_0} is closed in U_F by the inclusion of projective subbundles. Its least index is $n + t$ by Proposition 4.5.10, and Lemma 4.5.18 applies again. The upper bound is Theorem 4.5.6 with $s = 0$. In the mixed case these bounds leave the least index undetermined.

4.6 Pluriharmonic currents

A current is *pluriharmonic* if its dd^c vanishes. The normalized Gauduchon currents of Section 4.4 are positive pluriharmonic currents of bidegree $(n - 1, n - 1)$. This section proves four basic properties of positive pluriharmonic currents of arbitrary bidegree. Positivity and the second-order equation control their concentration on a smooth hypersurface. On compact Kähler manifolds, a closed test form bounds the mass of their pullbacks, and the heat equation smooths those with continuous coefficients. Finally, a positive pluriharmonic $(1, 1)$ -current with vanishing vertical trace descends along a fiber bundle whose fibers are entire lines or compact curves; this is used for elliptic fibrations in Chapter 27.

Lemma 4.6.1 *Let Z be a complex manifold of dimension $m \geq 2$, and let $j : D \hookrightarrow Z$ be a smooth closed hypersurface. If a positive (q, q) -current R , $1 \leq q \leq m$, is supported on D and $\mathrm{dd}^c R$ has order zero, then there is a unique positive $(q - 1, q - 1)$ -current S on D such that $R = j_* S$. If $\mathrm{dd}^c R = 0$, then $\mathrm{dd}^c S = 0$. In particular, if $q = 1$, D is compact and connected, and $\mathrm{dd}^c R = 0$, then $R = c[D]$ for some $c \geq 0$.*

Proof Use local coordinates $(z, w_1, \dots, w_{m-1})$ with $D = \{z = 0\}$. Both R and $\mathrm{dd}^c R$ have measure coefficients supported on D . Suppose first that $q < m$. For every compactly supported smooth form η of bidegree $(m - q - 1, m - q - 1)$,

$$0 = \langle \mathrm{dd}^c R, |z|^2 \eta \rangle = \langle R, \mathrm{dd}^c(|z|^2 \eta) \rangle = \langle R, \mathrm{dd}^c |z|^2 \wedge \eta \rangle,$$

where the first equality holds because $\mathrm{dd}^c R$ is a measure supported on D , on which $|z|^2$ vanishes, and the last one because the terms containing $|z|^2$ or its first derivatives vanish on D . Thus $R \wedge i dz \wedge d\bar{z} = 0$, which removes the coefficients of R containing neither normal differential.

Fix a constant positive Hermitian form τ in the w variables. The current $M_\tau = R \wedge \tau^{m-q-1}$ is positive of bidegree $(m - 1, m - 1)$, and $M_\tau \wedge i dz \wedge d\bar{z} = 0$. Its Hermitian matrix of measure densities therefore has zero diagonal entry in the normal direction, and positivity removes the corresponding row and column, so

$$M_\tau \wedge dz = 0, \quad M_\tau \wedge d\bar{z} = 0.$$

Put $s = m - q - 1$. The powers τ^s , as τ varies over the positive Hermitian forms, span the real horizontal (s, s) -forms. Indeed, a linear functional vanishing on these powers vanishes on a polynomial over an open cone; polarization makes it vanish on products of arbitrary real $(1, 1)$ -forms, and these products span the forms of that bidegree. Their products with a horizontal one-form span the complementary test forms for the mixed coefficients of R . The identities above therefore remove every coefficient containing exactly one normal differential. For $q = m$, every top-degree coefficient already contains both normal differentials, and this reduction is unnecessary.

The remaining coefficients are measures on $\{z = 0\}$ multiplying both normal differentials. They therefore define a unique current S on D with $R = j_* S$. Testing against extensions of strongly positive forms on D proves positivity of S , and uniqueness makes these local currents agree on overlaps. Pushforward commutes with dd^c and is injective for a closed embedding, so $dd^c R = 0$ implies $dd^c S = 0$.

When $q = 1$, the current S is a nonnegative distribution on D . The equation $dd^c S = 0$ and Weyl's lemma make it a smooth nonnegative pluriharmonic function. If D is compact and connected, the maximum principle makes it a constant $c \geq 0$, proving the last assertion. $\square$

For smooth pluriharmonic forms on compact Kähler manifolds, the mass of the pullback under a fixed holomorphic map is controlled by pairing with a fixed closed form. The test object is the pushforward of a power of the Kähler form on the source, which is closed; the form being pulled back need only be dd^c -closed.

Lemma 4.6.2 *Let $F : Y \rightarrow X$ be a holomorphic map between compact Kähler manifolds of dimensions $N \geq n$, with Kähler forms Ω and ω . For $1 \leq p \leq n$, there is a constant C such that every smooth positive (p, p) -form S on X with $dd^c S = 0$ satisfies*

$$\int_Y F^* S \wedge \Omega^{N-p} \leq C \int_X S \wedge \omega^{n-p}.$$

Proof The positive closed current $\Gamma = F_*(\Omega^{N-p})$ has bidegree $(n-p, n-p)$ on X . The classical dd^c -lemma for currents on compact Kähler manifolds gives a smooth real closed form γ of this bidegree and a current U with $\Gamma = \gamma + dd^c U$. For $p = n$, a closed current of degree zero is already a smooth locally constant function, and one may take $U = 0$. Since S is smooth, pairing it with U is legitimate, and

$$\int_Y F^* S \wedge \Omega^{N-p} = \langle \Gamma, S \rangle = \int_X \gamma \wedge S + \langle U, dd^c S \rangle = \int_X \gamma \wedge S.$$

The pairing with the fixed smooth form γ is bounded in absolute value by a constant times the trace mass $\int_X S \wedge \omega^{n-p}$ of the positive form S . This proves the estimate. $\square$

For continuous coefficients on a compact Kähler manifold, the Hodge heat flow smooths a positive form while preserving the pluriharmonic equation, and a small multiple of a power of the Kähler form restores positivity.

Lemma 4.6.3 *Let (X, ω) be a compact Kähler manifold of dimension n , and let $1 \leq p \leq n$. Every continuous positive real (p, p) -form R satisfying $\text{dd}^c R = 0$ in the sense of currents is a uniform limit of smooth positive real (p, p) -forms R_j with $\text{dd}^c R_j = 0$. If R is closed, the approximants can also be chosen closed.*

Proof Let Δ be the real Hodge Laplacian of the Kähler metric. Its heat operators $H_t = e^{-t\Delta}$ are smoothing for $t > 0$. The Kähler identities give $\Delta = 2\Delta_{\partial} = 2\Delta_{\bar{\partial}}$, so H_t preserves bidegree, reality and the equation $\text{dd}^c R = 0$.

We recall why $H_t R \rightarrow R$ uniformly for a continuous form R . The Weitzenböck formula writes $\Delta = \nabla^* \nabla + A$, with a bounded curvature term A of order zero. For smooth initial data β , the heat equation and the maximum principle give

$$\|H_t \beta\|_{C^0} \leq e^{Ct} \|\beta\|_{C^0} \quad (0 < t \leq 1),$$

where C depends only on the fixed metric and the degree. Indeed, the scalar equation for $|H_t \beta|^2$ has a nonpositive gradient term and a curvature term bounded above by $2C|H_t \beta|^2$. The classical smooth heat solution converges uniformly to its smooth initial data. Approximating a continuous form by smooth forms and using this bound proves uniform convergence for continuous initial data. The resulting heat solution is smooth for $t > 0$, and since the commutation with dd^c extends to currents, $\text{dd}^c H_t R = 0$.

Set $\epsilon_t = \|H_t R - R\|_{C^0}$, which tends to zero. A fixed constant $c > 0$ satisfies

$$E + c\|E\|_{C^0} \omega^p \geq 0$$

for every continuous real (p, p) -form E ; to see this, evaluate on decomposable unit p -vectors, on which ω^p has a uniformly positive value. Consequently

$$R_t = H_t R + c\epsilon_t \omega^p$$

is smooth and positive. Since ω is Kähler, $\text{dd}^c \omega^p = 0$, and hence $\text{dd}^c R_t = 0$. Moreover, $R_t \rightarrow R$ uniformly. The Hodge heat flow also commutes with d , and ω^p is closed, so $dR = 0$ implies $dR_t = 0$. Choosing any sequence $t_j \downarrow 0$ proves the assertion. $\square$

We next consider a positive $(1, 1)$ -current with vanishing vertical trace on the total space of a fiber bundle. Positivity removes its vertical and mixed coefficients. For a closed current the remaining coefficients are constant along the fibers. For a pluriharmonic current they are only harmonic along the fibers, but positivity gives the same conclusion when the fiber is the whole complex line or a compact connected curve.

Lemma 4.6.4 *Let Y be a complex manifold of dimension $\ell \geq 1$, let η be a Hermitian form on Y , and let $\pi : Z \rightarrow Y$ be a holomorphic fiber bundle whose fiber is either $\mathbb{C}$ or a compact connected Riemann surface. If S is a positive real $(1, 1)$ -current on Z with $\text{dd}^c S = 0$ and $S \wedge \pi^* \eta^\ell = 0$, then there is a unique positive dd^c -closed $(1, 1)$ -current R on Y such that $S = \pi^* R$. If S is closed, then R is closed.*

Proof Fix a local trivialization $\pi^{-1}(U) = U \times F$ of the bundle, with base coordinates $w = (w_1, \dots, w_\ell)$ and a local fiber coordinate z . The coefficient measures of S

have a positive Hermitian matrix of densities relative to their trace measure. The identity $S \wedge \pi^* \eta^\ell = 0$ makes the vertical diagonal entry zero, and the inequality $|s_{\alpha\bar{\alpha}}|^2 \leq s_{\alpha\bar{\alpha}} s_{z\bar{z}}$ then removes all mixed entries. Thus

$$S = \frac{i}{2\pi} \sum_{\alpha, \beta=1}^{\ell} s_{\alpha\bar{\beta}}(w, z) dw_\alpha \wedge d\bar{w}_\beta,$$

with distribution coefficients. In the equation $\partial\bar{\partial}S = 0$, the coefficient containing both vertical differentials and the horizontal pair (α, β) gives $\partial_z \partial_{\bar{z}} s_{\alpha\bar{\beta}} = 0$.

Fix $v \in \mathbb{C}^\ell$ and a nonnegative smooth function ξ with compact support in U . Pairing the positive coefficient distribution $\sum_{\alpha, \beta} s_{\alpha\bar{\beta}} v_\alpha \bar{v}_\beta$, in the base variables, with ξ times the Euclidean volume form defines a nonnegative harmonic distribution on the whole fiber F . Its definition does not depend on the fiber coordinate, since the remaining differentials are horizontal. Weyl's lemma makes it a nonnegative harmonic function. Such a function is constant on $\mathbb{C}$ by the Liouville theorem for harmonic functions, and on a compact connected curve by the maximum principle.

Polarization in v and linearity in the base test function show that every coefficient $s_{\alpha\bar{\beta}}$ is the pullback of a distribution $r_{\alpha\bar{\beta}}$ on U . To identify this distribution, pair against any nonnegative smooth fiber density of total integral one; this also proves positivity of the resulting current R_U on U and injectivity of the pullback. Consequently $\text{dd}^c S = \pi^*(\text{dd}^c R_U) = 0$ implies $\text{dd}^c R_U = 0$. On overlaps, injectivity makes the currents R_U agree, so they glue to a current R , and injectivity also proves uniqueness. If $dS = 0$, the same argument gives $dR = 0$. $\square$

The assumption that the fibers are entire lines or compact curves is essential. On the bidisk $\Delta_z \times \Delta_w$, the current

$$S = (2 + \text{Re } z) \frac{i}{2\pi} dw \wedge d\bar{w}$$

is positive and dd^c -closed, and its vertical trace vanishes. Its horizontal coefficient depends on z , so it does not descend under the projection to Δ_w .

4.7 The adjoint measure of the linearization

The derivative of the logarithmic Monge–Ampère operator $u \mapsto \log(\omega_u^n/dV)$ annihilates the constants, so its linearized equation can be solved only under a compatibility condition. The Gauduchon multiplier of [Theorem 4.1.1](#) identifies this condition. Fix $u \in \mathcal{H}_\omega$ and write $\eta = \omega_u$. For a smooth real direction v , logarithmic differentiation gives the linearized operator

$$L_u v = n \frac{\text{dd}^c v \wedge \eta^{n-1}}{\eta^n}. \quad (4.8)$$

Choose the Gauduchon multiplier ρ_u of η given by [Theorem 4.1.1](#), normalized by

$$\int_X \rho_u \eta^n = 1, \quad \text{and put} \quad d\mu_u := \rho_u \eta^n.$$

The *adjoint measure* μ_u is a smooth positive probability measure.

Proposition 4.7.1 *For every smooth real v ,*

$$\int_X L_u v \, d\mu_u = 0. \quad (4.9)$$

Moreover, for smooth real h , the equation $L_u v = h$ has a smooth solution if and only if $\int_X h \, d\mu_u = 0$. When it exists, the solution is unique modulo constants.

Proof The integral in (4.9) is

$$n \int_X dd^c v \wedge \rho_u \eta^{n-1} = n \int_X v \, dd^c (\rho_u \eta^{n-1}) = 0.$$

This proves that the compatibility condition is necessary.

By the Fredholm argument in the proof of [Theorem 4.1.1](#), the range of $L_u : C^{k+2,\alpha}(X) \rightarrow C^{k,\alpha}(X)$ has codimension one for every integer $k \geq 0$ and $0 < \alpha < 1$. The nonzero functional $h \mapsto \int_X h \, d\mu_u$ annihilates that range, so its kernel is the range. Elliptic regularity gives a smooth solution, and since the kernel of L_u consists of the constants, the solution is unique modulo constants. $\square$

By its defining equation and the uniqueness in [Theorem 4.1.1](#), the multiplier ρ_u is constant precisely when η is Gauduchon. Thus

$$\mu_u = \frac{\eta^n}{\int_X \eta^n} \quad \text{if } dd^c(\eta^{n-1}) = 0.$$

On a surface, $dd^c \omega_u = dd^c \omega$, so every positive potential perturbation of a Gauduchon form is still Gauduchon. In higher dimension this persistence requires more than the Gauduchon condition at $u = 0$. Write $M = \int_X \omega^n$.

Proposition 4.7.2 *Every form ω_u with $u \in \mathcal{H}_\omega$ is Gauduchon if and only if*

$$\int_X \omega_u^n = M \quad \text{for every } u \in \mathcal{H}_\omega.$$

In that case the normalized multiplier is $\rho_u = M^{-1}$ and $\mu_u = M^{-1}\omega_u^n$ for every $u \in \mathcal{H}_\omega$.

Proof If all the forms ω_u are Gauduchon, the mass derivative (2.2) vanishes at every point of $\mathcal{H}_\omega$ and in every direction. Since $\mathcal{H}_\omega$ is convex, integration along the segment from 0 to u gives the mass identity. Conversely, Proposition 2.2.1 shows that constant mass forces $\text{dd}^c(\omega_u^{n-1}) = 0$ for every $u \in \mathcal{H}_\omega$. In that case the normalized multiplier is the constant M^{-1} , by Theorem 4.1.1. $\square$

By Theorem 2.2.2, this persistence is equivalent to $\text{dd}^c(\omega^j) = 0$ for all integers $1 \leq j \leq n-1$. The following example distinguishes it from the single Gauduchon identity in dimension three.

Example 4.7.1 Let $E = \mathbb{C}/(\mathbb{Z} + i\mathbb{Z})$ and $X = E^3$. For $1 \leq j \leq 3$, write $z_j = x_j + iy_j$ for the coordinates on the covering space, and let η_j be the form on X induced by $(i/2)dz_j \wedge d\bar{z}_j$. The periodic functions

$$b = \exp(\cos(2\pi x_1)), \quad c = b^{-1}$$

define a Hermitian form

$$\omega = \eta_1 + b\eta_2 + c\eta_3.$$

Since $bc = 1$,

$$\omega^2 = 2b\eta_1 \wedge \eta_2 + 2c\eta_1 \wedge \eta_3 + 2\eta_2 \wedge \eta_3.$$

The functions b and c depend only on x_1 , so $\text{dd}^c b$ and $\text{dd}^c c$ are multiples of η_1 , and $\text{dd}^c(\omega^2) = 0$. Thus ω is Gauduchon.

Put $v = \cos(2\pi x_2)$ and $h = -\pi \cos(2\pi x_2)$, so that $\text{dd}^c v = h\eta_2$. For a real s with $0 < |s| < 1/(\pi e)$, the form

$$\omega_{sv} = \eta_1 + (b + sh)\eta_2 + c\eta_3$$

is positive, since $b \geq e^{-1}$ and $|h| \leq \pi$. However,

$$\text{dd}^c(\omega_{sv}^2) = 2s\text{dd}^c\omega \wedge \text{dd}^c v = 2sh\text{dd}^c c \wedge \eta_2 \wedge \eta_3 \neq 0.$$

Indeed, $\text{dd}^c c = (c''/(4\pi))\eta_1$, where the prime denotes differentiation in x_1 , and $c''(0) = 4\pi^2 e^{-1}$, while $h = -\pi$ at $x_2 = 0$. Thus a Gauduchon form can have arbitrarily small positive potential perturbations that are not Gauduchon.

When persistence holds, the one-form $v \mapsto \int_X v \, d\mu_u$ on $\mathcal{H}_\omega$ is the Monge–Ampère one-form of Chapter 3 divided by M . By Theorem 3.1.1, it therefore has a primitive exactly when ω is closed.

4.7.1 Convex entropies along a Monge–Ampère flow

The logarithmic Monge–Ampère operator generates a parabolic flow whose linearization is the operator L_u of (4.8). Along this flow, the ratio of the Monge–Ampère measure to a fixed target measure satisfies a heat-type equation. Integrating a convex function of this ratio by parts produces, besides the usual nonpositive gradient term, a term involving $\text{dd}^c(\omega_{u_t}^{n-1})$. The Gauduchon condition along the flow is therefore exactly what makes all convex entropies decrease.

Recall that $M = \int_X \omega^n$, and fix a smooth strictly positive probability volume form ν on X . Consider a smooth solution on an interval $[0, T)$ of the *logarithmic Monge–Ampère flow*

$$\dot{u}_t = \log \rho_t, \quad \rho_t = \frac{\omega_{u_t}^n}{M\nu}, \quad u_0 = 0, \quad \omega_{u_t} > 0. \quad (4.10)$$

The normalizing constant M is the initial mass and stays fixed along the flow. Define the linearized operator Δ_t by

$$\Delta_t \nu \omega_{u_t}^n = n \text{dd}^c \nu \wedge \omega_{u_t}^{n-1};$$

it is the operator L_{u_t} of (4.8). Logarithmic differentiation gives $\partial_t \log \rho_t = \Delta_t \dot{u}_t = \Delta_t \log \rho_t$. Integration by parts against $\omega_{u_t}^{n-1}$ then produces the same derivative of the background power that appears in the mass variation of [Proposition 2.2.1](#).

Proposition 4.7.3 *Let $\Phi \in C^2((0, +\infty), \mathbb{R})$, and choose a function G with $G'(r) = \Phi'(r)/r$. Along (4.10),*

$$\begin{aligned} \frac{d}{dt} \int_X \Phi(\rho_t) \nu &= \frac{n}{M} \int_X G(\rho_t) \text{dd}^c(\omega_{u_t}^{n-1}) \\ &\quad - \frac{n}{M} \int_X \frac{\Phi''(\rho_t)}{\rho_t} d\rho_t \wedge d^c \rho_t \wedge \omega_{u_t}^{n-1}. \end{aligned} \quad (4.11)$$

In particular, for $p > 1$,

$$\begin{aligned} \frac{d}{dt} \int_X \rho_t^p \nu &= \frac{np}{(p-1)M} \int_X \rho_t^{p-1} \text{dd}^c(\omega_{u_t}^{n-1}) \\ &\quad - \frac{np(p-1)}{M} \int_X \rho_t^{p-3} d\rho_t \wedge d^c \rho_t \wedge \omega_{u_t}^{n-1}. \end{aligned} \quad (4.12)$$

Proof Using $\partial_t \rho_t = \rho_t \Delta_t \log \rho_t$ and $\rho_t \nu = M^{-1} \omega_{u_t}^n$, we find that the derivative of the entropy is

$$\frac{n}{M} \int_X \Phi'(\rho_t) \text{dd}^c \log \rho_t \wedge \omega_{u_t}^{n-1}.$$

The chain rule and the definition of G give

$$\Phi'(r) \text{dd}^c \log r = \text{dd}^c G(r) - \frac{\Phi''(r)}{r} dr \wedge d^c r,$$

and **Lemma 2.1.1** applies to the first term. Adding a constant to G does not change the result, since $\int_X \text{dd}^c(\omega_{u_t}^{n-1}) = 0$. Taking $\Phi(r) = r^p$ and $G(r) = pr^{p-1}/(p-1)$ proves the second formula. $\square$

Corollary 4.7.1 *Suppose that every form ω_{u_t} in (4.10) is Gauduchon. Then $\int_X \rho_t \nu = 1$, and $t \mapsto \int_X \Phi(\rho_t) \nu$ is nonincreasing for every convex function $\Phi \in C^2((0, +\infty), \mathbb{R})$. In particular,*

$$\|\rho_t\|_{L^p(\nu)} \leq \|\rho_s\|_{L^p(\nu)} \quad (0 \leq s \leq t < T, \quad p > 1).$$

If $\Phi'' > 0$, the derivative of the entropy vanishes at a time t precisely when $\rho_t = 1$, in which case $\dot{u}_t = 0$.

The hypothesis holds on a Gauduchon surface, and in any dimension it holds if $\text{dd}^c(\omega^j) = 0$ for $1 \leq j \leq n-1$.

Proof The derivative of the mass is

$$\frac{d}{dt} \int_X \rho_t \nu = \frac{n}{M} \int_X \dot{u}_t \text{dd}^c(\omega_{u_t}^{n-1}) = 0,$$

and its initial value is one. In (4.11) the first term vanishes, while the second is nonpositive, because $d\rho_t \wedge d^c\rho_t$ is a semipositive $(1, 1)$ -form and $\Phi'' \geq 0$. If $\Phi'' > 0$, the vanishing of this term forces $d\rho_t = 0$, and connectedness together with the mass normalization gives $\rho_t = 1$. The converse and the assertion about $\dot{u}_t$ follow from the equation.

On a surface, $\text{dd}^c\omega_{u_t} = \text{dd}^c\omega = 0$. Under the power identities, expand $\omega_{u_t}^{n-1}$ by the binomial theorem; since the factors $\text{dd}^c u_t$ are annihilated by d and d^c , each term has vanishing complex Hessian. These are also the persistence conditions of **Proposition 4.7.2** and **Theorem 2.2.2**. $\square$

For $\Phi(r) = r \log r$, the same formula gives the dissipation of the relative entropy. In higher dimension, the Gauduchon condition on the initial form alone need not persist along potential perturbations, as **Example 4.7.1** shows. The next criterion determines the role of this condition at the initial time, without assuming that the flow exists.

Proposition 4.7.4 *Fix $p > 1$. For each smooth strictly positive probability volume form ν , put $\rho_\nu = \omega^n / (M\nu)$ and define*

$$\mathcal{D}_p(\omega, \nu) := \left. \frac{d}{dt} \right|_{t=0} \int_X \left(\frac{(\omega + t \text{dd}^c \log \rho_\nu)^n}{M\nu} \right)^p \nu.$$

Then $\mathcal{D}_p(\omega, \nu) \leq 0$ for every such ν if and only if ω is Gauduchon. If ω is not Gauduchon, there is such a ν with $\mathcal{D}_p(\omega, \nu) > 0$.

Proof The form in the definition is positive for sufficiently small $|t|$. The path $u_t = t \log \rho_\nu$ starts at $u_0 = 0$ with the velocity $\log \rho_\nu$ prescribed by (4.10) at time zero. The proof of **Proposition 4.7.3** at a given time uses only the potential and its

velocity at that time, so (4.12) holds for the derivative at $t = 0$. If ω is Gauduchon, its first term vanishes and the derivative is nonpositive.

Conversely, suppose that $\lambda := \text{dd}^c(\omega^{n-1}) \neq 0$. Write $\lambda = f\omega^n/M$, where f is smooth and real. Stokes' theorem gives $\int_X f\omega^n = 0$, whereas

$$\int_X f\lambda = \frac{1}{M} \int_X f^2 \omega^n > 0.$$

For small $\varepsilon > 0$, set

$$c_\varepsilon = \frac{1}{M} \int_X e^{-\varepsilon f} \omega^n, \quad r_\varepsilon = c_\varepsilon e^{\varepsilon f}, \quad \nu_\varepsilon = \frac{\omega^n}{M r_\varepsilon}.$$

Then ν_ε is a smooth strictly positive probability volume form, and $\rho_{\nu_\varepsilon} = r_\varepsilon$. Since $c_\varepsilon = 1 + O(\varepsilon^2)$, $\int_X \lambda = 0$ and $dr_\varepsilon = \varepsilon r_\varepsilon df$, the two terms in (4.12) give

$$\mathcal{D}_p(\omega, \nu_\varepsilon) = \frac{np}{M} \varepsilon \int_X f\lambda + O(\varepsilon^2) > 0$$

for sufficiently small $\varepsilon > 0$. This proves necessity and the last assertion. $\square$

The criterion involves only the initial velocity: every smooth solution of (4.10) with target ν has the same initial entropy derivative, independently of its existence for later times or its convergence.

4.7.2 Total variation between two evolving probabilities

The entropies of Section 4.7.1 compare one evolving probability with the fixed target. Two solutions of the flow with different initial potentials can nevertheless move apart. On a flat torus, even with a closed background, their total-variation distance can increase at the initial time, while no convex entropy relative to the target increases. We show this by computing the initial derivatives explicitly. By a *logarithmic Monge–Ampère flow with target ν* we mean a smooth solution of the equation in (4.10), with an arbitrary smooth initial potential.

For this example, let $E = \mathbb{C}/(\mathbb{Z} + i\mathbb{Z})$ and $X = E^2$, with covering coordinates $z_j = x_j + iy_j$. Write

$$\eta_j = \frac{i}{2} dz_j \wedge d\bar{z}_j, \quad \kappa = \eta_1 + \eta_2, \quad \mu = \eta_1 \wedge \eta_2 = \frac{\kappa^2}{2}.$$

Thus μ is a probability volume form and $\int_X \kappa^2 = 2$. Put

$$c_j = \cos(2\pi x_j), \quad S = c_1 + c_2, \quad P = c_1 c_2.$$

Lemma 4.7.1 *The averages of $|S|$ and $P|S|$ are*

$$\int_X |S| \mu = \frac{8}{\pi^2}, \quad \int_X P|S| \mu = \frac{8}{3\pi^2}.$$

Proof The integrands do not depend on y_1, y_2 . The degree-two map of real tori $(a, b) \mapsto (a+b, a-b)$ preserves normalized Haar averages. With the angles $A = 2\pi a$ and $B = 2\pi b$, it gives

$$S = 2 \cos A \cos B, \quad P = \frac{\cos(2A) + \cos(2B)}{2}.$$

The one-variable averages of $|\cos A|$ and $|\cos A|^3$ are $2/\pi$ and $4/(3\pi)$, respectively, so the average of $\cos(2A)|\cos A|$ is $2/(3\pi)$. Multiplying the averages over the two independent angles gives both formulas. $\square$

For a fixed real number $K > 3$, define the smooth target probability ν_K by

$$Z_K = \int_X e^{KP} \mu, \quad f_K = Z_K^{-1} e^{KP}, \quad \nu_K = f_K \mu.$$

For $0 < \varepsilon < 1/\pi$, the initial potentials εS and zero give positive forms. Set

$$A_\varepsilon = 1 - \pi \varepsilon c_1, \quad B_\varepsilon = 1 - \pi \varepsilon c_2, \quad r_\varepsilon = A_\varepsilon B_\varepsilon,$$

so that $\kappa + \text{dd}^c(\varepsilon S) = A_\varepsilon \eta_1 + B_\varepsilon \eta_2$ and its normalized Monge–Ampère probability is $r_\varepsilon \mu$.

Consider the short smooth paths

$$U_\varepsilon(t) = \varepsilon S + t \log \frac{r_\varepsilon}{f_K}, \quad V(t) = -t \log f_K. \quad (4.13)$$

They remain positive for sufficiently small $|t|$, and at $t = 0$ their velocities are exactly those prescribed by the logarithmic Monge–Ampère flow with target ν_K . Their normalized probabilities are

$$\mu_\varepsilon(t) = \frac{(\kappa + \text{dd}^c U_\varepsilon(t))^2}{2}, \quad \mu_0(t) = \frac{(\kappa + \text{dd}^c V(t))^2}{2},$$

which have mass one because the background κ is closed. Define their total-variation distance, with the convention for probabilities, by

$$D_\varepsilon(t) = \frac{1}{2} \int_X |\mu_\varepsilon(t) - \mu_0(t)|.$$

Proposition 4.7.5 *For the paths (4.13),*

$$D'_\varepsilon(0) = 4\varepsilon \left(\frac{K}{3} - 1 \right) + o(\varepsilon) \quad \text{as } \varepsilon \downarrow 0.$$

In particular, this derivative is positive for sufficiently small $\varepsilon > 0$. Any two logarithmic Monge–Ampère flows with target ν_K and these initial potentials have the same positive initial derivative of their total-variation distance.

Proof For a real function h depending only on x_1, x_2 , the coefficient matrix of $dd^c h$ with respect to the forms $(i/2)dz_j \wedge d\bar{z}_k$ is $(4\pi)^{-1}(h_{x_j x_k})$. Put $R_\varepsilon(t) = d\mu_\varepsilon(t)/d\mu$ and $R_0(t) = d\mu_0(t)/d\mu$. Differentiating the determinant at the diagonal initial matrices gives

$$\begin{aligned} \partial_t(R_\varepsilon - R_0)|_{t=0} = & \frac{1}{4\pi} (B_\varepsilon \partial_{x_1}^2 \log A_\varepsilon + A_\varepsilon \partial_{x_2}^2 \log B_\varepsilon \\ & - K(B_\varepsilon - 1) \partial_{x_1}^2 P - K(A_\varepsilon - 1) \partial_{x_2}^2 P). \end{aligned}$$

Since $\partial_{x_j}^2 P = -4\pi^2 P$, Taylor expansion in ε yields the uniform estimate

$$\partial_t(R_\varepsilon - R_0)|_{t=0} = \pi^2 \varepsilon S(1 - KP) + O(\varepsilon^2).$$

At $t = 0$, the difference of the densities is

$$q_\varepsilon = r_\varepsilon - 1 = -\pi \varepsilon S + \pi^2 \varepsilon^2 P.$$

For each fixed x_2 , its coefficient of c_1 is $-\pi \varepsilon(1 - \pi \varepsilon c_2) \neq 0$, so as a function of x_1 it has at most two zeros in a period, and its zero set has measure zero. Differentiation under the integral sign, justified by the uniform bound on the derivatives of the smooth densities, gives

$$D'_\varepsilon(0) = \frac{1}{2} \int_X \operatorname{sgn}(q_\varepsilon) \partial_t(R_\varepsilon - R_0)|_{t=0} \mu.$$

The set $\{S = 0\}$ also has measure zero, and $\operatorname{sgn}(q_\varepsilon) \rightarrow -\operatorname{sgn}(S)$ off this set. Dominated convergence and [Lemma 4.7.1](#) give

$$\lim_{\varepsilon \downarrow 0} \frac{D'_\varepsilon(0)}{\varepsilon} = \frac{\pi^2}{2} \int_X |S|(KP - 1) \mu = 4 \left(\frac{K}{3} - 1 \right).$$

Every flow with the stated initial data has the velocities [\(4.13\)](#) at $t = 0$, so its initial density derivatives, and hence the derivative of the distance, coincide with this computation. $\square$

Corollary 4.7.2 *For these paths, the initial derivative of every C^2 convex entropy of each probability relative to ν_K is nonpositive, while the total-variation distance between the two probabilities has positive initial derivative for sufficiently small $\varepsilon > 0$.*

Proof The initial velocities are those of the logarithmic flow, and both initial forms are closed. The chain-rule calculation in the proof of [Proposition 4.7.3](#) therefore applies at $t = 0$: its background term vanishes and its gradient term is nonpositive. The preceding proposition gives the assertion about the pair. $\square$

Since only initial velocities enter, the example shows, without any existence or convergence theorem for the flow, that the logarithmic Monge–Ampère flow need not contract the total-variation distance infinitesimally, even though no convex entropy relative to the target increases at the initial time.

4.8 Limits of adjoint measures

When every positive potential perturbation of ω is Gauduchon, the adjoint probability is the normalized Monge–Ampère measure. Mass invariance and the continuity of bounded products then extend this description to bounded potentials.

Proposition 4.8.1 *Assume that ω_v is Gauduchon for every $v \in \mathcal{H}_\omega$. For every $u \in \text{PSH}(X, \omega) \cap L^\infty(X)$, the measure*

$$\mu_u := M^{-1}(\omega + \text{dd}^c u)^n$$

is a probability measure, which agrees with the preceding definition when $u \in \mathcal{H}_\omega$. If $u_j, u \in \text{PSH}(X, \omega) \cap L^\infty(X)$ are uniformly bounded and $u_j \rightarrow u$ in capacity, then $\mu_{u_j} \rightharpoonup \mu_u$.

Proof By [Proposition 4.7.2](#) and [Theorem 2.2.2](#), the positive bounded product $(\omega + \text{dd}^c u)^n$ has mass M , and for $u \in \mathcal{H}_\omega$ its normalization is the smooth adjoint measure by [Proposition 4.7.2](#). The continuity of bounded products under convergence in capacity, in the sense of [Section 1.8](#), gives weak convergence of the products, and division by M preserves it. $\square$

The proposition applies in particular to Gauduchon surfaces. For a general Hermitian background, passing from smooth $u_j \in \mathcal{H}_\omega$ to a limit $u \in \text{PSH}(X, \omega)$ requires control of the multipliers ρ_{u_j} as well as of the potentials. The supporting probabilities of [Chapter 14](#) recover μ_u in the smooth case and give a conditional approximation theorem. We do not know whether, in general, the limit is independent of the approximating sequence, or whether a weak linearization satisfies an adjoint identity.

4.9 Conformal changes and directional curvature positivity

The compatibility condition of [Proposition 4.7.1](#) decides which right-hand sides a scalar trace equation can have, and it can be used to improve the curvature of a Hermitian metric on a vector bundle. A conformal change $h \mapsto e^{-t f} h$ adds the same form $t i \partial \bar{\partial} f$ to the curvature in every fiber direction. Solving a Poisson equation for a Gauduchon form, we can make the trace of this form positive outside any prescribed ball. If the original curvature already has a positive direction for every fiber vector over that ball, a small conformal change produces such a direction everywhere.

Throughout this section, $E \rightarrow X$ is a holomorphic vector bundle of positive rank, and $n \geq 2$. For a smooth Hermitian metric h on E , we use the Chern curvature F_h , the Hermitian endomorphisms $R_h(u, \bar{u})$, the directional forms $\alpha_{h,v}$ and the mean curvature $K_{\omega,h}$ of [Section 4.5.9](#); recall that h is linear in its first argument.

Definition 4.9.1 The metric h is *RC-positive* at x if, for every $0 \neq v \in E_x$, there is a tangent vector $u \in T_x^{1,0}X$ such that

$$h(R_h(u, \bar{u})v, v) > 0.$$

It is *uniformly RC-positive* at x if one tangent vector u works for every nonzero $v \in E_x$. A metric has either property on a set if it has that property at every point of the set.

Lemma 4.9.1 Suppose that $K_{\omega,h}(x) \geq 0$. Then h is RC-positive at x if and only if $\alpha_{h,v} \neq 0$ for every $0 \neq v \in E_x$.

Proof The trace of $\alpha_{h,v}$ with respect to ω is $h(K_{\omega,h}v, v) \geq 0$. A nonzero Hermitian form with nonnegative trace has a positive eigenvalue, since if all its eigenvalues were nonpositive, their nonnegative sum would force all of them to vanish. This gives the required tangent direction. Conversely, a tangent vector with positive evaluation shows that $\alpha_{h,v} \neq 0$. $\square$

Theorem 4.9.1 Suppose that $K_{\omega,h} \geq 0$ on X and that h is RC-positive on a nonempty open set U . Then there is a smooth real function f such that $h_t = e^{-tf}h$ is RC-positive on all of X for every sufficiently small $t > 0$.

Proof By [Theorem 4.1.1](#), choose a conformal Gauduchon form $\gamma = e^a\omega$. Then $K_{\gamma,h} = e^{-a}K_{\omega,h} \geq 0$. Choose a closed coordinate ball $Q \subset U$ and a smooth function $\chi \geq 0$ supported in its interior, with $\int_X \chi \gamma^n > 0$, and set

$$\rho = 1 - \frac{\int_X \gamma^n}{\int_X \chi \gamma^n} \chi.$$

Thus $\rho = 1$ on $X \setminus Q$ and $\int_X \rho \gamma^n = 0$. Since γ is Gauduchon, [Proposition 4.7.1](#), applied with γ in place of ω and $u = 0$, gives a smooth real solution f of

$$P_\gamma f := \text{tr}_\gamma(i\partial\bar{\partial}f) = \rho. \quad (4.14)$$

Indeed, with $L_\gamma f = n \text{dd}^c f \wedge \gamma^{n-1} / \gamma^n$ as in [\(4.8\)](#), we have $P_\gamma = 2\pi L_\gamma$, and the adjoint probability of L_γ is $\gamma^n / \int_X \gamma^n$.

The curvature transforms by

$$F_{h_t} = F_h + t\partial\bar{\partial}f \text{Id}_E, \quad \alpha_{h_t,v} = e^{-tf}(\alpha_{h,v} + t|v|_h^2 i\partial\bar{\partial}f). \quad (4.15)$$

On $X \setminus Q$, the γ -trace of the expression in parentheses is at least $t|v|_h^2 \rho = t|v|_h^2 > 0$ for $v \neq 0$, so it has a positive eigenvalue there.

Over Q , the unit sphere bundle $\{|v|_h = 1\}$ is compact. The largest γ -eigenvalue of $\alpha_{h,v}$ is continuous and strictly positive on it, so it has a positive minimum δ . Let C be the maximum on X of the operator norm of $i\partial\bar{\partial}f$ relative to γ . For every unit vector over Q , the largest eigenvalue of the expression in parentheses in (4.15) is at least $\delta - tC$, which is positive for small $t > 0$. Homogeneity in v and the positive factor e^{-tf} prove the assertion on Q as well. $\square$

In this conclusion, the positive direction may depend on the fiber vector v . The distinction from uniform RC-positivity already occurs for a local metric with zero mean curvature.

Example 4.9.1 On a sufficiently small ball in $\mathbb{C}^2$, equip the trivial bundle of rank two with the metric

$$H(z) = \text{Id} - zz^* + \frac{1}{2}|z|^2 \text{Id}.$$

At the origin this metric has zero mean curvature for the Euclidean Hermitian form and is RC-positive, but it is not uniformly RC-positive.

Proof The two eigenvalues of $H(z)$ are $1 - \frac{1}{2}|z|^2$ and $1 + \frac{1}{2}|z|^2$, so the metric is positive on a small ball. Its first derivatives vanish at the origin, where

$$F_{i\bar{j}} = e_i e_j^* - \frac{1}{2}\delta_{ij} \text{Id}, \quad h(R_h(u, \bar{u})v, v) = |v^*u|^2 - \frac{1}{2}|u|^2|v|^2.$$

The sum $F_{1\bar{1}} + F_{2\bar{2}}$ is zero. For each nonzero v , taking $u = v$ gives a positive evaluation. For each nonzero u , taking $v \perp u$ gives a negative evaluation, so no single u works for every v . $\square$

Proposition 4.9.1 *If $\det E$ admits a flat Hermitian metric, then no smooth Hermitian metric on E is uniformly RC-positive on X or has positive definite mean curvature relative to a Hermitian form. This applies in particular when $\det E$ is holomorphically trivial.*

Proof If h were uniformly RC-positive, then at each point some u would make the h -Hermitian endomorphism $R_h(u, \bar{u})$ positive definite, and its trace would be strictly positive. Since the curvature of the induced metric on $\det E$ is $\text{tr } F_h$, the determinant metric would be RC-positive as a metric on a line bundle. If instead $K_{\omega,h} > 0$, the ω -trace of the determinant curvature would be $\text{tr } K_{\omega,h} > 0$, which again gives a positive tangent evaluation.

Fix a flat Hermitian metric h_0 on $\det E$ and write $\det h = e^b h_0$ for a smooth real function b . The determinant curvature is then $-\partial\bar{\partial}b$. At a global minimum of b , this curvature has no positive tangent evaluation, contradicting the RC-positivity of the determinant metric. Finally, a holomorphic trivialization of $\det E$ gives a flat metric, by assigning constant norm to the trivializing frame. $\square$

Consequently, if $\det E$ admits a flat Hermitian metric and the hypotheses of **Theorem 4.9.1** hold, the conformally changed metric is RC-positive, whereas E admits neither a uniformly RC-positive metric nor a metric with positive definite

mean curvature. The next section shows that the tangent bundle of a nonflat Ricci-flat Kähler surface has these properties, and the local example above shows the pointwise distinction.

4.10 Ricci-flat Kähler surfaces

The tangent bundle of a Ricci-flat Kähler surface gives an example for the conformal construction of [Section 4.9](#). Ricci-flatness makes the mean curvature of the tangent metric zero and its determinant metric flat, but it does not make every directional curvature zero. In real dimension four, the remaining curvature acts on the three-dimensional space of anti-self-dual two-forms, and its invertibility gives exactly the positive directions needed for the conformal construction.

In this section, X is a compact complex surface, so $n = 2$, and ω is a Ricci-flat Kähler form on X . Write h for the Hermitian metric on $T^{1,0}X$ defined by ω , and g for the associated Riemannian metric, so that $\omega(S, T) = g(JS, T)$.

Use g to identify bivectors and two-forms. For the complex orientation, the Hodge star gives

$$\Lambda^2 = \Lambda^+ \oplus \Lambda^-, \quad \Lambda^\pm = \{\zeta : *\zeta = \pm\zeta\}.$$

Each summand has real rank three. The first is spanned by ω and the real parts of $(2, 0)$ -forms, and the second consists of the real primitive $(1, 1)$ -forms; both descriptions follow by writing the star in a unitary real frame.

Let R^∇ be the curvature of the Levi-Civita connection, with $R^\nabla(S, T) = \nabla_S \nabla_T - \nabla_T \nabla_S - \nabla_{[S, T]}$, and define the self-adjoint curvature operator $\mathcal{R}$ on Λ^2 by

$$\langle \mathcal{R}(S \wedge T), U \wedge V \rangle = g(R^\nabla(S, T)V, U).$$

Since the curvature of a Kähler metric has type $(1, 1)$, the operator $\mathcal{R}$ annihilates the real parts of $(2, 0)$ -forms. Its value on ω is the Ricci form, which vanishes. Thus

$$\mathcal{R} = 0 \oplus A, \quad A : \Lambda^- \longrightarrow \Lambda^-.$$

The endomorphism A is symmetric and trace free, since the trace of $\mathcal{R}$ is half the scalar curvature; in this Ricci-flat setting it is the anti-self-dual Weyl operator. Norms of curvature tensors below are Hilbert–Schmidt norms of these endomorphisms.

Lemma 4.10.1 *At a point x , the metric h is RC-positive if and only if A_x is invertible.*

Proof For a real tangent vector V , set $v = \frac{1}{2}(V - iJV)$. The Chern and Levi-Civita connections agree on a Kähler manifold. Their curvature pairings give

$$\alpha_{h,v} = \frac{1}{2}(\mathcal{R}(V \wedge JV))^b.$$

Indeed, $h(v, w) = \frac{1}{2}(g(V, W) - ig(JV, W))$ for $w = \frac{1}{2}(W - iJW)$, and R^∇ commutes with J . Since R^∇ is skew-adjoint, the real part of $h(F_h v, v)$ vanishes, which gives the formula.

The anti-self-dual projection of $V \wedge JV$ is

$$\Pi(V) = V \wedge JV - \frac{1}{2}|V|^2\omega.$$

It is nonzero for $V \neq 0$, and every nonzero element of Λ^- is of this form. To see this, diagonalize a nonzero real primitive $(1, 1)$ -form in a unitary real frame. It has the form $c(e_1 \wedge Je_1 - e_2 \wedge Je_2)$, with $c > 0$ after interchanging the two complex lines. Taking $V = \sqrt{2}c e_1$ gives exactly this form as $\Pi(V)$. Also $|\Pi(V)|^2 = |V|^4/2$.

Consequently, since $\mathcal{R}$ vanishes on Λ^+ , we have $\alpha_{h,v} \neq 0$ for every nonzero v if and only if $\ker A_x = 0$. Since $K_{\omega,h} = 0$, Lemma 4.9.1 gives the assertion. $\square$

Lemma 4.10.2 *If g is not flat, the open set $\{x : \det A_x \neq 0\}$ is nonempty.*

Proof Suppose that $\det A = 0$ everywhere. On the open set where $A \neq 0$, its three eigenvalues are $\lambda_0, -\lambda_0, 0$ with $\lambda_0 > 0$; they are distinct, so A has smooth local eigenframes there.

Step 1: a Bochner identity. On an open set where A has distinct eigenvalues, we compute $\Delta|A|^2$, keeping track of the normalizations.

Choose an oriented local eigenframe ξ_1, ξ_2, ξ_3 of Λ^- with $|\xi_i|^2 = 2$, and denote the corresponding eigenvalues by λ, μ, ν . As skew-adjoint endomorphisms, these forms satisfy the multiplication rules of the quaternions. Write

$$\nabla\xi_1 = c \otimes \xi_2 - b \otimes \xi_3, \quad \nabla\xi_2 = -c \otimes \xi_1 + a \otimes \xi_3, \quad \nabla\xi_3 = b \otimes \xi_1 - a \otimes \xi_2.$$

Here a, b, c are real one-forms. The Ricci identity and the contracted Bianchi identity, using $\text{Ric}(g) = 0$, give

$$da + b \wedge c = \lambda\xi_1, \quad d\lambda = (\lambda - \mu)\xi_3c + (\lambda - \nu)\xi_2b,$$

and their simultaneous cyclic permutations. In the second formula the two-forms act as skew-adjoint endomorphisms on one-forms. Put $D = d^*d = -\text{div}_g \nabla$ on functions. Applying d^* to the second formula yields

$$D\lambda = 2\lambda^2 + 4\mu\nu + 2(\nu - \lambda)|b|^2 + 2(\mu - \lambda)|c|^2.$$

For example, the calculation uses

$$\begin{aligned} d^*(\xi_3 c) &= -\langle b, \xi_1 c \rangle + \langle a, \xi_2 c \rangle + \langle a, \xi_3 b \rangle - 2\nu, \\ d^*(\xi_2 b) &= -\langle b, \xi_1 c \rangle - \langle a, \xi_2 c \rangle - \langle a, \xi_3 b \rangle - 2\mu, \end{aligned}$$

which follow from the connection and curvature formulas above; substitution and the cyclic formulas for $d\mu, d\nu$ cancel the mixed pairings.

Now $\lambda + \mu + \nu = 0$ and $|A|^2 = \lambda^2 + \mu^2 + \nu^2$. Multiplying the three scalar equations by their eigenvalues and adding gives

$$\lambda D\lambda + \mu D\mu + \nu D\nu = 18\lambda\mu\nu - 2((\mu - \nu)^2|a|^2 + (\nu - \lambda)^2|b|^2 + (\lambda - \mu)^2|c|^2).$$

The connection expression also gives

$$|\nabla A|^2 = |d\lambda|^2 + |d\mu|^2 + |d\nu|^2 + 2((\mu - \nu)^2|a|^2 + (\nu - \lambda)^2|b|^2 + (\lambda - \mu)^2|c|^2).$$

The product rule therefore gives, with $\Delta = \operatorname{div}_g \nabla = -D$,

$$\Delta|A|^2 = 2|\nabla A|^2 - 36 \det A = 2|\nabla A|^2. \quad (4.16)$$

This identity also holds on the interior of $\{A = 0\}$. Both sides are smooth functions, and the two open sets have dense union in X , so the identity holds everywhere. Integration over X gives $\nabla A = 0$.

Step 2: a parallel operator A forces flatness. If g is not flat, then $A \neq 0$ somewhere, and since A is parallel and $\det A = 0$, it is nonzero everywhere and has three distinct constant eigenvalues. Its eigenlines are parallel; local unit sections of them are parallel as well. The induced connection on Λ^- therefore has zero curvature. Under $\mathfrak{so}(4) = \Lambda^+ \oplus \Lambda^-$, the two summands commute, while the action of Λ^- on itself is faithful. These facts follow directly from the bases $e_1 \wedge e_2 \pm e_3 \wedge e_4$, $e_1 \wedge e_3 \mp e_2 \wedge e_4$, $e_1 \wedge e_4 \pm e_2 \wedge e_3$. Thus zero induced curvature forces $\mathcal{R}(S \wedge T)$ to lie in Λ^+ for every S, T . It already lies in Λ^- , so $\mathcal{R} = 0$, a contradiction. $\square$

Theorem 4.10.1 *If X has a nonflat Ricci-flat Kähler metric, then $T^{1,0}X$ admits an RC-positive Hermitian metric whose associated $(1, 1)$ -form is nonclosed. It admits neither a uniformly RC-positive Hermitian metric nor a metric with positive definite mean curvature relative to any Hermitian form.*

Proof By Lemmas 4.10.1 and 4.10.2, the original tangent metric h is RC-positive on a nonempty open set. Its mean curvature is zero, so Theorem 4.9.1 gives a metric $h_t = e^{-tf}h$ that is RC-positive everywhere.

In that construction we may take the Gauduchon form to be ω itself, and the closed coordinate ball to be a proper subset of X . Since $P_\omega f = 1$ off that ball, f is not constant. The associated form is $\omega_t = e^{-tf}\omega$, with

$$d\omega_t = -te^{-tf}df \wedge \omega.$$

On a real four-dimensional symplectic vector space, $\zeta \mapsto \zeta \wedge \omega$ is injective on one-forms, as a unitary real frame shows. Thus $d\omega_t \neq 0$ somewhere.

Finally, the induced determinant metric of h is flat because its Chern curvature is the Ricci form of ω , which vanishes. The two obstructions follow from [Proposition 4.9.1](#). $\square$

The construction does not change the complex surface: it starts from a Ricci-flat Kähler form and produces a nonclosed Hermitian form whose tangent metric is RC-positive. Nonflat Ricci-flat Kähler metrics exist, for example, on K3 surfaces, by Yau's solution of the Calabi conjecture.

Combined with [Theorem 4.5.6](#), the RC-positive tangent metric of [Theorem 4.10.1](#) bounds the convexity of the complement of the zero section in the projective completion of the tangent bundle. This bundle admits no metric with positive definite mean curvature, so [Corollary 4.5.9](#) does not apply to it.

Corollary 4.10.1 *For a connected compact complex surface X admitting a nonflat Ricci-flat Kähler metric, the complement*

$$\mathbb{P}(O_X \oplus T^{1,0}X) \setminus \mathbb{P}(O_X)$$

is 3-convex. The tangent bundle admits no Hermitian metric with positive definite mean curvature relative to any Hermitian form.

Proof By [Theorem 4.10.1](#), the tangent bundle has an RC-positive Hermitian metric. Its directional curvature form has a positive eigenvalue for every nonzero fiber vector. Apply [Theorem 4.5.6](#) with $n = r = 2$ and $s = 1$. The mean-curvature obstruction is the second assertion of [Theorem 4.10.1](#). $\square$

4.11 Projective first jets and positive bundle metrics

RC-positivity asks for one positive tangent direction for each fiber vector, whereas Griffiths positivity asks for positivity on every pair of nonzero tangent and fiber vectors. The Lamari criterion of [Theorem 4.3.1](#) characterizes positivity of a $(1, 1)$ -form by a duality with Gauduchon tests, and Griffiths positivity on a projective manifold admits an analogous duality. A Griffiths-positive metric on E is the same as a strictly plurisubharmonic squared norm on the dual bundle, which is a linear condition on the dual Hermitian form. Twisting by powers of a very ample line bundle gives finite-dimensional spaces of candidate forms. At each level, either some candidate is strictly plurisubharmonic or a finite atomic positive measure annihilates the Levi forms of all candidates, and if every level fails, a weak limit of these measures annihilates the Levi forms of all smooth Hermitian forms. This measure lives over the dual bundle, whereas the Gauduchon currents in [Theorem 4.3.1](#) live on the base.

Throughout this section, X is a projective manifold of dimension $n \geq 2$, $E \rightarrow X$ is a holomorphic vector bundle of positive rank, and $F = E^*$. Fix a very ample line bundle A , a basis $t_1, \dots, t_d$ of $H^0(X, A)$, and the Fubini–Study metric a on A determined by this basis. Fix also an integer $m_0 \geq 0$ for which $E \otimes A^{m_0}$ is globally generated; this integer is part of the data. In a local frame of A , put

$$\rho = \sum_{\alpha=1}^d |t_\alpha|^2, \quad a = e^{-\phi}, \quad \phi = \log \rho.$$

We use the curvature conventions of [Section 4.5.9](#). A Hermitian metric g on a holomorphic vector bundle over X is *strictly Griffiths-positive* if $g(R_g(u, \bar{u})v, v) > 0$ for every $x \in X$, every nonzero $u \in T_x^{1,0}X$ and every nonzero vector v in the fiber over x ; it is *strictly Griffiths-negative* if the reverse strict inequality holds.

For a smooth Hermitian form h on F , not initially assumed positive, let $G_h(v) = h(v, v)$ on its total space. Write $\mathcal{L}G_h(\xi)$ for the complex Hessian evaluated on $\xi \in T^{1,0}F$; in local coordinates it is $\sum (G_h)_{j\bar{k}} \xi_j \bar{\xi}_k$, the coefficient form of $i\partial\bar{\partial}G_h$, without the factor $1/(2\pi)$.

Lemma 4.11.1 *The function G_h is strictly plurisubharmonic off the zero section if and only if h is a smooth positive Hermitian metric with strictly Griffiths-negative curvature. Equivalently, its dual metric on E is strictly Griffiths-positive.*

Proof On vertical tangent vectors the Levi form is h itself, so strict positivity forces $h > 0$. At a fixed base point, choose a holomorphic frame in which the matrix H of h is the identity and has vanishing first derivatives. Then $R_h(u, \bar{u}) = -H_{u\bar{u}}$ at this point. A tangent vector to F has horizontal and vertical components (u, w) , and

$$\mathcal{L}G_h(u, w) = |w|^2 + v^* H_{u\bar{u}} v = |w|^2 - h(R_h(u, \bar{u})v, v).$$

For $v \neq 0$, this is positive for every nonzero (u, w) precisely when the curvature evaluation is negative for every nonzero u . The curvature of the dual metric is the negative transpose of the original curvature, with respect to the dual Hermitian pairing, which gives the last assertion. $\square$

The Levi forms will be tested on a compact set. Choose any smooth Hermitian metric k on F , let $S = \{v : k(v, v) = 1\}$ be its unit sphere bundle, and choose a smooth positive Hermitian form b on the complex vector bundle $W = T^{1,0}F|_S$ over S . The set

$$K = \{(v, \xi) : v \in S, \xi \in W_v, b(\xi, \xi) = 1\}$$

is compact. Define the real-linear operator D by $Dh = \mathcal{L}G_h|_S$, viewed as a Hermitian form on W . It is continuous from the C^2 norm of Hermitian forms on F to the uniform norm on W , since its coefficients involve at most two base derivatives of h and the fiber vectors range over a compact set. Fiber dilation $v \mapsto cv$ gives

$$G_h(cv) = |c|^2 G_h(v), \quad \mathcal{L}G_h|_{cv}(d(v \mapsto cv)\xi) = |c|^2 \mathcal{L}G_h|_v(\xi).$$

Thus strict positivity of $\mathcal{L}G_h$ on K is equivalent to strict positivity off the zero section.

4.11.1 The finite-dimensional alternative

For $m \geq m_0$, choose a basis of $V_m = H^0(X, E \otimes A^m)$ and write $N_m = \dim V_m$. Pairing these sections with $v \in F_x$ and using a local frame of A^m , we obtain a column $p_m(v)$ of local holomorphic functions on the total space of F . For any Hermitian $N_m \times N_m$ matrix B , set

$$G_{m,B}(v) = e^{-m\phi(x)} p_m(v)^* B p_m(v).$$

This function is globally defined and quadratic on each fiber, so $G_{m,B} = G_{h_{m,B}}$ for a smooth Hermitian form $h_{m,B}$ on F . The matrix B is allowed to have negative eigenvalues.

For $(v, \xi) \in K$, let u be the projection of ξ to $T_x^{1,0}X$, write $\phi_u = \partial\phi(u)$, and put

$$\begin{aligned} r_m &= dp_m(\xi) - m\phi_u p_m(v), & \kappa &= \phi_{u\bar{u}}, \\ \Psi_m(v, \xi) &= e^{-m\phi} (r_m r_m^* - m\kappa p_m p_m^*). \end{aligned}$$

Differentiating the weighted quadratic function gives

$$(Dh_{m,B})_v(\xi, \xi) = \text{tr}(B\Psi_m(v, \xi)). \quad (4.17)$$

All entries involve only the first jets of the sections: if $t = (t_\alpha)$ is the column of the sections of A , then

$$\phi_u = \frac{t^* dt(u)}{\rho}, \quad \kappa = \frac{\rho |dt(u)|^2 - |t^* dt(u)|^2}{\rho^2}.$$

Changing the frame of A by a nowhere-zero holomorphic factor λ changes p_m to $\lambda^{-m} p_m$ and ϕ to $\phi - \log |\lambda|^2$. It changes r_m by the same factor and leaves κ unchanged, so Ψ_m is frame independent. A change of the basis of V_m replaces Ψ_m by a congruent matrix, so whether the convex hull of the values of Ψ_m contains zero does not depend on that choice.

Proposition 4.11.1 *At each fixed m , exactly one of the following holds:*

- (1) *Some Hermitian matrix B satisfies $\text{tr}(B\Psi_m) > 0$ everywhere on K .*
- (2) *There is a probability measure μ on K , supported on at most $N_m^2 + 1$ points, such that $\int_K \Psi_m d\mu = 0$.*

The first alternative holds precisely when $0 \notin \text{conv}(\Psi_m(K))$.

Proof The real vector space of Hermitian $N_m \times N_m$ matrices has dimension N_m^2 . Carathéodory's theorem expresses every point of the convex hull as a convex combination of at most $N_m^2 + 1$ points of the compact image $\Psi_m(K)$, so the hull is compact. If it contains zero, the coefficients of such an expression define the required atomic probability measure μ , and then $\int_K \text{tr}(B\Psi_m) d\mu = 0$ excludes the first alternative.

If the hull misses zero, let Z_0 be its point of least Hilbert–Schmidt norm. Differentiating the squared norm along the segment from Z_0 to any Z in the hull

gives

$$\mathrm{tr}(Z_0 Z) \geq \mathrm{tr}(Z_0^2) > 0.$$

Taking $B = Z_0$ proves the first alternative. $\square$

4.11.2 Approximation with two derivatives

Let $\mathcal{H}_m = \{h_{m,B} : B = B^*\}$. To pass from these finite-dimensional tests to all smooth metrics, we need approximation in C^2 , since D involves two derivatives.

Lemma 4.11.2 *The matrix-valued map $Y = tt^*/\rho$ embeds X as a compact smooth submanifold of the real vector space of Hermitian $d \times d$ matrices. Restrictions of real polynomials in its real coordinates are dense in $C^2(X, \mathbb{R})$ for the C^2 norm.*

Proof The normalized rank-one projector Y determines the point $[t]$ of projective space, and its differential vanishes only in directions in which dt is proportional to t . Since A is very ample, Y is therefore injective with injective differential, and compactness makes it an embedding. A C^2 function on this image extends to a C^2 function on an ambient cube: use local coordinates in which the image is a graph, extend constantly in the normal coordinates, and combine these extensions with a finite smooth partition of unity and a cutoff. Rescale the cube to $[0, 1]^q$.

For such an extension f , its multivariate Bernstein polynomial is

$$B_N f(y) = \sum_{0 \leq j_1, \dots, j_q \leq N} f(j/N) \prod_{\ell=1}^q \binom{N}{j_\ell} y_\ell^{j_\ell} (1 - y_\ell)^{N-j_\ell},$$

where $j = (j_1, \dots, j_q)$. For a multi-index α with $|\alpha| \leq 2$, differentiation expresses $\partial^\alpha B_N f$ as an average of $\Delta_{1/N}^\alpha f(j/N)$, with prefactor $\prod_\ell (N)_{\alpha_\ell}$ and Bernstein degrees $N - \alpha_\ell$. Here $(N)_r = N(N-1) \cdots (N-r+1)$, and $\Delta_{1/N}^\alpha$ is the corresponding iterated forward difference with step $1/N$. Repeated use of the fundamental theorem of calculus expresses $N^{|\alpha|} \Delta_{1/N}^\alpha f(j/N)$ as an average of $\partial^\alpha f$ at points within $2/N$ in each affected coordinate.

The remaining Bernstein weights are the law of independent binomial variables of degrees $N - \alpha_\ell$, divided by N . Their means differ from y_ℓ by at most $2/N$ and their variances are at most $1/(4N)$. Uniform continuity of $\partial^\alpha f$, splitting the average into a fixed small neighborhood of y and its complement, and Chebyshev's inequality give uniform convergence to $\partial^\alpha f$. The prefactor divided by $N^{|\alpha|}$ tends to one. This proves convergence for every derivative of order at most two, including the function itself. Restrict to the embedded image and use the chain rule in a finite collection of charts to obtain the asserted C^2 approximation. $\square$

Lemma 4.11.3 *The spaces $\mathcal{H}_m$ are nested, and their union is C^2 dense in the space of C^2 Hermitian forms on F .*

Proof For nesting, multiply the sections in V_m by each t_α and express the products in the basis of V_{m+1} . The identity $\sum_\alpha e^{-\phi} |t_\alpha|^2 = 1$ writes $G_{m,B}$ as the sum of the corresponding weighted quadratic functions at level $m+1$, which combine into one Hermitian coefficient matrix at that level. Surjectivity of the multiplication map is not needed.

For density, write $p_{m_0}(v) = P_0 v$ in a local frame of F , and put $L = e^{-m_0 \phi/2} P_0$. Global generation of $E \otimes A^{m_0}$ means that L is injective, so $M = L^* L$ is positive definite. If a C^2 Hermitian form has matrix H , define

$$C(x) = LM^{-1}HM^{-1}L^*.$$

Then $L^*CL = H$. A change of frame of F cancels in this expression; a change of frame of A multiplies L by a scalar of modulus one, which also cancels. Thus C is a globally defined C^2 Hermitian matrix function on X .

Applying [Lemma 4.11.2](#) to its real coordinates in the vector space of Hermitian matrices, we obtain Hermitian matrix polynomials in the entries of Y that converge to C in C^2 ; their degrees may increase along the sequence. Let $C_q(Y)$ be such a polynomial, of degree at most q . Every monomial of degree k in Y has the form $t^I \bar{t}^J / \rho^k$, with $|I| = |J| = k$. For a polynomial of degree at most q , multiply each numerator by ρ^{q-k} to use the common denominator ρ^q . Consequently

$$e^{-m_0 \phi} p_{m_0}^* C_q(Y) p_{m_0}$$

is a quadratic expression in the product sections $\sigma_i t^I$ of $E \otimes A^{m_0+q}$, with weight $e^{-(m_0+q)\phi}$. Express these products in the basis of V_{m_0+q} and replace the coefficient matrix by its Hermitian part, which does not change the real function. The result is an element of $\mathcal{H}_{m_0+q}$. Since $L^*CL = H$ and multiplication by the fixed smooth matrix L is continuous in C^2 , these elements converge to H . $\square$

4.11.3 The metric and measure alternatives

A *positive matrix-valued measure* on $W \rightarrow S$ is a linear functional T on the space of continuous Hermitian forms Φ on W such that $\langle T, \Phi \rangle \geq 0$ whenever $\Phi \geq 0$. Its trace mass relative to b is $\langle T, b \rangle$. We write $D^*T = 0$ if $\langle T, Dh \rangle = 0$ for every smooth Hermitian form h on F .

Theorem 4.11.1 *With the fixed projective data above, the following are equivalent:*

- (1) *E admits a smooth strictly Griffiths-positive Hermitian metric.*
- (2) *For some $m \geq m_0$, a Hermitian matrix B makes $G_{m,B}$ strictly plurisubharmonic off the zero section.*
- (3) *For some $m \geq m_0$, $0 \notin \text{conv}(\Psi_m(K))$.*
- (4) *There is no nonzero positive matrix-valued measure T on $W \rightarrow S$ satisfying $D^*T = 0$.*

Proof Given a metric as in the first assertion, its dual metric h on F satisfies $Dh \geq \delta b$ on S for some $\delta > 0$, by Lemma 4.11.1 and compactness. The C^2 density in Lemma 4.11.3 and the continuity of D give a form $h_{m,B}$ with $Dh_{m,B} \geq \delta b/2$, which proves the second assertion. Conversely, if $G_{m,B}$ is strictly plurisubharmonic, its vertical Levi form shows that $h_{m,B}$ is positive, and Lemma 4.11.1 shows that its dual metric is strictly Griffiths-positive. The second and third assertions are equivalent by Proposition 4.11.1.

If the first assertion holds, every nonzero positive matrix-valued measure T has positive trace mass, and

$$\langle T, Dh \rangle \geq \delta \langle T, b \rangle > 0,$$

so such a measure cannot satisfy $D^*T = 0$. Conversely, suppose that the third assertion fails at every level. By Proposition 4.11.1, choose at each level m an atomic probability measure μ_m on K with $\int_K \Psi_m d\mu_m = 0$, so that μ_m annihilates Dh for every $h \in \mathcal{H}_m$. A subsequence converges weakly to a probability measure μ on the compact set K . Since the spaces $\mathcal{H}_m$ are nested, the limit annihilates Dh for every h in each fixed $\mathcal{H}_j$, and the C^2 density and the continuity of D extend this to every smooth Hermitian form.

Define

$$\langle T, \Phi \rangle = \int_K \Phi_v(\xi, \xi) d\mu(v, \xi).$$

This is a positive matrix-valued measure on $W \rightarrow S$ with $\langle T, b \rangle = 1$ and $D^*T = 0$. Its entries in local frames are represented by scalar measures; positivity bounds the functional on Hermitian forms of uniform norm at most one by the trace mass, so the Riesz representation theorem applies to the coordinate functionals, and a finite partition of unity combines these local representations. This contradicts the fourth assertion and completes the proof. $\square$

The equation $D^*T = 0$ concerns a bundle over the sphere bundle $S \subset F = E^*$; it should not be confused with the equation $dd^c T = 0$ for currents on X . The theorem gives no bound for the first successful level, and no finite procedure for deciding that all levels fail.

Corollary 4.11.1 *If E is globally generated and $m_0 = 0$, the level-zero test succeeds exactly when the complete evaluation map $\Phi : F \rightarrow H^0(X, E)^*$ is an immersion off the zero section.*

Proof At $m = 0$, one has $\Psi_0 = d\Phi(\xi)d\Phi(\xi)^*$, where Φ is written in the coordinates given by the chosen basis. If $d\Phi$ is injective off the zero section, $B = \text{Id}$ gives a strictly positive Levi form. If $d\Phi$ has a nonzero kernel vector there, fiber dilation and normalization of the tangent vector place such a vector in K , where $\Psi_0 = 0$, and no Hermitian matrix can separate the image from zero. $\square$

When this untwisted test fails, the higher twists remain available. The finite alternatives use all Hermitian coefficient matrices and the complete spaces of sections; testing only positive coefficient matrices or a smaller collection of sections gives a different criterion.

4.12 Ramified section tests and a positive root metric

The untwisted test of [Corollary 4.11.1](#) can fail even for a line bundle with a positively curved metric, because the evaluation map of a globally generated bundle may fail to be an immersion where a holomorphic map ramifies. We give an explicit example on the product of a hyperelliptic curve with a projective space, where the complete spaces of sections can be computed. The same example gives a family of weighted tests, built from a root of the Fubini–Study weight of a very ample power instead of the twists of the preceding section, whose first successful level is explicit and can be made arbitrarily large.

Fix integers $n \geq 2$ and $q \geq 2$. Choose a section $\beta \in H^0(\mathbb{P}^1, \mathcal{O}(2q))$ with $2q$ distinct zeros. Let $\pi : C \rightarrow \mathbb{P}^1$ be the double cover defined in the total space of $\mathcal{O}(q)$ by the equation $w^2 = \beta$, where w is the tautological coordinate, and put

$$\begin{aligned} X &= C \times \mathbb{P}^{n-1}, & L_C &= \pi^* \mathcal{O}(1), \\ L &= L_C \boxtimes \mathcal{O}(1), & A &= L^q, & F &= L^{-1}. \end{aligned}$$

Lemma 4.12.1 *The manifold X is smooth compact projective. The line bundle L is globally generated, A is very ample, and for every integer $k \geq 0$,*

$$\begin{aligned} H^0(X, L^k) &= (H^0(\mathbb{P}^1, \mathcal{O}(k)) \oplus H^0(\mathbb{P}^1, \mathcal{O}(k-q))) \\ &\quad \otimes H^0(\mathbb{P}^{n-1}, \mathcal{O}(k)). \end{aligned}$$

In the second summand, the sections are multiplied by the coordinate w of the cover. In particular,

$$h^0(X, L^k) = (k+1 + \max(k-q+1, 0)) \binom{n-1+k}{k}.$$

For a basis $\sigma_1, \dots, \sigma_N$ of $H^0(X, A)$, the Fubini–Study weight and the corresponding root weight, in a local frame of L and the induced frame of $A = L^q$, are

$$\phi_A = \log \sum_{i=1}^N |\sigma_i|^2, \quad \phi = \phi_A/q.$$

The metric $e^{-\phi}$ on L has strictly positive curvature. Thus it is strictly Griffiths-positive, and $G(v) = e^{\phi} |v|^2$ is strictly plurisubharmonic on F off its zero section.

Proof The direct image of the structure sheaf of C is $\mathcal{O} \oplus \mathcal{O}(-q)$ with multiplication of the second summand given by $w^2 = \beta$. Tensoring by $\mathcal{O}(k)$, the local basis $1, w$ gives the stated decomposition of sections on C . Simple zeros of β make the cover smooth: near a branch point the equation gives a coordinate w with the base coordinate a nonzero multiple of w^2 to leading order. The cover is connected because the rational function representing β has a simple zero and therefore is not a square. Finiteness over compact $\mathbb{P}^1$ makes C compact.

On C , the complete sections of L_C^q are the degree- q base monomials together with w . The map to projective space defined by these sections separates the base points by the Veronese coordinates, separates the two sheets by w , and has injective differential. At the ramification points the coordinate w gives the missing derivative, and elsewhere the base coordinates do. Compactness makes this map an embedding. This shows that C is projective and that L_C^q is very ample.

For the decomposition of sections on the product, expand a section on each $\mathbb{P}^{n-1}$ fiber in its complete degree- k monomial basis. The coefficients depend holomorphically on C and transform as sections of L_C^k . This proves the displayed tensor identity without a cohomological vanishing assumption. The dimensions follow from the monomial counts, since line bundles of negative degree on $\mathbb{P}^1$ have no nonzero sections. The degree-one base sections generate L_C , hence L . The product of the curve embedding and the degree- q Veronese embedding, followed by the Segre embedding, shows that A is very ample.

Its complete linear system therefore defines an immersion, so the Fubini–Study metric on A has strictly positive curvature. Dividing its weight by q defines a metric on L , since the transition functions of $A = L^q$ are the q th powers of those of L , and its curvature is $1/q$ times that positive form. The final assertion follows from [Lemma 4.11.1](#). $\square$

4.12.1 The weighted family and its first successful level

Keep the root metric $e^{-\phi}$ on L , and choose the sphere bundle S and the compact set K for F as in [Section 4.11](#). For each integer $j \geq 0$, use the complete space

$$\tilde{V}_j = H^0(X, L^{j+1})$$

and pair its basis with $v \in F_x$ to get a local column $p_j(v)$, written in a local frame of L^j . For every Hermitian coefficient matrix B , define

$$\tilde{G}_{j,B}(v) = e^{-j\phi(x)} p_j(v)^* B p_j(v).$$

These are globally defined functions, quadratic on each fiber. Their Levi matrices are

$$\begin{aligned} \tilde{\Psi}_j(v, \xi) &= e^{-j\phi} (r_j r_j^* - j \kappa p_j p_j^*), \\ r_j &= dp_j(\xi) - j \phi_u p_j, \quad \kappa = \phi_{u\bar{u}}, \end{aligned}$$

where u is the projection of ξ to the base. As in [\(4.17\)](#), direct differentiation gives $\mathcal{L} \tilde{G}_{j,B}(\xi) = \text{tr}(B \tilde{\Psi}_j)$, and $\tilde{\Psi}_j$ transforms in the same way under changes of frames.

Proposition 4.12.1 *The first integer $j \geq 0$ for which some $\tilde{G}_{j,B}$, with B an arbitrary Hermitian matrix, is strictly plurisubharmonic off the zero section is $j = q - 1$. At every lower level, zero belongs to $\text{conv}(\tilde{\Psi}_j(K))$; one atom witnesses this at $j = 0$, and two atoms suffice at each $1 \leq j < q - 1$.*

Proof At $j = q - 1$, choose the basis σ_i that defines ϕ_A and take $B = \text{Id}$. Since $p_j(v) = v(\sigma_i(x))_i$ in the chosen frames,

$$\tilde{G}_{q-1, \text{Id}}(v) = e^{-(q-1)\phi} |v|^2 e^{q\phi} = e^\phi |v|^2.$$

This function is strictly plurisubharmonic by [Lemma 4.12.1](#).

Now suppose that $0 \leq j < q - 1$. Then $j + 1 < q$, so by [Lemma 4.12.1](#) every section in V_j comes from the first summand of the decomposition, which does not involve w . At a ramification point of C , choose a local coordinate t on C , and use frames of the bundles pulled back from $\mathbb{P}^1 \times \mathbb{P}^{n-1}$. Writing ζ for the coordinates of the factor $\mathbb{P}^{n-1}$, the column has the form $p_j(v) = vU_j(\pi(t), \zeta)$. It is nonzero for $v \neq 0$, since L^{j+1} is globally generated, and since π ramifies at the point, its derivative in the t direction vanishes there when v is held fixed.

Choose such a fiber vector v on the sphere bundle S . Write tangent vectors to the total space of F by their components in the t direction, in the ζ directions and in the fiber direction. Let $\xi_v = (0, 0, v)$ be the vertical radial vector, let $u = \partial/\partial t$, and let $\xi_h = (u, 0, j\phi_u v)$. At this point $dp_j(\xi_v) = p_j$ and $r_j(\xi_h) = 0$. Thus

$$\begin{aligned} \tilde{\Psi}_j(v, \xi_v) &= e^{-j\phi} p_j p_j^*, \\ \tilde{\Psi}_j(v, \xi_h) &= -j\kappa e^{-j\phi} p_j p_j^*, \quad \kappa > 0. \end{aligned}$$

Let a_v and a_h be the squared norms of ξ_v and ξ_h for the form b , and divide each tangent vector by its norm to obtain points of K . At $j = 0$ the second matrix is zero, which gives the witness with one atom. For $j > 0$, the matrix at the second normalized point is $-c$ times the matrix at the first, with $c = j\kappa a_v/a_h > 0$. The probability measure giving these two points the weights $c/(1+c)$ and $1/(1+c)$ has zero matrix integral, which excludes strict positivity for every Hermitian B . This proves failure at all lower levels, so the first successful level is $j = q - 1$. $\square$

4.12.2 Relation to the fixed very ample criterion

Corollary 4.12.1 *For the data $E = L$ and $A = L^q$, with the Fubini–Study metric of a basis of $H^0(X, A)$, the criterion of [Theorem 4.11.1](#) applies with $m_0 = 0$. Its untwisted level fails, although E carries a strictly Griffiths-positive metric, and a higher level succeeds. The atom witnessing the failure at level zero annihilates only the Levi forms of the level-zero test space, and does not give a measure with $D^*T = 0$.*

Proof By [Lemma 4.12.1](#), L is globally generated and A is very ample, as the criterion requires. At a ramification point, the complete untwisted evaluation map has a nonzero tangent vector in its kernel, in the direction of the cover, as in the preceding proof; hence [Corollary 4.11.1](#) gives failure at level zero. The positive root metric and [Theorem 4.11.1](#) give success at some higher level. Moreover, the Levi form of the dual of this positive metric pairs strictly positively with every nonzero positive matrix-valued measure on $W \rightarrow S$, so the atom at level zero cannot annihilate the Levi forms of all smooth Hermitian forms. $\square$

The level m of the criterion in [Theorem 4.11.1](#) corresponds to $j = qm$ in the root-weight family, since $E \otimes A^m = L^{qm+1}$ and $m\phi_A = qm\phi$. The first success at $j = q - 1$ therefore gives no bound on the first successful level m of that criterion. The root-weight family is nested in steps of q , because multiplication by the sections of A uses $\sum_i |\sigma_i|^2 = e^{q\phi}$; we do not claim that it is nested in steps of one. As q grows, the root-weight family has arbitrarily many failed initial levels, although the bundle carries a strictly positive metric.

Chapter 5

Gauduchon traces and the topology of potentials

Throughout this chapter, θ is a smooth real $(1, 1)$ -form on X , dV is a smooth positive probability volume form used for L^1 norms, and γ is a Gauduchon metric, that is, a Hermitian form with $\text{dd}^c(\gamma^{n-1}) = 0$ (Definition 4.1.1). In dimension one every Hermitian form is Gauduchon, since $\gamma^{n-1} = 1$.

The Monge–Ampère measure of a θ -plurisubharmonic function can have infinite mass, as we shall see in Chapter 6, but its linear part is always under control. By Proposition 4.2.1, the positive measure $(\theta + \text{dd}^c u) \wedge \gamma^{n-1}$ has the same total mass for every $u \in \text{PSH}(X, \theta)$. Since $f \mapsto \text{dd}^c f \wedge \gamma^{n-1}$ is a second-order elliptic operator whose kernel consists of the constants, this trace measure determines u up to an additive constant. We show that it also determines the topology: on mean-normalized potentials, weak convergence of the trace measures is equivalent to L^1 convergence of the potentials. Testing the trace measures against Lipschitz functions turns this equivalence into an explicit complete metric, and the inverse of the elliptic operator compares this metric with the L^1 norm by sharp power bounds. Finally, the smooth form γ^{n-1} can be replaced by a positive pluriharmonic current when the potential is continuous; the product then involves first derivatives of the potential, which are controlled by an energy estimate.

5.1 The trace map

Adding a constant to a potential does not change its current, so we normalize potentials by their mean and consider

$$\mathcal{K}_{\theta, dV}^0 = \left\{ u \in \text{PSH}(X, \theta) : \int_X u \, dV = 0 \right\}.$$

For $u \in \mathcal{K}_{\theta, dV}^0$ we call the measure

$$\mathcal{T}_\gamma(u) = (\theta + \text{dd}^c u) \wedge \gamma^{n-1}$$

the *Gauduchon trace* of u , and $\mathcal{T}_\gamma$ the *trace map*. By [Proposition 4.2.1](#) (by Stokes' theorem when $n = 1$), $\mathcal{T}_\gamma(u)$ is a positive measure of total mass

$$M_{\theta,\gamma} = \int_X \theta \wedge \gamma^{n-1}.$$

The trace map is governed by the linear operator

$$Af = \frac{\mathrm{dd}^c f \wedge \gamma^{n-1}}{\mathrm{d}V}, \quad f \in C^\infty(X, \mathbb{R}).$$

It is a real second-order elliptic operator without zeroth-order term, and $\mathcal{T}_\gamma(u) - \mathcal{T}_\gamma(v) = A(u - v) \mathrm{d}V$ in the sense of distributions.

Theorem 5.1.1 *The trace map $\mathcal{T}_\gamma$ is an affine homeomorphism from the compact convex set $\mathcal{K}_{\theta,\mathrm{d}V}^0$, with its L^1 topology, onto a compact convex set of positive measures of mass $M_{\theta,\gamma}$, with the weak topology. In other words, for $u_j, u \in \mathcal{K}_{\theta,\mathrm{d}V}^0$,*

$$u_j \longrightarrow u \text{ in } L^1 \iff \mathcal{T}_\gamma(u_j) \rightharpoonup \mathcal{T}_\gamma(u).$$

If $M_{\theta,\gamma} = 0$ and $\mathrm{PSH}(X, \theta) \neq \emptyset$, both sets consist of a single point.

Proof The set $\mathcal{K}_{\theta,\mathrm{d}V}^0$ is convex. It is the image of the compact set $\mathcal{K}_\theta$ of [Theorem 1.4.1](#) under the continuous map $v \mapsto v - \int_X v \mathrm{d}V$, and is therefore compact.

If $u_j \rightarrow u$ in L^1 , then $\mathrm{dd}^c u_j \rightarrow \mathrm{dd}^c u$ as currents, so the trace measures converge in the sense of distributions. Since they are positive measures of the same finite mass, and every continuous function is a uniform limit of smooth functions, they also converge weakly as measures. Thus $\mathcal{T}_\gamma$ is continuous.

To prove injectivity, suppose that $\mathcal{T}_\gamma(u) = \mathcal{T}_\gamma(v)$. Then $A(u - v) = 0$ in the sense of distributions. Elliptic regularity for A shows that $u - v$ agrees almost everywhere with a smooth function, and the maximum principle shows that this function is constant. Its mean is zero, so $u = v$ almost everywhere, and hence everywhere by [Lemma 1.3.3](#).

A continuous injection from a compact space into a Hausdorff space is a homeomorphism onto its image; here the target is the space of positive measures of mass $M_{\theta,\gamma}$ with the weak topology. Since $\mathcal{T}_\gamma$ is affine, its image is convex. If $M_{\theta,\gamma} = 0$, every trace measure is zero, so injectivity shows that $\mathcal{K}_{\theta,\mathrm{d}V}^0$ has at most one point; it has exactly one when $\mathrm{PSH}(X, \theta)$ is nonempty, since the mean of any θ -plurisubharmonic function can be subtracted. In this case [Lemma 4.3.1](#) also gives $\theta + \mathrm{dd}^c u = 0$ for the unique normalized potential u , which is therefore smooth. $\square$

The inverse of the trace map can be described by a Green operator for A . By the maximum principle, $\ker A = \mathbb{R}$, and A has Fredholm index zero, because the linear path joining it to a Laplace operator consists of elliptic operators. Let A^* be the formal adjoint of A with respect to $\mathrm{d}V$. Stokes' theorem gives $\int_X Af \mathrm{d}V = 0$ for all smooth f , that is, $A^*1 = 0$; hence $\ker A^* = \mathbb{R}$ as well. By the Fredholm alternative, A maps smooth functions onto the smooth functions g with $\int_X g \mathrm{d}V = 0$, and the same holds

for A^* . In particular, A^* has a continuous inverse on smooth functions of mean zero, normalized to take values of mean zero. By duality with this inverse, every top-degree distribution σ of total mass zero, and in particular every finite signed measure with $\sigma(X) = 0$, determines a unique distribution $G_\gamma \sigma$ with mean zero against dV such that

$$dd^c(G_\gamma \sigma) \wedge \gamma^{n-1} = \sigma. \quad (5.1)$$

Inverting the trace map at a positive measure therefore amounts to solving (5.1) and then checking positivity of the full current.

Proposition 5.1.1 *A positive measure ν of mass $M_{\theta, \gamma}$ belongs to the image of $\mathcal{T}_\gamma$ if and only if the distribution*

$$w = G_\gamma(\nu - \theta \wedge \gamma^{n-1})$$

satisfies $\theta + dd^c w \geq 0$. In that case the θ -plurisubharmonic representative of w is the unique $u \in \mathcal{K}_{\theta, dV}^0$ with $\mathcal{T}_\gamma(u) = \nu$.

Proof If $\nu = \mathcal{T}_\gamma(u)$ with $u \in \mathcal{K}_{\theta, dV}^0$, then u is a mean-zero solution of (5.1) with $\sigma = \nu - \theta \wedge \gamma^{n-1}$, so uniqueness gives $w = u$ as distributions. Conversely, if $\theta + dd^c w \geq 0$, then Proposition 1.1.1 gives a θ -plurisubharmonic representative u of w . It has mean zero by construction, and (5.1) gives $\mathcal{T}_\gamma(u) = \nu$. $\square$

In dimension one the positivity condition is automatic, because $\theta + dd^c w = \nu$; thus every positive measure of mass $M_{\theta, \gamma}$ is the trace of a normalized potential. In higher dimensions, positivity of the trace measure ν does not imply positivity of the $(1, 1)$ -current $\theta + dd^c w$, and the condition in Proposition 5.1.1 must be checked separately.

5.2 A metric on normalized potentials

By Theorem 5.1.1, every metric for the weak topology on positive measures of mass $M_{\theta, \gamma}$ pulls back to a metric for the L^1 topology on $\mathcal{K}_{\theta, dV}^0$. We use the bounded Lipschitz metric on measures, which can be compared quantitatively with the L^1 norm through the inverse of A . Fix a distance d on X induced by a smooth Riemannian metric. For a real Lipschitz function f on X , write $\text{Lip}_d(f) = \sup_{x \neq y} |f(x) - f(y)|/d(x, y)$, and for $u, v \in \mathcal{K}_{\theta, dV}^0$ put

$$d_{\gamma, d}(u, v) = \sup_{\substack{\|f\|_\infty \leq 1 \\ \text{Lip}_d(f) \leq 1}} \left| \int_X f d(\mathcal{T}_\gamma(u) - \mathcal{T}_\gamma(v)) \right|.$$

We call $d_{\gamma, d}$ the *Gauduchon trace metric*.

Corollary 5.2.1 *The function $d_{\gamma,d}$ is a bounded complete metric on $\mathcal{K}_{\theta,dV}^0$ inducing its L^1 topology. Changing γ or d gives the same topology and a uniformly equivalent metric on this compact space.*

Proof Symmetry and the triangle inequality follow directly from the definition, and $d_{\gamma,d} \leq 2M_{\theta,\gamma}$ because both trace measures have mass $M_{\theta,\gamma}$. Let $\mathcal{F}$ denote the family of test functions in the supremum. After rescaling, $\mathcal{F}$ contains a positive multiple of every Lipschitz function, and Lipschitz functions are uniformly dense in $C(X)$. Hence $\mathcal{F}$ separates finite measures, and together with the injectivity of $\mathcal{T}_\gamma$ this shows that $d_{\gamma,d}$ is a metric. The same density, together with the common mass bound, shows that convergence in $d_{\gamma,d}$ implies weak convergence of the trace measures. Conversely, $\mathcal{F}$ is uniformly bounded and equicontinuous, so the Arzelà–Ascoli theorem gives a finite uniform ϵ -net in $\mathcal{F}$ for every $\epsilon > 0$. Weak convergence on the finitely many functions of the net, and the bound $2M_{\theta,\gamma}\epsilon$ for the remaining error, give convergence in $d_{\gamma,d}$.

Thus $d_{\gamma,d}$ is the pullback by the homeomorphism of [Theorem 5.1.1](#) of a metric for the weak topology. The resulting metric space is compact, hence complete. For two choices of the auxiliary data, both metrics induce the same compact L^1 topology, so the identity map is uniformly continuous in both directions. $\square$

Proposition 5.2.1 *There is a constant $C \geq 1$, depending only on X, θ, γ, dV and d , such that*

$$C^{-1}\|u - v\|_{L^1} \leq d_{\gamma,d}(u, v) \leq C\|u - v\|_{L^1}^{1/2} \quad (u, v \in \mathcal{K}_{\theta,dV}^0).$$

Proof The lower bound follows by duality from the inverse of A^* , and the upper bound by smoothing the test functions. Put $w = u - v$, $\sigma = \mathcal{T}_\gamma(u) - \mathcal{T}_\gamma(v)$ and $M = M_{\theta,\gamma}$, and write $\|\sigma\|_{TV}$ for the total variation of σ . Then $\int_X w \, dV = 0$, $\sigma = dd^c w \wedge \gamma^{n-1}$ and $\|\sigma\|_{TV} \leq 2M$. If $M = 0$, [Theorem 5.1.1](#) gives $u = v$, and both estimates hold trivially.

For the lower bound, let g be a smooth real function. Since $\ker A = \ker A^* = \mathbb{R}$, the equation

$$A^* \phi = g - \int_X g \, dV, \quad \int_X \phi \, dV = 0,$$

has a unique smooth solution. For $p > 2n$, elliptic $W^{2,p}$ estimates on functions of mean zero and the Sobolev embedding theorem give $\|\phi\|_\infty + \text{Lip}_d(\phi) \leq C\|g\|_\infty$.

Pairing the distributional equation $Aw \, dV = \sigma$ with ϕ , and using $\int_X w \, dV = 0$, we obtain

$$\left| \int_X w g \, dV \right| = \left| \int_X \phi \, d\sigma \right| \leq C\|g\|_\infty d_{\gamma,d}(u, v).$$

Taking the supremum over smooth real g with $\|g\|_\infty \leq 1$ gives $\|w\|_{L^1} \leq C d_{\gamma,d}(u, v)$.

For the upper bound, let f be any test function in the definition of $d_{\gamma,d}$. Using a fixed finite coordinate cover, a smooth partition of unity and convolution at scale $0 < \epsilon < \epsilon_0$, we obtain smooth functions f_ϵ satisfying

$$\|f - f_\epsilon\|_\infty \leq C\epsilon, \quad \|A^* f_\epsilon\|_\infty \leq C\epsilon^{-1},$$

with constants uniform over this family of test functions. To see the second bound, localize f by the fixed partition of unity. The localized functions have uniformly bounded values and first weak derivatives. In each second derivative of their convolutions, move one derivative onto the mollifier, whose derivative has L^1 norm $O(\epsilon^{-1})$. The lower-order terms of A^* have fixed smooth coefficients and satisfy the same bound. Since $\int_X f_\epsilon d\sigma = \int_X w A^* f_\epsilon dV$, it follows that

$$\left| \int_X f d\sigma \right| \leq C(M\epsilon + \epsilon^{-1}\|w\|_{L^1}).$$

If $0 < \|w\|_{L^1} < \epsilon_0^2$, choose $\epsilon = \|w\|_{L^1}^{1/2}$. For larger norms use $d_{\gamma,d}(u, v) \leq 2M$, and for $w = 0$ use injectivity. Taking the supremum over f proves the upper bound. $\square$

Both exponents in [Proposition 5.2.1](#) are optimal, already on an elliptic curve.

Example 5.2.1 Let $X = \mathbb{C}/(\mathbb{Z} + i\mathbb{Z})$, with coordinate $z = x + iy$. Take $\theta = \gamma = \eta$, where $\eta = (i/2)dz \wedge d\bar{z}$, together with $dV = \eta$ and the flat distance d . For integers $k \geq 1$, set

$$u_k = \frac{\cos(2\pi kx)}{2\pi k^2}.$$

These smooth potentials have mean zero and satisfy

$$\theta + dd^c u_k = \left(1 - \frac{1}{2} \cos(2\pi kx)\right) \eta > 0, \quad \|u_k\|_{L^1} = \frac{1}{\pi^2 k^2}.$$

The function $f_k = \cos(2\pi kx)/(2\pi k)$ has supremum norm at most one and Lipschitz constant at most one. It follows that

$$d_{\gamma,d}(u_k, 0) \geq \left| \int_X f_k dd^c u_k \right| = \frac{1}{8\pi k}.$$

Consequently, the exponent $1/2$ in [Proposition 5.2.1](#) cannot be replaced by any larger exponent, even for smooth strictly positive potentials on a fixed curve. Nor can the power one in the lower bound be replaced by a smaller positive power: for $0 < t \leq 1$, both $\|tu_1\|_{L^1}$ and $d_{\gamma,d}(tu_1, 0)$ equal t times their positive values at $t = 1$.

5.3 Continuous potentials and pluriharmonic traces

The Gauduchon trace pairs $\theta + dd^c u$ with the smooth form γ^{n-1} , which is positive and pluriharmonic. In this section $n \geq 2$, ω is a Hermitian form on X , and G is a positive pluriharmonic $(n-1, n-1)$ -current, that is, a positive current with $dd^c G = 0$ (see [Section 4.6](#)). Such currents include γ^{n-1} , but in general their coefficients are only measures, and the product $(\theta + dd^c u) \wedge G$ is not defined a priori. The equation $dd^c G = 0$ converts uniform control of a potential difference into a bound for its

gradient energy against G , and this is enough to define the product for continuous potentials.

Lemma 5.3.1 *Let (X, ω) be a compact Hermitian manifold of dimension $n \geq 2$, and let G be a positive $(n-1, n-1)$ -current with $\text{dd}^c G = 0$. Put $\mu = \omega \wedge G$ and $M = \mu(X)$. If a, b are smooth real functions and $C \geq 0$ is a constant with $\text{dd}^c a, \text{dd}^c b \geq -C\omega$, then*

$$0 \leq \int_X d(a-b) \wedge d^c(a-b) \wedge G \leq 2CM \|a-b\|_\infty.$$

For every smooth real function v , the total variation norms of the order-zero currents $dv \wedge G$ and $d^c v \wedge G$ satisfy

$$\|dv \wedge G\|_{\text{TV}} + \|d^c v \wedge G\|_{\text{TV}} \leq C_\omega M^{1/2} \left(\int_X dv \wedge d^c v \wedge G \right)^{1/2}.$$

Here the total variation norms are computed with respect to ω , and C_ω depends only on (X, ω) .

Proof Set $v = a - b$. The identity $\text{dd}^c(v^2) = 2dv \wedge d^c v + 2v\text{dd}^c v$, integrated against G , and the equation $\text{dd}^c G = 0$ give

$$\int_X dv \wedge d^c v \wedge G = - \int_X v \text{dd}^c v \wedge G.$$

The measures $(\text{dd}^c a + C\omega) \wedge G$ and $(\text{dd}^c b + C\omega) \wedge G$ are positive, and each has mass CM , because the terms $\text{dd}^c a \wedge G$ and $\text{dd}^c b \wedge G$ integrate to zero. Their difference $\text{dd}^c v \wedge G$ therefore has total variation at most $2CM$, which proves the upper bound. The lower bound holds because $dv \wedge d^c v = (i/2\pi)\partial v \wedge \bar{\partial} v$ is a positive $(1, 1)$ -form.

For the second estimate, work in a local unitary frame for ω . Positivity of G means that its coefficients form a positive semidefinite matrix of measures. These entries are absolutely continuous with respect to the trace measure μ : the diagonal entries are dominated by the trace, and the off-diagonal entries by the Cauchy–Schwarz inequality for positive semidefinite matrices. The resulting matrix of densities has trace bounded by a constant depending only on the normalization. Pairing $dv \wedge G$ or $d^c v \wedge G$ with a test one-form η , and applying the matrix Cauchy–Schwarz inequality and then the integral Cauchy–Schwarz inequality, we obtain

$$|\langle dv \wedge G, \eta \rangle| + |\langle d^c v \wedge G, \eta \rangle| \leq C_\omega \|\eta\|_\infty M^{1/2} \left(\int_X dv \wedge d^c v \wedge G \right)^{1/2}.$$

A finite cover by such frames and a partition of unity give the global estimate. Taking the supremum over smooth test forms of norm at most one yields the total variation bound. When $M = 0$, positivity gives $G = 0$, and both estimates hold trivially. $\square$

Theorem 5.3.1 *Let (X, ω) be a compact Hermitian manifold of dimension $n \geq 2$, let α be a smooth real $(1, 1)$ -form, and let $u \in \text{PSH}(X, \alpha) \cap C^0(X)$. For every positive $(n-1, n-1)$ -current G with $\text{dd}^c G = 0$, the product*

$$(\alpha + \text{dd}^c u) \wedge G$$

has a canonical definition as a positive measure of mass $\int_X \alpha \wedge G$, which agrees with the usual product if u or G is smooth. If $u_j, u \in \text{PSH}(X, \alpha) \cap C^0(X)$ and $u_j \rightarrow u$ uniformly, and if positive pluriharmonic currents G_j converge weakly to G , then

$$(\alpha + \text{dd}^c u_j) \wedge G_j \rightarrow (\alpha + \text{dd}^c u) \wedge G.$$

Proof We first define the gradient currents $du \wedge G$ and $d^c u \wedge G$ as limits, then define the product by an integration-by-parts formula, and finally prove joint continuity.

Step 1: gradient currents. Choose smooth approximants $a_k \rightarrow u$ as in [Lemma 1.21.4](#). There is a common constant $C > 0$ such that $\text{dd}^c a_k \geq -C\omega$. Write $M = \int_X \omega \wedge G$. Since a_k converges uniformly, [Lemma 5.3.1](#) shows that $da_k \wedge G$ and $d^c a_k \wedge G$ are Cauchy sequences in total variation. Denote their limits, which are currents of order zero, by $du \wedge G$ and $d^c u \wedge G$. Applying the same lemma to two uniformly convergent smooth sequences with a common lower Hessian bound shows that the limits do not depend on the sequence. Uniform convergence also gives $a_k G \rightarrow uG$ in total variation.

Step 2: the product. Define

$$(\alpha + \text{dd}^c u) \wedge G = \alpha \wedge G + d(d^c u \wedge G) - d^c(du \wedge G) - \text{dd}^c(uG) \quad (5.2)$$

in the sense of distributions. For smooth u , the Leibniz rule and $\text{dd}^c G = 0$ show that this agrees with the usual product. Consequently $(\alpha + \text{dd}^c a_k) \wedge G$ converges in distributions to the right-hand side of (5.2). With $\varepsilon_k \rightarrow 0$ as in [Lemma 1.21.4](#), the measures $(\alpha + \text{dd}^c a_k + \varepsilon_k \omega) \wedge G$ are positive, with masses $\int_X \alpha \wedge G + \varepsilon_k M$. Their distributional limit is therefore a positive measure, and testing against the constant function one gives its mass. The uniform mass bound upgrades distributional convergence to weak convergence of measures. If G is smooth, the uniform convergence of a_k also identifies the limit with the product of the current $\alpha + \text{dd}^c u$ and the smooth form G .

Step 3: independence of the decomposition. Adding a smooth function h to u adds $dh \wedge G$ and $d^c h \wedge G$ to the gradient currents, so replacing (α, u) by $(\alpha - \text{dd}^c h, u + h)$ leaves the product unchanged. If two continuous decompositions define the same $(1, 1)$ -current, the difference of their potentials has smooth dd^c ; taking its trace in a coordinate chart and applying elliptic regularity shows that this difference is smooth. Thus the product depends only on the current $\alpha + \text{dd}^c u$ and on G .

Step 4: joint continuity. For u and for each u_j , keep only those smooth approximants from [Lemma 1.21.4](#) whose curvature errors are at most one. Choosing C with $\alpha \leq (C - 1)\omega$, all these approximants satisfy the same lower Hessian bound $-C\omega$. The numbers $M_j = \int_X \omega \wedge G_j$ are bounded, by weak convergence. Fix a smooth approximant a_k of u , and put $\delta_{j,k} = \|u_j - a_k\|_\infty$. Applying [Lemma 5.3.1](#) to a_k and to smooth approximants of u_j , and passing to the gradient limits, we find that the total variations of the differences $(du_j - da_k) \wedge G_j$ and $(d^c u_j - d^c a_k) \wedge G_j$ are at most $C' M_j \sqrt{\delta_{j,k}}$, where C' is independent of j and k .

For a smooth real test function ϕ , formula (5.2) now gives

$$\left| \langle (\alpha + \text{dd}^c u_j) \wedge G_j - (\alpha + \text{dd}^c a_k) \wedge G_j, \phi \rangle \right| \leq C_\phi M_j(\sqrt{\delta_{j,k}} + \delta_{j,k}),$$

where C_ϕ depends on the first two derivatives of ϕ , on ω and on C . The same estimate holds with u_j, G_j replaced by u, G . For fixed k , the products $(\alpha + \text{dd}^c a_k) \wedge G_j$ of a fixed smooth form with G_j converge weakly to $(\alpha + \text{dd}^c a_k) \wedge G$. Let first $j \rightarrow \infty$ and then $k \rightarrow \infty$; since $u_j \rightarrow u$ uniformly, the error tends to zero. This proves convergence in distributions, and positivity together with the bounded masses $\int_X \alpha \wedge G_j$ upgrades it to weak convergence of measures. $\square$

For $G = \gamma^{n-1}$ and $\alpha = \theta$, the product in Theorem 5.3.1 is the Gauduchon trace of a continuous potential. Since the construction uses only the gradient energy, it also applies to pluriharmonic currents G with singular coefficients.

Chapter 6

Non-pluripolar Monge–Ampère measures

Throughout this chapter, ω is a Hermitian form on X and dV is a smooth positive probability volume form used for L^1 norms and integrals. As in [Section 1.7](#), we write $\theta_v = \theta + dd^c v$, and $MA_\theta(v) = (\theta + dd^c v)^n$ when v is bounded; convergence in capacity refers to the capacity Cap_ω of [Section 1.8](#).

For an unbounded θ -plurisubharmonic function u , the Bedford–Taylor products of [Proposition 1.7.1](#) are not defined. On the set $\{u > -t\}$, however, u coincides with its bounded truncation $\max(u, -t)$, and since bounded products are plurifinely local, the restricted measures are compatible as t increases. Their limit is a measure on the complement of the pole set, the non-pluripolar Monge–Ampère measure of u . Two features of the non-Kähler setting appear. First, for a general smooth background θ the truncation need not be θ -plurisubharmonic, so positivity of the restricted products requires a local argument. Second, the total mass of the limit may be infinite, since there is no cohomological bound. For a Hermitian background, finiteness of this mass for every potential is equivalent to a uniform bound on the Monge–Ampère masses of bounded potentials, the bounded mass property. When the property fails, we construct a potential of infinite mass whose multiplier ideals are all trivial; its complex Hessian even has integrable coefficients, although its determinant is not integrable.

6.1 Truncation and non-pluripolar measures

Let θ be a smooth real $(1, 1)$ -form and $u \in \text{PSH}(X, \theta)$. For $t > 0$, put

$$u_t = \max(u, -t), \quad D_t = \{u > -t\}.$$

Choose a Hermitian form $\Omega \geq \theta$. Then u_t is bounded and Ω -plurisubharmonic, so [Proposition 1.7.1](#) defines the product $(\theta + dd^c u_t)^n$ as a signed measure. It need not be positive on X , but its restriction to the plurifinely open set D_t is positive. The

proof replaces u_t near each point by a local truncation that preserves positivity up to an arbitrarily small smooth error.

Lemma 6.1.1 *With the notation above,*

$$0 \leq \mathbf{1}_{D_t}(\theta + \text{dd}^c u_t)^n \leq \mathbf{1}_{D_t}(\Omega + \text{dd}^c u_t)^n.$$

More generally, let $\theta_1, \dots, \theta_n$ be smooth real $(1, 1)$ -forms, let $u^i \in \text{PSH}(X, \theta_i)$, and let D be the set where $u^i > -t$ for every i . Then the mixed product of the currents $\theta_i + \text{dd}^c \max(u^i, -t)$ is positive on D .

Proof Work in a coordinate ball with a fixed positive constant form κ , and fix $\epsilon > 0$. Every point has a smaller neighborhood carrying a constant real form θ' such that

$$-\epsilon\kappa \leq \theta - \theta' \leq \epsilon\kappa.$$

Take a smooth local potential r for $\theta' + \epsilon\kappa$. Then $u + r$ is plurisubharmonic. On a relatively compact smaller neighborhood choose $k > t + \sup |r|$ and set

$$h_k = \max(u + r, -k) - r.$$

This function is locally bounded and equals $u_t = u$ on D_t . Moreover,

$$\theta + \text{dd}^c h_k + 2\epsilon\kappa = \text{dd}^c \max(u + r, -k) + (\theta - \theta' + \epsilon\kappa)$$

is the sum of a positive closed current with bounded potential and a smooth positive form, so its bounded products are positive. By plurifine locality, the restriction of $(\theta + \text{dd}^c u_t + 2\epsilon\kappa)^n$ to D_t is positive on this neighborhood.

These neighborhoods cover the coordinate ball. Now let $\epsilon \downarrow 0$. The product with the fixed bounded potential u_t is a polynomial in ϵ whose coefficients have locally finite variation, so it converges in local total variation, also after restriction to D_t . This proves the first inequality. The same construction, applied to each factor, gives the positivity of mixed products.

For the second inequality, expand the difference of the two powers by the telescoping identity, using the smooth positive form $\Omega - \theta$. Every summand is a mixed product of factors that are positive on D_t , as just proved. The difference is therefore nonnegative there. $\square$

Theorem 6.1.1 (Extended non-pluripolar measure) *Let θ be a smooth real $(1, 1)$ -form and $u \in \text{PSH}(X, \theta)$. The measures $\mathbf{1}_{D_t}(\theta + \text{dd}^c u_t)^n$ increase with t . Their limit*

$$\text{MA}_\theta^{\text{ext}}(u) := \lim_{t \rightarrow +\infty} \mathbf{1}_{\{u > -t\}}(\theta + \text{dd}^c \max(u, -t))^n \quad (6.1)$$

is a positive Borel measure that puts no mass on pluripolar sets; it is finite on each D_t and σ -finite on X . It depends only on the current $\theta + \text{dd}^c u$; in particular, it is unchanged when a constant is added to u . If Ω is a Hermitian form with $\theta \leq \Omega$, then

$$\text{MA}_\theta^{\text{ext}}(u) \leq \text{MA}_\Omega^{\text{ext}}(u).$$

The total mass of $\text{MA}_\theta^{\text{ext}}(u)$ may be infinite.

Proof For $s > t$, plurifine locality on $D_t \subset D_s$ gives

$$\mathbf{1}_{D_t}(\theta + \text{dd}^c u_s)^n = \mathbf{1}_{D_t}(\theta + \text{dd}^c u_t)^n.$$

Together with [Lemma 6.1.1](#), this proves that the measures increase. Their increasing limit is countably additive by monotone convergence, and it vanishes on pluripolar sets because each bounded product does. The comparison with Ω passes to the limit. By the compatibility just proved,

$$\mathbf{1}_{D_t} \text{MA}_\theta^{\text{ext}}(u) = \mathbf{1}_{D_t}(\theta + \text{dd}^c u_t)^n,$$

and the mass of this measure is bounded by that of the bounded product $(\Omega + \text{dd}^c u_t)^n$. The sets D_t exhaust the complement of $\{u = -\infty\}$, which has zero mass, so the limit is σ -finite.

For a smooth real function f , consider $\theta' = \theta + \text{dd}^c f$ and $u' = u - f$. On a common superlevel set of u and u' , sufficiently deep truncations of u and u' define the same current with bounded potentials, so their restricted products agree. These sets exhaust the complement of the common pole set, which proves invariance under this change of decomposition. By the elliptic-regularity argument in the proof of [Proposition 1.7.1](#), any two smooth decompositions of the same current differ in this way, and adding a constant is a special case. $\square$

We call $\text{MA}_\theta^{\text{ext}}(u)$ the *extended non-pluripolar Monge–Ampère measure* of u ; the word *extended* indicates that its total mass may be infinite. On compact X it defines a current of order zero exactly when its total mass is finite. In that case it is the non-pluripolar Monge–Ampère measure in the usual sense, namely the extension by zero across $\{u = -\infty\}$ of the plurifinely local bounded products. If u is bounded, then $D_t = X$ for large t , and $\text{MA}_\theta^{\text{ext}}(u) = \text{MA}_\theta(u)$. In accordance with the usual notation for non-pluripolar products, we also write $\langle(\theta + \text{dd}^c u)^n\rangle$ for $\text{MA}_\theta^{\text{ext}}(u)$; lower powers $\langle(\theta + \text{dd}^c u)^k\rangle$ are defined by the same truncation where they are used.

6.2 Contact sets

The bounded contact inequality of [Lemma 1.7.1](#) extends to unbounded potentials on common finite levels. As in the previous section, local positive corrections are needed, because the global truncations need not remain θ -plurisubharmonic.

Proposition 6.2.1 *Let θ be a smooth real $(1, 1)$ -form and let $u, v \in \text{PSH}(X, \theta)$ satisfy $u \leq v$. Then*

$$\mathbf{1}_{\{u=v\}} \text{MA}_{\theta}^{\text{ext}}(u) \leq \mathbf{1}_{\{u=v\}} \text{MA}_{\theta}^{\text{ext}}(v).$$

Proof Fix a coordinate ball with a constant positive form κ , a level $t > 0$, and $\epsilon > 0$. On smaller neighborhoods, freeze θ to a constant form θ' with $-\epsilon\kappa \leq \theta - \theta' \leq \epsilon\kappa$, and choose a quadratic function r with $\text{dd}^c r = \theta' + \epsilon\kappa$. Then $u + r$ and $v + r$ are plurisubharmonic. For a large integer k put

$$a_k = \max(u + r, -k) - r, \quad b_k = \max(v + r, -k) - r.$$

These functions are bounded on relatively compact neighborhoods, satisfy $a_k \leq b_k$, and

$$\theta + 2\epsilon\kappa + \text{dd}^c a_k = \text{dd}^c \max(u + r, -k) + (\theta - \theta' + \epsilon\kappa) \geq 0,$$

with the same inequality for b_k . We may therefore apply the top-degree case of [Lemma 1.7.1](#) with background $\theta + 2\epsilon\kappa$.

On $D_t = \{u > -t\}$, both u and v are larger than $-t$. Taking $k > t + \sup |r|$ makes $a_k = u$ and $b_k = v$ on D_t . Restricting the bounded inequality to $\{u = v\} \cap D_t$ and using locality, we obtain the contact inequality for the background $\theta + 2\epsilon\kappa$ on that set. The smaller neighborhoods cover the original ball, so the restricted inequality holds throughout it.

Choose a Hermitian form $\Omega \geq \theta$. The truncations $u_t = \max(u, -t)$ and $v_t = \max(v, -t)$ are bounded and Ω -plurisubharmonic, so their signed products with background θ are defined. On D_t , the products used above are the restrictions of $(\theta + \text{dd}^c u_t + 2\epsilon\kappa)^n$ and $(\theta + \text{dd}^c v_t + 2\epsilon\kappa)^n$. These are polynomials in ϵ whose coefficients have locally finite variation, so they converge in local total variation as $\epsilon \downarrow 0$, also after restriction to $\{u = v\} \cap D_t$. This proves the inequality for the background θ on each finite level. Finally let $t \rightarrow +\infty$: the common pole set has zero extended mass, and the sets $\{u = v\} \cap D_t$ exhaust its complement in the contact set. $\square$

6.3 Weighted lower semicontinuity

Products of uniformly bounded potentials are continuous under convergence in capacity. Multiplying the extended measure by a cutoff in the potential that vanishes below a fixed level reduces it to such bounded products, and letting the level tend to $-\infty$ gives lower semicontinuity of the extended measures, even when their masses are infinite. The weights are allowed to vary with the potentials.

Lemma 6.3.1 *Let θ be a smooth real $(1, 1)$ -form. Suppose $u_j, u \in \text{PSH}(X, \theta)$ have a common upper bound and $u_j \rightarrow u$ in capacity. If b_j, b are nonnegative uniformly bounded quasi-continuous functions and $b_j \rightarrow b$ in capacity, then*

$$\int_X b \text{MA}_\theta^{\text{ext}}(u) \leq \liminf_j \int_X b_j \text{MA}_\theta^{\text{ext}}(u_j).$$

Both sides may be infinite.

Proof Subtracting a common constant, we may assume that all the potentials are nonpositive. Choose a Hermitian form $\Omega \geq \theta$. For $T > 0$, let $g_T : [-\infty, 0] \rightarrow [0, 1]$ be a continuous nondecreasing cutoff, equal to zero on $[-\infty, -2T]$ and to one on $[-T, 0]$, chosen so that g_T increases pointwise to one on $(-\infty, 0]$ as $T \rightarrow \infty$. Put $v_j = \max(u_j, -2T)$ and $v = \max(u, -2T)$. These are uniformly bounded Ω -plurisubharmonic functions, and they converge in capacity.

Fix T . Expanding $(\theta + \text{dd}^c v_j)^n$ by means of $\theta + \text{dd}^c v_j = (\Omega + \text{dd}^c v_j) + (\theta - \Omega)$, and bounding each smooth factor by a constant multiple of Ω , we see that the total variations of the signed terms are controlled by positive bounded mixed measures. By Lemma 1.8.3, these have a common capacity bound. Bounded Bedford–Taylor continuity gives weak convergence term by term. It also allows the weights $b_j g_T(v_j)$: their differences from the limiting weight tend to zero in capacity, so the common capacity bound makes the corresponding integrals tend to zero. For the fixed limiting weight, remove an open set of arbitrarily small capacity, extend the weight continuously from its complement, and control the discarded part by the same bound. Since the cutoff vanishes at the truncation level $-2T$, locality gives

$$\begin{aligned} \int_X b_j g_T(u_j) \text{MA}_\theta^{\text{ext}}(u_j) &= \int_X b_j g_T(v_j) (\theta + \text{dd}^c v_j)^n \\ &\longrightarrow \int_X b g_T(u) \text{MA}_\theta^{\text{ext}}(u). \end{aligned}$$

The first integral is nonnegative and at most the corresponding integral without the cutoff, although the bounded product $(\theta + \text{dd}^c v_j)^n$ may be signed. Hence the limit is bounded by the lower limit in the assertion. Letting $T \rightarrow \infty$ and using monotone convergence completes the proof. $\square$

6.4 Density and trace inequalities

The mixed density inequality of Lemma 1.7.3 passes to unbounded potentials on common finite levels. It gives a lower bound for the extended measure of a convex combination of potentials and, by comparison with a smooth metric, a lower bound for the full trace measure.

Lemma 6.4.1 *Let θ be a smooth semipositive $(1, 1)$ -form and let $f, g \geq 0$ be measurable functions on X . Suppose $u, v \in \text{PSH}(X, \theta)$ satisfy*

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) \geq f \, dV, \quad \mathrm{MA}_\theta^{\mathrm{ext}}(v) \geq g \, dV.$$

Then, for $0 \leq t \leq 1$,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(tu + (1-t)v) \geq (tf^{1/n} + (1-t)g^{1/n})^n \, dV. \quad (6.2)$$

Proof The cases $t = 0$ and $t = 1$ are the hypotheses. Let $0 < t < 1$, translate u, v to be nonpositive, and put $u_k = \max(u, -k)$ and $v_k = \max(v, -k)$. Since θ is semipositive, these are bounded θ -plurisubharmonic functions, and by locality

$$\mathrm{MA}_\theta(u_k) \geq \mathbf{1}_{\{u > -k\}} f \, dV, \quad \mathrm{MA}_\theta(v_k) \geq \mathbf{1}_{\{v > -k\}} g \, dV.$$

Apply [Lemma 1.7.3](#) to each mixed term in the positive expansion of $\theta_{tu_k + (1-t)v_k}^n$. On $E_k = \{u > -k\} \cap \{v > -k\}$ this gives the density on the right of [\(6.2\)](#). On the same set, plurifine locality identifies the left-hand side with the extended measure of $tu + (1-t)v$. As $k \rightarrow \infty$, the sets E_k exhaust the complement of the two pole sets, which have zero smooth volume. Monotone convergence on Borel sets proves the inequality. $\square$

The same mixed inequality gives a lower bound for the full trace measure of an unbounded potential. Unlike the extended measure, the full current $\omega + \mathrm{dd}^c u$ keeps its mass on the pole set; the bound below concerns only its absolutely continuous part.

Lemma 6.4.2 *Let γ be a Hermitian form. If $u \in \mathrm{PSH}(X, \omega)$ and $0 \leq g \in L^1(dV)$ satisfy $\mathrm{MA}_\omega^{\mathrm{ext}}(u) \geq g \, dV$, then*

$$(\omega + \mathrm{dd}^c u) \wedge \gamma^{n-1} \geq (g \, dV / \gamma^n)^{1/n} \gamma^n.$$

Proof For bounded u , [Lemma 1.7.3](#), applied in local coordinates with $T_1 = \omega + \mathrm{dd}^c u$, $T_2 = \gamma$ and $k = 1$, gives the asserted inequality.

In general, subtract a constant so that $u \leq 0$, and put $u_k = \max(u, -k)$. Positivity and locality give

$$\mathrm{MA}_\omega(u_k) \geq \mathbf{1}_{\{u > -k\}} g \, dV,$$

so the bounded case applies to u_k with the density $\mathbf{1}_{\{u > -k\}} g$. Since $u_k \rightarrow u$ in L^1 , the positive measures $(\omega + \mathrm{dd}^c u_k) \wedge \gamma^{n-1}$ converge weakly to $(\omega + \mathrm{dd}^c u) \wedge \gamma^{n-1}$. The densities on the right converge in L^1 , because $g^{1/n}$ is integrable and the pole set has zero smooth volume. Passing to the limit proves the assertion. $\square$

6.5 The bounded mass property

On a compact Kähler manifold, all bounded ω -plurisubharmonic functions have the same Monge–Ampère mass $\int_X \omega^n$. For a Hermitian form, the mass depends on the potential, and the following two numbers measure how far it can vary.

Definition 6.5.1 Let ω be a Hermitian form on X . The *lower mass* and the *upper mass* of ω are

$$v_-(\omega) = \inf_{v \in \text{PSH}(X, \omega) \cap L^\infty(X)} \int_X (\omega + \text{dd}^c v)^n,$$

$$v_+(\omega) = \sup_{v \in \text{PSH}(X, \omega) \cap L^\infty(X)} \int_X (\omega + \text{dd}^c v)^n.$$

The manifold X has the *bounded mass property*, abbreviated BMP, if $v_+(\omega) < +\infty$. The form ω has *positive lower mass* if $v_-(\omega) > 0$.

Testing with $v = 0$ gives $v_-(\omega) \leq \int_X \omega^n \leq v_+(\omega)$. By the next proposition, the bounded mass property does not depend on the choice of ω . Since the extended measure (6.1) is built from products of bounded potentials, the upper mass also controls the extended measures of unbounded potentials (Proposition 6.5.2).

Proposition 6.5.1 *The bounded mass property is independent of the Hermitian form. Moreover, the supremum in Definition 6.5.1 is unchanged if only smooth potentials are used.*

Proof For another Hermitian form η , choose $C > 0$ such that $\eta \leq C\omega$. If v is a bounded η -plurisubharmonic function, then v/C is ω -plurisubharmonic and

$$0 \leq \eta + \text{dd}^c v \leq C(\omega + \text{dd}^c(v/C)).$$

By positivity of mixed bounded products, $\int_X (\eta + \text{dd}^c v)^n \leq C^n v_+(\omega)$. Interchanging the two forms proves metric independence.

For the last assertion, approximate a bounded potential by Theorem 1.11.1. The smooth approximants decrease and remain uniformly bounded, so the continuity of bounded products along decreasing sequences gives convergence of their total masses. The reverse inequality between the two suprema is immediate. $\square$

Proposition 6.5.2 *Assume $v_+(\omega) < +\infty$. If θ is a smooth real $(1, 1)$ -form with $\theta \leq C\omega$ for some $C > 0$, and $u \in \text{PSH}(X, \theta)$, then*

$$\text{MA}_\theta^{\text{ext}}(u)(X) \leq C^n v_+(\omega).$$

Proof The comparison in Theorem 6.1.1, applied with the Hermitian form $C\omega$, gives

$$\mathbf{1}_{D_t} \text{MA}_\theta^{\text{ext}}(u) \leq \mathbf{1}_{D_t} (C\omega + \text{dd}^c u_t)^n.$$

Since u_t/C is bounded and ω -plurisubharmonic, the right-hand side has mass at most $C^n v_+(\omega)$. Let $t \rightarrow \infty$. $\square$

6.6 Infinite mass with trivial multiplier ideals

If the bounded mass property fails, there are smooth ω -plurisubharmonic functions u_j whose masses M_j tend to infinity. In a convex combination $U = \sum_j a_j u_j$, positivity of mixed products shows that each summand contributes at least $a_j^n M_j$ to the extended measure of U . Choosing the masses M_j to outgrow a_j^{-n} therefore forces infinite mass. On the other hand, each tail $\sum_{j>N} a_j u_j$ is a small multiple of a convex combination of normalized potentials, and the uniform exponential integrability of [Lemma 1.5.1](#) applies to it at every exponent.

Theorem 6.6.1 *If $v_+(\omega) = +\infty$, there is $U \in \text{PSH}(X, \omega)$, $U \leq 0$, such that*

$$\text{MA}_\omega^{\text{ext}}(U)(X) = +\infty, \quad \int_X e^{-pU} dV < +\infty \quad \text{for every } p > 0.$$

In particular, $\mathcal{I}(pU) = O_X$ for every $p > 0$.

Proof Set $a_j = 2^{-j}$ for $j \geq 1$. By [Proposition 6.5.1](#), we can choose smooth ω -plurisubharmonic functions u_j with $\sup_X u_j = 0$ and

$$M_j := \int_X \omega_{u_j}^n \geq 2^{j(n+1)}.$$

The partial sums $U_N = \sum_{j \leq N} a_j u_j$ decrease and satisfy

$$\omega + \text{dd}^c U_N = \sum_{j \leq N} a_j \omega_{u_j} + \left(1 - \sum_{j \leq N} a_j\right) \omega \geq 0.$$

Their L^1 norms are bounded by [\(1.1\)](#), so their limit U is ω -plurisubharmonic and nonpositive.

We first prove that the mass is infinite. Fix j and write $v_j = U - a_j u_j$. Passing to the limit in the remaining partial sums gives $(1 - a_j)\omega + \text{dd}^c v_j \geq 0$. For $t > 0$, put

$$v_{j,t} = \max(v_j, -t), \quad W_{j,t} = a_j u_j + v_{j,t}.$$

The function $v_{j,t}$ is a bounded potential for the positive background $(1 - a_j)\omega$, so $W_{j,t}$ is bounded and ω -plurisubharmonic.

On $D_t = \{U > -t\}$, the inequality $u_j \leq 0$ gives $v_j = U - a_j u_j \geq U > -t$, and hence $W_{j,t} = U = \max(U, -t)$ there. Plurifine locality and positivity of bounded mixed products yield

$$\begin{aligned} \mathbf{1}_{D_t} \omega_{\max(U, -t)}^n &= \mathbf{1}_{D_t} (a_j \omega_{u_j} + (1 - a_j)\omega + \text{dd}^c v_{j,t})^n \\ &\geq a_j^n \mathbf{1}_{D_t} \omega_{u_j}^n. \end{aligned}$$

The sets D_t exhaust $X \setminus \{U = -\infty\}$. This pole set is pluripolar, hence has zero smooth volume, so the smooth measure $\omega_{u_j}^n$ gives it no mass. Letting $t \rightarrow +\infty$, we obtain

$$\mathrm{MA}_\omega^{\mathrm{ext}}(U)(X) \geq a_j^n M_j \geq 2^j.$$

Since j is arbitrary, the mass is infinite.

For the integrability, fix $p > 0$, let α be the exponent of [Lemma 1.5.1](#), and take N so large that $p\delta \leq \alpha$, where $\delta = \sum_{j>N} a_j = 2^{-N}$. Write $U = A_N + V_N$ with $A_N = \sum_{j \leq N} a_j u_j$ smooth. For a finite tail ending at $m > N$, Jensen's inequality for the convex exponential function, with the unused weight assigned to the value zero, gives

$$\exp\left(-p \sum_{N < j \leq m} a_j u_j\right) \leq \sum_{N < j \leq m} \frac{a_j}{\delta} e^{-p\delta u_j} + 1 - \sum_{N < j \leq m} \frac{a_j}{\delta}.$$

Because $u_j \leq 0$ and $p\delta \leq \alpha$, the integrals of the exponentials on the right are uniformly bounded. Integrating and letting $m \rightarrow +\infty$ by monotone convergence, we obtain $\int_X e^{-pV_N} dV < +\infty$. Multiplication by the bounded smooth function e^{-pA_N} proves $\int_X e^{-pU} dV < +\infty$.

Consequently, the constant germ 1 is locally integrable against each weight e^{-pU} , and every multiplier ideal $\mathcal{I}(pU)$ is the whole structure sheaf. $\square$

Corollary 6.6.1 *The bounded mass property holds if and only if $\mathrm{MA}_\omega^{\mathrm{ext}}(u)(X) < +\infty$ for every $u \in \mathrm{PSH}(X, \omega)$. If the bounded mass property fails, there are potentials with infinite extended mass and trivial multiplier ideals $\mathcal{I}(pu) = \mathcal{O}_X$, $p > 0$, arbitrarily close to zero in L^1 .*

Proof The first assertion follows from [Proposition 6.5.2](#) and [Theorem 6.6.1](#). For the second, take εU , $0 < \varepsilon \leq 1$, with U as in [Theorem 6.6.1](#). It is ω -plurisubharmonic and has the required exponential integrability. On $D_t = \{U > -t\}$, its truncation at level εt is $\varepsilon \max(U, -t)$, and

$$\omega + \mathrm{dd}^c(\varepsilon \max(U, -t)) = \varepsilon \omega_{\max(U, -t)} + (1 - \varepsilon)\omega.$$

Positivity of mixed products bounds the restricted measure of εU below by ε^n times that of U . Its limiting mass is therefore infinite. Finally, $\|\varepsilon U\|_{L^1} \rightarrow 0$ as $\varepsilon \rightarrow 0$. $\square$

6.7 Integrable Hessians and infinite mass

In the construction of [Theorem 6.6.1](#), the Gauduchon identity of [Proposition 4.2.1](#) fixes the trace integral of every positive summand $\omega + \mathrm{dd}^c u_j$. The weighted series defining $\omega + \mathrm{dd}^c U$ therefore converges in the L^1 norm of the coefficients, so that $\omega + \mathrm{dd}^c U$ has integrable coefficients; nevertheless, its pointwise determinant is not integrable. This sharpens the distinction between linear convergence and nonlinear mass: even convergence of the trace measures in total variation does not control Monge–Ampère masses.

Fix a Gauduchon form γ and set $M = \int_X \omega \wedge \gamma^{n-1}$. For a real $(1, 1)$ -form T with measurable coefficients, let A_T be its Hermitian matrix relative to γ , and let $|A_T| = (A_T^2)^{1/2}$ be its positive matrix absolute value. We use the norm

$$\|T\|_{L^1(\gamma)} = \frac{1}{n} \int_X \operatorname{tr} |A_T| \gamma^n.$$

For $T \geq 0$ this equals $\int_X T \wedge \gamma^{n-1}$. On compact X , any other smooth Hermitian form gives an equivalent norm and hence the same space of integrable coefficients. When the coefficients of T are integrable, we write $\det_\gamma T = \det A_T$; this function is defined almost everywhere, and $T^n = (\det_\gamma T) \gamma^n$ when T is smooth.

Proposition 6.7.1 *Suppose $v_+(\omega) = +\infty$. For the potential U and its smooth decreasing approximants U_N constructed in the proof of [Theorem 6.6.1](#), the current $T = \omega + \operatorname{dd}^c U$ has integrable coefficients and*

$$\|\omega + \operatorname{dd}^c U_N - T\|_{L^1(\gamma)} \leq 2^{1-N} M.$$

Its pointwise determinant satisfies

$$\operatorname{MA}_\omega^{\operatorname{ext}}(U) \geq (\det_\gamma T) \gamma^n, \quad \int_X (\det_\gamma T) \gamma^n = +\infty.$$

Moreover,

$$\int_X (\omega + \operatorname{dd}^c U_N)^n \longrightarrow +\infty.$$

Proof Write $T_j = \omega + \operatorname{dd}^c u_j$ for the smooth positive forms in that construction, and put

$$S_N = \sum_{j \leq N} a_j T_j, \quad \delta_N = \sum_{j > N} a_j = 2^{-N}.$$

The smooth positive forms S_N increase pointwise, and the Gauduchon identity gives

$$\int_X S_N \wedge \gamma^{n-1} = (1 - \delta_N) M.$$

By monotone convergence of their traces, the series of matrices has a finite positive limit S almost everywhere. The coefficients of S are integrable, because in a γ -unitary frame the absolute value of every coefficient of a positive matrix is bounded by its trace. Positivity and the same trace identity give

$$\|S - S_N\|_{L^1(\gamma)} = \delta_N M.$$

In particular, $S_N \rightarrow S$ in the sense of distributions. Since

$$\omega + \operatorname{dd}^c U_N = S_N + \delta_N \omega \longrightarrow \omega + \operatorname{dd}^c U$$

in the sense of distributions, by L^1 convergence of the potentials, we obtain $T = S$. The triangle inequality now gives

$$\|\omega + \text{dd}^c U_N - T\|_{L^1(\gamma)} \leq \|S_N - S\|_{L^1(\gamma)} + \delta_N \|\omega\|_{L^1(\gamma)} = 2\delta_N M.$$

To compare $\text{MA}_\omega^{\text{ext}}(U)$ with the determinant, fix N and set $V_N = U - U_N$. The remaining partial sums give $\delta_N \omega + \text{dd}^c V_N \geq 0$ and $V_N \leq 0$. For $t > 0$, the function $W_{N,t} = U_N + \max(V_N, -t)$ is bounded, and its current is the sum of two positive terms:

$$\omega + \text{dd}^c W_{N,t} = S_N + (\delta_N \omega + \text{dd}^c \max(V_N, -t)).$$

On $D_t = \{U > -t\}$, the inequality $U_N \leq 0$ gives $V_N \geq U > -t$, and consequently $W_{N,t} = U = \max(U, -t)$ there. Locality and positivity of bounded products imply

$$\mathbf{1}_{D_t} \text{MA}_\omega^{\text{ext}}(U) \geq \mathbf{1}_{D_t} S_N^n.$$

The smooth measure S_N^n gives no mass to the pluripolar pole set of U , so letting $t \rightarrow \infty$ proves $\text{MA}_\omega^{\text{ext}}(U) \geq S_N^n$. The positive matrices S_N increase to T almost everywhere, so their determinants increase to $\det_\gamma T$. Monotone convergence on every Borel set gives the asserted inequality between $\text{MA}_\omega^{\text{ext}}(U)$ and the determinant measure.

Finally, for every $N \geq j$, positivity gives $S_N \geq a_j T_j$. Hence both the measurable limit and the smooth approximating forms satisfy

$$\int_X (\det_\gamma T) \gamma^n \geq a_j^n \int_X T_j^n \geq 2^j, \quad \int_X (\omega + \text{dd}^c U_N)^n \geq a_j^n \int_X T_j^n \geq 2^j.$$

The first bound holds for every j , and the second for every $N \geq j$; together they prove the two assertions about infinite mass. $\square$

Corollary 6.7.1 *If the bounded mass property fails, there are nonpositive potentials $w_\varepsilon \in \text{PSH}(X, \omega)$, $0 < \varepsilon < 1$, such that*

$$\omega + \text{dd}^c w_\varepsilon \geq (1 - \varepsilon)\omega, \quad \mathcal{I}(p w_\varepsilon) = O_X \quad (p > 0),$$

and such that both the integral of the pointwise determinant $\det_\gamma(\omega + \text{dd}^c w_\varepsilon)$ against γ^n and the extended Monge–Ampère mass of w_ε are infinite. As $\varepsilon \downarrow 0$, the potentials converge to zero in L^1 , their currents converge to ω in the coefficient L^1 norm, and their full trace measures $(\omega + \text{dd}^c w_\varepsilon) \wedge \gamma^{n-1}$ converge to $\omega \wedge \gamma^{n-1}$ in total variation.

Proof Take $w_\varepsilon = \varepsilon U$, with U and $T = \omega + \text{dd}^c U$ as in [Proposition 6.7.1](#). Its current is

$$T_\varepsilon = (1 - \varepsilon)\omega + \varepsilon T.$$

The lower bound and the two L^1 convergence assertions follow immediately. The full trace measures have integrable densities, and their distance from $\omega \wedge \gamma^{n-1}$ in total variation is at most

$$\varepsilon \|T - \omega\|_{L^1(\gamma)}.$$

Every multiplier ideal is trivial by the exponential integrability of U proved in [Theorem 6.6.1](#). Since $T_\varepsilon \geq \varepsilon T$ almost everywhere, the determinant integral of T_ε is

at least ε^n times that of T , hence infinite. The extended mass of w_ε is infinite by the proof of [Corollary 6.6.1](#). $\square$

For smooth potentials, the total masses can be prescribed in advance while both the currents and the exponential weights converge.

Corollary 6.7.2 *Suppose $v_+(\omega) = +\infty$. Let $(\varepsilon_j)_{j \geq 1}$ and $(b_j)_{j \geq 1}$ be real sequences with $0 < \varepsilon_j < 1$, $\varepsilon_j \rightarrow 0$, and $b_j > \int_X \omega^n$. There are smooth potentials $w_j \in \text{PSH}(X, \omega)$ with $\sup_X w_j = 0$ such that*

$$\begin{aligned} \omega + \text{dd}^c w_j &\geq (1 - \varepsilon_j)\omega, & \int_X (\omega + \text{dd}^c w_j)^n &= b_j, \\ \|\text{dd}^c w_j\|_{L^1(\gamma)} &\leq 2M\varepsilon_j. \end{aligned}$$

Moreover, $w_j \rightarrow 0$ in $L^1(dV)$ and $e^{-pw_j} \rightarrow 1$ in $L^1(dV)$ for every fixed $p > 0$. The full Gauduchon trace measures converge to $\omega \wedge \gamma^{n-1}$ in total variation.

Proof By [Proposition 6.5.1](#), we can choose a smooth $u_j \in \text{PSH}(X, \omega)$ with $\sup_X u_j = 0$ and

$$\int_X (\omega + \text{dd}^c u_j)^n > \varepsilon_j^{-n} b_j.$$

Put $T_j = \omega + \text{dd}^c u_j$. The polynomial

$$F_j(s) = \int_X ((1-s)\omega + sT_j)^n, \quad 0 \leq s \leq \varepsilon_j,$$

satisfies $F_j(0) < b_j$, and also $F_j(\varepsilon_j) \geq \varepsilon_j^n \int_X T_j^n > b_j$ by positivity of the mixed terms. The intermediate value theorem gives $s_j \in (0, \varepsilon_j)$ with $F_j(s_j) = b_j$. Set $w_j = s_j u_j$. Then $\sup_X w_j = 0$, $\omega + \text{dd}^c w_j = (1-s_j)\omega + s_j T_j \geq (1-\varepsilon_j)\omega$, and w_j has the prescribed mass b_j .

The Gauduchon identity gives $\|T_j\|_{L^1(\gamma)} = \|\omega\|_{L^1(\gamma)} = M$. Hence

$$\|\text{dd}^c w_j\|_{L^1(\gamma)} = s_j \|T_j - \omega\|_{L^1(\gamma)} \leq 2M\varepsilon_j.$$

Since the absolute value of the trace of a Hermitian matrix is bounded by the trace of its absolute value, the same bound holds for the total variation of $\text{dd}^c w_j \wedge \gamma^{n-1}$. With K_ω as in [\(1.1\)](#), we also have $\|w_j\|_{L^1(dV)} \leq K_\omega \varepsilon_j$.

Finally, let α, C be the constants of [Lemma 1.5.1](#) for (X, ω, dV) , and fix $p > 0$. For all sufficiently large j , one has $ps_j \leq \alpha$. Convexity of the exponential function, applied with weight ps_j/α , gives

$$0 \leq e^{-pw_j} - 1 \leq \frac{ps_j}{\alpha} (e^{-\alpha u_j} - 1).$$

Integrating, we bound the $L^1(dV)$ norm of $e^{-pw_j} - 1$ by $pC\varepsilon_j/\alpha$, which proves the last convergence. $\square$

Chapter 7

Weighted Monge–Ampère measures

Throughout this chapter, ω is a Hermitian form on X , and capacity refers to the capacity Cap_ω of [Section 1.8](#). For nonpositive $u \in \text{PSH}(X, \omega)$ we write

$$\mu_u = \text{MA}_\omega^{\text{ext}}(u)$$

for the extended non-pluripolar Monge–Ampère measure of [Theorem 6.1.1](#), and we put

$$r_n = \max(n - 2, 0).$$

By [Chapter 6](#), the measure μ_u can have infinite mass when the bounded mass property fails. Its mass on a sublevel set $\{u \geq -t\}$, however, grows at most like a polynomial of degree r_n in t , because the Monge–Ampère masses of bounded potentials grow at most polynomially in their range. Multiplying μ_u by a weight that decreases sufficiently fast in the depth $-u$ compensates for this growth. If $w : [0, +\infty) \rightarrow [0, +\infty)$ is a nonincreasing function with $w(t) \rightarrow 0$ as $t \rightarrow +\infty$, we call

$$w(-u) \mu_u$$

the *damped Monge–Ampère measure* of u with weight w ; the weight is set to zero on the pole set $\{u = -\infty\}$, which μ_u does not charge. The main examples are the exponential weights e^{-pt} and the polynomial weights $(1+t)^{-q}$. For suitable weights the damped measures are finite, uniformly absolutely continuous with respect to capacity, and continuous under convergence in capacity, a property that the extended measures themselves lack. Removing the weight requires uniform control of the mass on deep sublevel sets; we characterize this control and show by examples that such mass can persist although the potentials converge in capacity.

7.1 Range and restricted mass

We first bound the Monge–Ampère mass of a bounded potential polynomially in its range. The first mixed mass $\int_X (\omega + \text{dd}^c v) \wedge \omega^{n-1}$ is bounded independently of v by the Gauduchon trace. Local Chern–Levine–Nirenberg estimates turn this into a bound of degree $j - 1$ in the range for the j th mixed mass, and Stokes’ theorem expresses the top mass in terms of the lower ones.

Proposition 7.1.1 *There is a constant C_ω such that, for every $A \geq 0$,*

$$\int_X (\omega + \text{dd}^c v)^n \leq C_\omega (1 + A)^{r_n} \quad \text{if } v \in \text{PSH}(X, \omega), \ 0 \leq v \leq A.$$

Proof Choose finitely many coordinate balls whose concentric smaller balls, with compact closure in the larger ones, cover X . On each larger ball choose a fixed quadratic function q with $\text{dd}^c q \geq \omega$, shifted so that $p = v + q$ is plurisubharmonic with $0 \leq p \leq A + C$. Let κ be the Euclidean form. In the identity

$$\text{dd}^c p = (\omega + \text{dd}^c v) + (\text{dd}^c q - \omega),$$

the integral of the first term against κ^{n-1} is bounded by a fixed multiple of the global trace mass, which is bounded by [Corollary 4.2.1](#), and the second term is smooth and fixed. Thus $\int \text{dd}^c p \wedge \kappa^{n-1}$ is bounded uniformly in v and A ; in dimension one, Stokes’ theorem replaces the trace bound. By [\(1.2\)](#), on each smaller ball,

$$\int (\text{dd}^c p)^j \wedge \kappa^{n-j} \leq C_j (1 + A)^{j-1} \quad (1 \leq j \leq n).$$

Expand $(\omega + \text{dd}^c v)^j = (\text{dd}^c p + \omega - \text{dd}^c q)^j$ and sum over the finite cover. Since the smooth factors have bounded coefficients, the positive mixed masses satisfy

$$0 \leq M_j(v) := \int_X (\omega + \text{dd}^c v)^j \wedge \omega^{n-j} \leq C_j (1 + A)^{\max(j-1, 0)} \quad (0 \leq j \leq n).$$

For smooth v , the exact form $(\text{dd}^c v)^n$ integrates to zero, as in the proof of [Theorem 2.2.1](#); the regularization of [Theorem 1.11.1](#) and the continuity of bounded products give the same identity for bounded v . Thus

$$0 = \int_X (\text{dd}^c v)^n = \sum_{j=0}^n (-1)^{n-j} \binom{n}{j} M_j(v).$$

Since the mixed masses are nonnegative, it follows that

$$M_n(v) \leq \sum_{j=0}^{n-1} \binom{n}{j} M_j(v) \leq C_\omega (1 + A)^{r_n}.$$

The largest power is $n - 2$ when $n \geq 2$; for $n = 1$, only the constant term remains. $\square$

For $n \leq 2$ the bound is uniform, so every compact complex curve or surface has the bounded mass property. In higher dimensions the bound grows with the range, and truncation turns it into a bound for the mass of an unbounded potential above a finite depth.

Lemma 7.1.1 *Let $u \in \text{PSH}(X, \omega)$ be nonpositive. For $t \geq 0$ and every Borel set $E \subset X$,*

$$\mu_u(\{u \geq -t\}) \leq C_\omega(1+t)^{r_n}, \quad \mu_u(E \cap \{u \geq -t\}) \leq (1+t)^n \text{Cap}_\omega(E). \quad (7.1)$$

Proof Put $v_t = \max(u, -t - 1) + t + 1$. It is ω -plurisubharmonic and takes values in $[0, t + 1]$, and by plurifine locality its Monge–Ampère measure equals μ_u on $\{u \geq -t\} \subset \{u > -t - 1\}$. The first estimate therefore follows from [Proposition 7.1.1](#), after enlarging the constant. For the second, $v_t/(1+t)$ is a test function for the capacity, and positivity gives

$$(\omega + \text{dd}^c v_t)^n \leq (1+t)^n (\omega + \text{dd}^c (v_t/(1+t)))^n.$$

Restricting this inequality to $E \cap \{u \geq -t\}$ proves the capacity bound. $\square$

7.2 Exponential damping

The exponential weight can be handled directly. A convex increasing function with bounded range transforms u into a bounded ω -plurisubharmonic function, and the chain rule shows that the transformed current dominates an exponential multiple of $\omega + \text{dd}^c u$. The Monge–Ampère measure of the bounded transform therefore controls the damped measure.

For $a > 0$ put $F_a(t) = a^{-1}e^{at}$ for $t \leq 0$, with $F_a(-\infty) = 0$. Then $0 \leq F_a \leq a^{-1}$, while $0 < F'_a \leq 1$ and $F''_a \geq 0$ at finite arguments.

Proposition 7.2.1 *If $u \in \text{PSH}(X, \omega)$ and $u \leq 0$, then $F_a(u)$ is a bounded ω -plurisubharmonic function, and*

$$e^{nau} \mu_u \leq \text{MA}_\omega(F_a(u)).$$

Proof First suppose that u is bounded. The chain rule [\(1.6\)](#) gives

$$\omega + \text{dd}^c F_a(u) = e^{au} (\omega + \text{dd}^c u) + (1 - e^{au})\omega + ae^{au} du \wedge d^c u.$$

All three summands are positive, and positivity of their bounded mixed products yields the claimed inequality.

For general u , use the truncations $u_t = \max(u, -t)$. The bounded functions $F_a(u_t)$ decrease and take values between zero and a^{-1} , so their limit $F_a(u)$ is a bounded

ω -plurisubharmonic function. On the plurifinely open set $D_t = \{u > -t\}$, it agrees with $F_a(u_t)$. Locality and the bounded case therefore give

$$e^{nau} \mathbf{1}_{D_t} \mu_u \leq \mathbf{1}_{D_t} \text{MA}_\omega(F_a(u)).$$

Let $t \rightarrow +\infty$. The pole set is not charged by μ_u , and it has zero mass for the bounded product on the right. $\square$

Theorem 7.2.1 *For $p > 0$, the damped measures $\nu_{p,u} = e^{pu} \mu_u$ satisfy*

$$\nu_{p,u}(X) \leq C_\omega(1 + p^{-1})^{r_n}, \quad \nu_{p,u}(E) \leq \max(1, n/p)^n \text{Cap}_\omega(E)$$

for every Borel set $E \subset X$, uniformly over all nonpositive $u \in \text{PSH}(X, \omega)$.

Proof Take $a = p/n$ in [Proposition 7.2.1](#). Since $F_{p/n}(u)$ takes values in $[0, n/p]$, [Proposition 7.1.1](#) with $A = n/p$ gives the total mass bound, after enlarging C_ω . For the capacity bound put $B = \max(1, n/p)$ and $v = F_{p/n}(u)$. Then v/B is a test function for the capacity, and

$$B(\omega + \text{dd}^c(v/B)) = (\omega + \text{dd}^c v) + (B-1)\omega \geq \omega + \text{dd}^c v.$$

Consequently $\nu_{p,u} \leq \text{MA}_\omega(v) \leq B^n \text{MA}_\omega(v/B)$, which gives the second bound. The measures $\nu_{p,u}$ do not charge pluripolar sets, because μ_u does not. $\square$

Since μ_u does not charge the pole set, multiplication by e^{-pu} recovers μ_u from $\nu_{p,u}$, including when its mass is infinite. An additive shift $u \mapsto u + c$ multiplies the damped measure by e^{pc} .

7.3 Decreasing weights and capacity continuity

For a general decreasing weight w , writing $w(s) = \int_s^\infty (-w'(t)) dt$ and integrating the sublevel estimate (7.1) in t bounds both the total mass and the mass on deep sublevel sets. Above any fixed depth, the damped measure is a weighted product of bounded potentials, which is continuous under convergence in capacity; the tail bound then removes the restriction to a fixed depth.

Theorem 7.3.1 *Let $w : [0, +\infty) \rightarrow (0, +\infty)$ be continuously differentiable and nonincreasing, with $w(t) \rightarrow 0$ as $t \rightarrow +\infty$. For $T \geq 0$ define*

$$B_w(T) = \int_T^\infty (1+t)^n (-w'(t)) dt.$$

Assume $B_w(0) < +\infty$. For nonpositive $u \in \text{PSH}(X, \omega)$, the damped measures $\nu_{w,u} = w(-u)\mu_u$ satisfy

$$\nu_{w,u}(X) \leq C_\omega B_w(0), \quad \nu_{w,u}(\{u < -T\}) \leq C_\omega B_w(T).$$

For every Borel set E and $T \geq 0$,

$$\nu_{w,u}(E) \leq w(0)(1+T)^n \text{Cap}_\omega(E) + C_\omega B_w(T).$$

In particular, these measures are uniformly absolutely continuous with respect to capacity. If nonpositive $u_j, u \in \text{PSH}(X, \omega)$ satisfy $u_j \rightarrow u$ in capacity, then $\nu_{w,u_j} \rightarrow \nu_{w,u}$.

Proof Write $s = -u$. Since $w(s) = \int_s^\infty (-w'(t)) dt$ for finite s , and since μ_u does not charge the pole set $\{s = +\infty\}$, Tonelli's theorem and [Lemma 7.1.1](#) give

$$\int_X w(s) d\mu_u = \int_0^\infty (-w'(t)) \mu_u(\{s \leq t\}) dt \leq C_\omega B_w(0).$$

Restricting the integral to $\{s > T\}$ gives the same bound with $B_w(T)$ in place of $B_w(0)$, since the inner set is then $\{T < s \leq t\}$, which is empty unless $t > T$.

For the capacity bound, the second estimate in [\(7.1\)](#) gives

$$\int_{E \cap \{s \leq T\}} w(s) d\mu_u \leq w(0)(1+T)^n \text{Cap}_\omega(E).$$

Adding the tail estimate for $\{s > T\}$ proves the asserted bound. Since $B_w(T) \rightarrow 0$, choosing first T large and then the capacity small gives uniform absolute continuity.

To prove continuity, fix a continuous nonincreasing $\eta : [0, +\infty) \rightarrow [0, 1]$, equal to one on $[0, 1]$ and zero on $[2, +\infty)$, and put $\eta_T(s) = \eta(s/T)$. For fixed $T > 0$, set $\nu_{j,T} = \max(u_j, -2T)$ and $g_T(t) = \eta_T(-t)w(-t)$ on $[-2T, 0]$. Since $g_T(-2T) = 0$, locality gives

$$\eta_T(-u_j)w(-u_j)\mu_{u_j} = g_T(\nu_{j,T}) \text{MA}_\omega(\nu_{j,T}). \quad (7.2)$$

Truncation preserves convergence in capacity. The functions $g_T(\nu_{j,T})$ are uniformly bounded and quasi-continuous, and they converge in capacity to the corresponding function for u . The weighted continuity of bounded products in [Sections 1.6](#) and [1.8](#) therefore gives weak convergence of the measures in [\(7.2\)](#) for each fixed T . The measure $(1 - \eta_T(-u_j))\nu_{w,u_j}$ is carried by $\{u_j < -T\}$, so by the tail bound its integral against a continuous test function f is at most $C_\omega B_w(T)\|f\|_\infty$, uniformly in j ; the same holds for u . Letting $T \rightarrow \infty$ completes the proof. $\square$

For $w(t) = e^{-pt}$, $p > 0$, the integral $B_w(0)$ is finite because the exponential dominates the polynomial factor. Thus the exponentially damped measures of [Theorem 7.2.1](#) are continuous under convergence in capacity. By that theorem, their tails also satisfy

$$\nu_{p,u}(\{u < -T\}) \leq e^{-pT/2} \nu_{p/2,u}(X) \leq C_p e^{-pT/2}.$$

For polynomial weights, the general estimate takes the following explicit form.

Theorem 7.3.2 *For every $q > r_n$, the damped measures*

$$\sigma_{q,u} := (1 - u)^{-q} \mu_u$$

have uniformly bounded mass for $u \in \text{PSH}(X, \omega)$, $u \leq 0$. More precisely,

$$\sigma_{q,u}(\{u < -T\}) \leq C \frac{q}{q - r_n} (1 + T)^{r_n - q} \quad (T \geq 0),$$

where C depends only on ω . There is also a constant C_q such that, for every Borel set $E \subset X$,

$$\sigma_{q,u}(E) \leq C_q \text{Cap}_\omega(E)^{(q-r_n)/(q+n-r_n)}.$$

Proof For $w(t) = (1 + t)^{-q}$, direct integration gives

$$B_w(T) = q \int_T^\infty (1 + t)^{r_n - q - 1} dt = \frac{q}{q - r_n} (1 + T)^{r_n - q}.$$

Thus [Theorem 7.3.1](#) gives the mass and tail estimates. For the capacity bound put $\delta = \text{Cap}_\omega(E)$. If $0 < \delta \leq 1$, choose $T = \delta^{-1/(q+n-r_n)} \geq 1$ in that theorem. Both $T^n \delta$ and $T^{r_n - q}$ equal $\delta^{(q-r_n)/(q+n-r_n)}$, so its two terms have the required bound. If $\delta = 0$, let $T \rightarrow \infty$; if $\delta > 1$, use the total mass bound. $\square$

For $n \geq 2$, the capacity exponent is $1 - n/(q + 2)$. The threshold $q > n - 2$ comes from the mixed-mass estimate in [Proposition 7.1.1](#).

Logarithmic factors give weights at the threshold. For $n \geq 3$ and $a > 1$, put $r = n - 2 > 0$ and

$$w(t) = (1 + t)^{-r} [\log(e + t)]^{-a}.$$

Differentiation gives

$$(1 + t)^r (-w'(t)) = \frac{r}{(1 + t)[\log(e + t)]^a} + \frac{a}{(e + t)[\log(e + t)]^{a+1}}.$$

The ratios $(e + t)/(1 + t)$ are bounded. The substitution $y = \log(e + t)$ therefore bounds the integrals of the two terms over $[T, +\infty)$ by fixed multiples of $[\log(e + T)]^{1-a}$ and $[\log(e + T)]^{-a}$, respectively. Since $a > 1$ and $\log(e + T) \geq 1$, we obtain $B_w(T) \leq C_{n,a} [\log(e + T)]^{1-a}$. Hence, by [Theorem 7.3.1](#), the damped measures $(1 - u)^{-(n-2)} [\log(e - u)]^{-a} \mu_u$ have uniformly bounded mass, their mass on $\{u < -T\}$ is at most a constant times $[\log(e + T)]^{1-a}$, and they are continuous under convergence

in capacity. In dimensions one and two, $r_n = 0$ and $B_w(T) = w(T)$, so every weight satisfying the monotonicity, differentiability and vanishing conditions of [Theorem 7.3.1](#) can be used.

Damping can remove an infinite mass entirely in the limit. When the bounded mass property fails, take the potential U of [Corollary 6.7.1](#), normalized by $\sup_X U = 0$. For $0 < \varepsilon < 1$, the potentials εU converge to zero in capacity as $\varepsilon \downarrow 0$: by (1.15), the capacity of $\{\varepsilon U < -\delta\}$ is at most $C\varepsilon/\delta$ for each fixed $\delta > 0$ and small ε . Consequently, for $p > 0$ and $q > r_n$,

$$e^{p\varepsilon U} \mu_{\varepsilon U} \rightharpoonup \omega^n, \quad (1 - \varepsilon U)^{-q} \mu_{\varepsilon U} \rightharpoonup \omega^n,$$

although $\mu_{\varepsilon U}(X) = +\infty$ for every $0 < \varepsilon < 1$. The full currents also converge to ω in the coefficient L^1 norm, and their Gauduchon traces converge in total variation.

7.4 Uniform tails and undamped convergence

Removing the weight requires uniform control of the mass on deep sublevel sets of the approximating potentials. The following condition gives both a finite limit measure and weak convergence of the undamped measures μ_{u_j} . It can equivalently be expressed by an increasing integrability weight.

Theorem 7.4.1 *Let $u_j, u \in \text{PSH}(X, \omega)$ be nonpositive and suppose $u_j \rightarrow u$ in capacity. Assume*

$$\lim_{T \rightarrow \infty} \sup_j \mu_{u_j}(\{u_j < -T\}) = 0.$$

Then μ_u is finite and $\mu_{u_j} \rightharpoonup \mu_u$.

Proof Choose T_0 such that every tail $\mu_{u_j}(\{u_j < -T\})$ with $T \geq T_0$ is at most one. By [Lemma 7.1.1](#), $\mu_{u_j}(X) \leq C(1 + T_0)^{r_n} + 1$, so the tail condition already gives a uniform bound for the total masses.

With the cutoffs η_T of (7.2), the fixed-level argument in the proof of [Theorem 7.3.1](#), applied with $w \equiv 1$, gives

$$\eta_T(-u_j) \mu_{u_j} \rightharpoonup \eta_T(-u) \mu_u \quad \text{for every fixed } T > 0.$$

The masses of the measures on the left are bounded by the uniform bound for the total masses. Since $\eta_T(-u)$ increases to one off the pole set as $T \rightarrow \infty$, monotone convergence proves $\mu_u(X) < +\infty$.

For a continuous test function $f : X \rightarrow \mathbb{R}$, the error made by inserting $\eta_T(-u_j)$ is at most $\|f\|_\infty \mu_{u_j}(\{u_j < -T\})$, which is small for large T , uniformly in j . For the limit potential, the corresponding error tends to zero because μ_u is finite and does not charge the pole set. Let first $j \rightarrow \infty$ with T fixed, and then $T \rightarrow \infty$. $\square$

Let $\chi : [0, +\infty) \rightarrow [1, +\infty)$ be continuous, nondecreasing and unbounded. For a nonpositive potential $u \in \text{PSH}(X, \omega)$ define

$$J_{\chi, \omega}(u) = \int_X \chi(-u) \, d\mu_u,$$

with the value $+\infty$ allowed. Since $\chi(T) \rightarrow +\infty$, a uniform bound for this functional forces the sublevel tails to vanish uniformly.

Corollary 7.4.1 *Let $u_j, u \in \text{PSH}(X, \omega)$ be nonpositive. If $u_j \rightarrow u$ in capacity and $\sup_j J_{\chi, \omega}(u_j) \leq C$, then*

$$J_{\chi, \omega}(u) \leq C, \quad \mu_{u_j} \rightarrow \mu_u.$$

Proof Since $\chi \geq 1$, the total masses are at most C , and

$$\mu_{u_j}(\{u_j < -T\}) \leq C/\chi(T).$$

Thus **Theorem 7.4.1** applies. For the bound on $J_{\chi, \omega}(u)$, use (7.2) with the compactly supported continuous function $s \mapsto \chi(s)\eta_T(s)$ in place of $w\eta_T$. The corresponding weighted integrals converge for each fixed T , and they are at most C . Let $T \rightarrow \infty$ and use monotone convergence. $\square$

Proposition 7.4.1 *For a family of nonpositive potentials in $\text{PSH}(X, \omega)$, the uniform tail condition of **Theorem 7.4.1** is equivalent to a uniform bound on $J_{\chi, \omega}$ for some continuous nondecreasing unbounded function $\chi \geq 1$.*

Proof One implication was proved in **Corollary 7.4.1**. Conversely, write the family as $(u_i)_{i \in I}$. As in the proof of **Theorem 7.4.1**, the tail condition and **Lemma 7.1.1** give a uniform bound for the total masses. Choose numbers $T_k \rightarrow +\infty$, with $T_{k+1} > T_k + 1$, such that $\mu_{u_i}(\{-u_i > T_k\}) \leq 2^{-k}$ for every $i \in I$. Let ρ_k be a continuous nondecreasing function, equal to zero on $[0, T_k]$ and to one on $[T_k + 1, +\infty)$, and define

$$\chi(s) = 1 + \sum_{k \geq 1} \rho_k(s).$$

The sum is locally finite, so χ is continuous, nondecreasing and unbounded. Tonelli's theorem gives

$$J_{\chi, \omega}(u_i) \leq \mu_{u_i}(X) + \sum_{k \geq 1} \mu_{u_i}(\{-u_i > T_k\}) \leq \sup_{i \in I} \mu_{u_i}(X) + 1,$$

so this weight gives a uniform integrability bound for the whole family. $\square$

7.5 Mass concentration

The tail condition excludes mass carried by sublevel sets that disappear in the capacity limit. On a curve this mass can concentrate at a pole of the limit. When the bounded mass property fails, it can also persist along smooth potentials converging to zero.

Example 7.5.1 On $X = \mathbb{P}^1$, let z be the standard affine coordinate and let δ_0 denote the unit Dirac measure at its origin. Take the Fubini–Study form

$$\omega = \text{dd}^c \log(1 + |z|^2), \quad \int_X \omega = 1,$$

and the global nonpositive potential

$$u(z) = \log \frac{|z|^2}{1 + |z|^2}, \quad u_j = \max(u, -j).$$

At infinity, in the coordinate $\zeta = 1/z$, the function u equals $-\log(1 + |\zeta|^2)$, so it is smooth there. The Poincaré–Lelong formula gives

$$\omega + \text{dd}^c u = \delta_0, \quad \text{MA}_\omega^{\text{ext}}(u) = 0.$$

The second identity holds because the extended measure discards the pole set and the current vanishes on its complement.

Each u_j is bounded and ω -plurisubharmonic. Its measure $\mu_j = \mu_{u_j} = \omega + \text{dd}^c u_j$ has mass one by Stokes' theorem, and $\mu_j = 0$ on the open set $\{u > -j\}$ by locality. Hence

$$\text{supp } \mu_j \subset \{u \leq -j\} = \left\{ |z|^2 \leq \frac{e^{-j}}{1 - e^{-j}} \right\}.$$

These disks shrink to the origin, so $\mu_j \rightarrow \delta_0$.

On their supports, $u_j = -j$. Consequently, for $j > T$,

$$\mu_j(\{u_j < -T\}) = 1, \quad e^{pu_j} \mu_j = e^{-pj} \mu_j \rightarrow 0 \quad (p > 0).$$

Nevertheless, $u_j \rightarrow u$ in capacity. Indeed, outside any neighborhood of the origin the functions eventually agree with u , and the origin has arbitrarily small neighborhoods of arbitrarily small capacity. Thus bounded mass and capacity convergence do not prevent the undamped measures from acquiring mass at a pole of the limit. The damped limit is the extended measure of u , as predicted by [Theorem 7.3.1](#).

We return to a general compact Hermitian manifold (X, ω) .

Corollary 7.5.1 *Assume $v_+(\omega) = +\infty$ and put $V_\omega = \int_X \omega^n$. Fix a real number $b > V_\omega$ and a sequence $0 < \varepsilon_j < 1$ tending to zero. The smooth potentials w_j of [Corollary 6.7.2](#), chosen with mass b , converge to zero in capacity. For every $T > 0$,*

$$\|\mathbf{1}_{\{w_j \geq -T\}}(\omega + \text{dd}^c w_j)^n - \omega^n\|_{\text{TV}} \longrightarrow 0, \quad \int_{\{w_j < -T\}} (\omega + \text{dd}^c w_j)^n \longrightarrow b - V_\omega.$$

After passage to a subsequence, there is a positive measure σ of mass $b - V_\omega$ such that

$$(\omega + \text{dd}^c w_j)^n \rightharpoonup \omega^n + \sigma, \quad \mathbf{1}_{\{w_j < -T\}}(\omega + \text{dd}^c w_j)^n \rightharpoonup \sigma \quad \text{for every } T > 0.$$

Proof The construction in [Corollary 6.7.2](#) gives $w_j = s_j u_j$, where u_j is smooth and ω -plurisubharmonic, $\sup_X u_j = 0$ and $0 < s_j < \varepsilon_j$. The sublevel estimate (1.15) gives, for every fixed $\delta > 0$ and all sufficiently large j ,

$$\text{Cap}_\omega(\{|w_j| > \delta\}) = \text{Cap}_\omega(\{u_j < -\delta/s_j\}) \leq C s_j / \delta \longrightarrow 0.$$

Put $\mu_j = (\omega + \text{dd}^c w_j)^n$. Fix $T > 0$ and write $E_{j,T} = \{w_j \geq -T\}$. The lower bound in [Corollary 6.7.2](#) gives

$$\mathbf{1}_{E_{j,T}} \mu_j \geq \lambda_{j,T} := (1 - \varepsilon_j)^n \mathbf{1}_{E_{j,T}} \omega^n.$$

Since $w_j \rightarrow 0$ in L^1 , the smooth volume of $X \setminus E_{j,T}$ tends to zero, and hence $\lambda_{j,T} \rightarrow \omega^n$ in total variation. For every $p > 0$, [Theorem 7.3.1](#) gives $\int_X e^{p w_j} d\mu_j \rightarrow V_\omega$, and therefore

$$\limsup_j \mu_j(E_{j,T}) \leq e^{pT} \lim_j \int_X e^{p w_j} d\mu_j = e^{pT} V_\omega.$$

Letting $p \downarrow 0$ and combining with the lower bound, we obtain $\mu_j(E_{j,T}) \rightarrow V_\omega$. Positivity now yields

$$\begin{aligned} \|\mathbf{1}_{E_{j,T}} \mu_j - \omega^n\|_{\text{TV}} &\leq \mu_j(E_{j,T}) - \lambda_{j,T}(X) + \|\lambda_{j,T} - \omega^n\|_{\text{TV}} \\ &\longrightarrow 0. \end{aligned}$$

Subtracting this shallow mass from $\mu_j(X) = b$ proves the assertion about the mass on $\{w_j < -T\}$.

The positive measures μ_j have fixed mass on the compact manifold X , so a subsequence converges weakly to a measure ν of mass b . The inequality $\mu_j \geq (1 - \varepsilon_j)^n \omega^n$ gives $\nu \geq \omega^n$. Set $\sigma = \nu - \omega^n$. For each $T > 0$, subtracting the total-variation limit of the shallow restrictions from $\mu_j \rightarrow \nu$ gives the last assertion along the same subsequence, for every T . $\square$

Thus the defect σ in [Corollary 7.5.1](#) carries the whole excess mass $b - V_\omega$, although the currents $\omega + \text{dd}^c w_j$ converge to ω in the coefficient L^1 norm and their

Gauduchon traces converge in total variation. The location of σ is constrained by the limits of the intermediate powers of $\text{dd}^c w_j$, as we now show.

7.5.1 Intermediate currents of a shrinking sequence

We formulate the result for a connected compact complex manifold Y of dimension $n \geq 1$ with a Hermitian form h , since it will be applied with different metrics in [Chapter 8](#). Consider smooth functions

$$v_j = s_j u_j, \quad u_j \in \text{PSH}(Y, h), \quad \sup_Y u_j = 0, \quad 0 < s_j \rightarrow 0.$$

Suppose that their Monge–Ampère masses $\int_Y (h + \text{dd}^c v_j)^n$ equal a fixed number b and that

$$(h + \text{dd}^c v_j)^n \rightarrow h^n + \sigma.$$

The lower bound $h + \text{dd}^c v_j \geq (1 - s_j)h$ shows that σ is positive. Although $\text{dd}^c v_j \rightarrow 0$ in the trace norm, its intermediate powers can have nonzero limits, and these limits determine σ .

Proposition 7.5.1 *After passage to a common subsequence, the positive forms*

$$H_j = \text{dd}^c v_j + s_j h = s_j (h + \text{dd}^c u_j)$$

satisfy $H_j^k \rightarrow K_k$ for $1 \leq k \leq n$. The currents K_k are positive and closed, and $K_1 = K_n = 0$. For every smooth real $(n - k, n - k)$ -form η with $d\eta = 0$ or $\text{dd}^c \eta = 0$,

$$\int_Y K_k \wedge \eta = 0.$$

Moreover,

$$\sigma = \sum_{k=2}^{n-1} \binom{n}{k} h^{n-k} \wedge K_k. \quad (7.3)$$

If ϑ is a smooth closed semipositive $(1, 1)$ -form on Y , then σ is supported on $\{\vartheta^n = 0\}$. In dimension three the same conclusion holds for every smooth semipositive $(1, 1)$ -form ϑ with $\text{dd}^c \vartheta = 0$.

Proof For $s_j < 1/2$, positivity in the expansion

$$(h + \text{dd}^c v_j)^n = \sum_{k=0}^n \binom{n}{k} (1 - s_j)^{n-k} h^{n-k} \wedge H_j^k$$

gives a uniform bound for each $\int_Y h^{n-k} \wedge H_j^k$. In local unitary coordinates, the coefficient matrix of the smooth positive form H_j^k on exterior powers is positive semidefinite, so its entries are bounded in absolute value by its trace, up to a

dimensional constant. The trace bounds therefore bound every coefficient in total variation, and weak compactness of measures gives a common subsequence and positive limits K_k .

For $n \geq 2$, choose a Gauduchon form γ . By [Proposition 4.2.1](#),

$$\int_Y H_j \wedge \gamma^{n-1} = s_j \int_Y h \wedge \gamma^{n-1}.$$

Since γ and h are equivalent smooth metrics, it follows that $H_j \rightarrow 0$ in coefficient total variation. For $n = 1$ the same conclusion follows from $\int_Y H_j = s_j \int_Y h$. Thus $K_1 = 0$ in all dimensions. Since $dH_j = s_j dh$,

$$d(H_j^k) = k s_j dh \wedge H_j^{k-1} \rightarrow 0$$

as currents, because the preceding trace bounds control multiplication by the fixed smooth form dh . Hence every K_k is closed.

The smooth form $(dd^c v_j)^k$ is both d -exact and dd^c -exact:

$$(dd^c v_j)^k = d(d^c v_j \wedge (dd^c v_j)^{k-1}) = dd^c(v_j (dd^c v_j)^{k-1}).$$

Its integral against either kind of test form η in the statement is therefore zero by Stokes' formula. Expanding $dd^c v_j = H_j - s_j h$ gives

$$\int_Y \eta \wedge H_j^k = - \sum_{r=0}^{k-1} \binom{k}{r} (-s_j)^{k-r} \int_Y \eta \wedge h^{k-r} \wedge H_j^r = O(s_j).$$

Each integral on the right is bounded by the trace bound for H_j^r . Taking $k = n$ and $\eta = 1$ shows that the positive measures H_j^n tend to zero in total variation, which proves $K_n = 0$; the other vanishing integrals follow by weak convergence. Finally, letting $j \rightarrow \infty$ in the positive expansion above, the terms with $k = 0$ tend to h^n and those with $k = 1$ and $k = n$ vanish in the limit, which proves [\(7.3\)](#).

For closed semipositive ϑ , apply the vanishing integrals to $\eta = \vartheta^{n-k}$. The measure $K_k \wedge \vartheta^{n-k}$ is positive and has zero mass. On every relatively compact open set where $\vartheta > 0$, it dominates a positive multiple of the trace measure of K_k , so K_k vanishes there. The decomposition gives the asserted support. In dimension three only K_2 occurs, and the same argument applies to the dd^c -closed test form ϑ itself. $\square$

In dimensions at most two the decomposition forces $\sigma = 0$. A threefold carrying a pluriclosed Hermitian metric, that is, a Hermitian form ϑ with $dd^c \vartheta = 0$, has no nonzero defect σ of this form either. In higher dimensions, the vanishing integrals impose necessary conditions on each intermediate current; they do not by themselves produce a smooth sequence with prescribed intermediate limits.

7.6 Damping for a smooth background

For a general smooth background θ , truncation at a constant level may fail to preserve θ -plurisubharmonicity. A larger Hermitian form makes the truncations plurisubharmonic and dominates the extended measure, and the local expansion of the θ -product gives continuity at each fixed truncation level.

Theorem 7.6.1 *Let θ be a smooth real $(1, 1)$ -form, and for nonpositive $u \in \text{PSH}(X, \theta)$ put $\mu_{\theta, u} = \text{MA}_{\theta}^{\text{ext}}(u)$. The mass bounds, capacity estimates and capacity-continuity statements for damped measures in this chapter, including [Theorem 7.3.1](#), hold for the measures $\mu_{\theta, u}$ in place of μ_u , with constants depending on θ and ω . In particular, for $p > 0$ and $q > r_n$,*

$$\int_X e^{pu} d\mu_{\theta, u} \leq C(1 + p^{-1})^{r_n}, \quad \int_X (1 - u)^{-q} d\mu_{\theta, u} \leq C_q.$$

The undamped tail criterion of [Theorem 7.4.1](#) and the integrability criterion of [Corollary 7.4.1](#) also hold with $\mu_{\theta, u}$ in place of μ_u .

Proof Choose $C_0 \geq 1$ such that $\theta \leq \Omega := C_0\omega$. Then $u \in \text{PSH}(X, \Omega)$, and [Theorem 6.1.1](#) gives

$$0 \leq \mu_{\theta, u} \leq \text{MA}_{\Omega}^{\text{ext}}(u).$$

All the mass, tail and capacity bounds therefore follow from the estimates already proved for Ω . The metric comparison in [Section 1.8](#) gives, for every Borel set $E \subset X$,

$$\text{Cap}_{\omega}(E) \leq \text{Cap}_{\Omega}(E) \leq C_0^n \text{Cap}_{\omega}(E).$$

For continuity, let nonpositive $u_j, u \in \text{PSH}(X, \theta)$ converge in capacity, and use [\(7.2\)](#) with the θ -product. The truncations are bounded and Ω -plurisubharmonic. The weighted capacity continuity of [Sections 1.6](#) and [1.8](#) applies term by term to the local expansion of their signed θ -products, with the same bounded quasi-continuous coefficients. Since the cutoff vanishes at the truncation level, the result is exactly the restricted positive measure. The uniform tails obtained from the domination by $\text{MA}_{\Omega}^{\text{ext}}$ remove the cutoff. Domination also gives the sublevel estimate, so the preceding proofs of the undamped tail and integrability criteria apply without change. $\square$

Chapter 8

Unbounded mass on a Gauduchon threefold

By [Proposition 7.1.1](#), every compact complex curve or surface has the bounded mass property. This chapter shows that the property fails on a Hopf threefold, one of the simplest non-Kähler manifolds, even for a Gauduchon metric. For a Hermitian form ω on a compact threefold, the mass polynomial of [Theorem 2.2.1](#) shows that the mass of a smooth potential V differs from $\int_X \omega^3$ by a term linear in V , which vanishes when ω is Gauduchon, and a term quadratic in V . For the Hopf threefold and its standard Gauduchon metric, the quadratic term is a positive multiple of the Dirichlet energy of V along the elliptic fibers of the projection to $\mathbb{P}^2$. It therefore suffices to construct smooth potentials with arbitrarily large vertical energy while keeping the perturbed form positive. The heat kernel of the fiber supplies the concentration; varying its time parameter across the base controls the mixed derivatives, and a function of the base alone restores positivity without changing the vertical energy. The same mass formula identifies all bounded potentials of minimal mass through their fiber averages, and the elliptic bundle determines exactly which excess measures survive when smooth potentials shrink to zero.

Theorem 8.0.1 (Xia–Zhang) *The compact threefold*

$$X = (\mathbb{C}^3 \setminus \{0\}) / \langle z \mapsto e^{-1} z \rangle$$

admits a Gauduchon form ω and smooth real functions V_j such that

$$\omega + \text{dd}^c V_j > 0, \quad \int_X (\omega + \text{dd}^c V_j)^3 \longrightarrow +\infty.$$

In particular, X does not have the bounded mass property.

8.1 The Hopf metric and its mass

The projection to $\mathbb{P}^2$ separates the horizontal and vertical parts of the metric. We normalize the fiber measure to have mass one; this fixes the constants in the mass formula.

On the covering space $\mathbb{C}^3 \setminus \{0\}$, with coordinates $z = (z_0, z_1, z_2)$, put

$$s = \log |z|^2, \quad \alpha = dd^c s, \quad \beta = ds \wedge d^c s = \frac{i}{2\pi} \partial s \wedge \bar{\partial} s, \quad \omega = \alpha + \beta.$$

The contraction $z \mapsto e^{-1} z$ changes s by the constant -2 , so these forms descend to X . A closed spherical shell between two successive radii is a compact fundamental domain; this also proves that the quotient is compact. Let ω_{FS} be the Fubini–Study form on $\mathbb{P}^2$, given by $dd^c \log(1 + |\xi|^2)$ in affine coordinates $\xi = (\xi_1, \xi_2)$. Projectivization gives a holomorphic map

$$\pi : X \longrightarrow \mathbb{P}^2, \quad \alpha = \pi^* \omega_{\text{FS}}, \quad \int_{\mathbb{P}^2} \omega_{\text{FS}}^2 = 1.$$

The form α has rank two and is positive transversally to the fibers, while the rank-one form β is positive on the vertical line. Their kernels intersect only in zero, and therefore $\omega > 0$.

We shall use the identities

$$\alpha^3 = 0, \quad \beta^2 = 0, \quad d\alpha = 0, \quad dd^c \beta = -\alpha^2, \quad dd^c(\omega^2) = 0. \quad (8.1)$$

The first three follow from the definitions and the dimension of the base. For the fourth, differentiating $\beta = i\partial s \wedge \bar{\partial} s / (2\pi)$ gives $dd^c \beta = (\partial \bar{\partial} s)^2 / (4\pi^2) = -\alpha^2$. Finally, $\omega^2 = \alpha^2 + 2\alpha \wedge \beta$, so $dd^c(\omega^2) = -2\alpha^3 = 0$. Thus ω is Gauduchon, although $dd^c \omega = -\alpha^2 \neq 0$.

On the affine base chart $U_0 = \{[z_0 : z_1 : z_2] \in \mathbb{P}^2 : z_0 \neq 0\} \simeq \mathbb{C}^2$ write

$$\xi_j = z_j / z_0 \quad (j = 1, 2), \quad w = \log z_0.$$

The choice of logarithm and the contraction change w by elements of $\Lambda = \mathbb{Z} + 2\pi i\mathbb{Z}$. Hence

$$\pi^{-1}(U_0) \simeq U_0 \times E, \quad E = \mathbb{C} / \Lambda, \quad dA_E = \frac{i}{4\pi} dw \wedge d\bar{w}, \quad \int_E dA_E = 1.$$

On another base chart the fiber coordinate changes by a holomorphic function of the base. Consequently, the vertical derivative ∂_w and the fiber integral below are globally defined. For a smooth function V on X , write $V_w = \partial V / \partial w$.

Proposition 8.1.1 *For every $V \in C^\infty(X, \mathbb{R})$,*

$$\int_X (\omega + dd^c V)^3 = 6 + 6 \int_{\mathbb{P}^2} \left(\int_{\pi^{-1}(y)} |V_w|^2 dA_E \right) \omega_{\text{FS}}^2(y). \quad (8.2)$$

In particular, positivity of $\omega + \text{dd}^c V$ is not required.

Proof Since β restricts to $2dA_E$ on each fiber,

$$\int_X \omega^3 = 3 \int_X \alpha^2 \wedge \beta = 6.$$

By (2.1) and (8.1), followed by an integration by parts against the closed form α^2 ,

$$\begin{aligned} \int_X (\omega + \text{dd}^c V)^3 - \int_X \omega^3 &= 3 \int_X V \text{dd}^c \omega \wedge \text{dd}^c V \\ &= -3 \int_X V \alpha^2 \wedge \text{dd}^c V = 3 \int_X dV \wedge d^c V \wedge \alpha^2. \end{aligned}$$

Wedging with α^2 removes every component of $dV \wedge d^c V$ except the vertical one, which is $i|V_w|^2 dw \wedge d\bar{w} / (2\pi) = 2|V_w|^2 dA_E$. Integration over the fibers proves the formula. $\square$

8.2 The radial–vertical block

We look for potentials that depend on the base point only through its distance from the origin of the affine chart. In a suitable frame, the matrix of $\omega + \text{dd}^c V$ then consists of one tangential horizontal coefficient and a two-by-two radial–vertical block, whose Schur complement isolates the mixed derivative that must be controlled. Subscripts denote partial derivatives in the indicated variables.

For $\xi \neq 0$ introduce

$$x = \log |\xi|^2, \quad \mu = \frac{e^x}{1 + e^x}, \quad \mu_x = \mu(1 - \mu).$$

We use smooth real functions $V : \mathbb{R} \times E \rightarrow \mathbb{R}$, written $V = V(x, w)$, that are independent of x for x near $-\infty$ and constant in both variables for x near $+\infty$. These conditions allow V to be extended smoothly across $\xi = 0$, and over the complement of the affine chart by the same constant. The region of the base where V is nonconstant may depend on V .

Lemma 8.2.1 *For such a function, at $\xi \neq 0$ the inequality $\omega + \text{dd}^c V > 0$ is equivalent to*

$$1 + V_{w\bar{w}} > 0, \quad \mu + V_x > 0, \quad Q[V] := V_{xx} + \mu - \frac{|\mu + V_{x\bar{w}}|^2}{1 + V_{w\bar{w}}} > 0. \quad (8.3)$$

At $\xi = 0$, the inequality $\omega + \text{dd}^c V > 0$ is equivalent to $1 + V_{w\bar{w}} > 0$.

Proof In these coordinates,

$$s = w + \bar{w} + \log(1 + e^x), \quad \partial s = dw + \mu \partial x,$$

and

$$2\pi\alpha = i\mu\partial\bar{\partial}x + i\mu(1-\mu)\partial x \wedge \bar{\partial}x.$$

Choose horizontal vectors of unit length for $2\pi\alpha$, one orthogonal to the radial direction and the other

$$e_r = \frac{\xi_1\partial_{\xi_1} + \xi_2\partial_{\xi_2}}{\sqrt{\mu(1-\mu)}}.$$

Adjoin the vertical vector ∂_w . In this frame the matrix of $2\pi(\omega + dd^c V)$ is

$$\begin{pmatrix} (\mu + V_x)/\mu & 0 & 0 \\ 0 & (\mu + V_{xx})/[\mu(1-\mu)] & (\mu + V_{x\bar{w}})/\sqrt{\mu(1-\mu)} \\ 0 & (\mu + V_{w\bar{x}})/\sqrt{\mu(1-\mu)} & 1 + V_{w\bar{w}} \end{pmatrix}.$$

Taking the Schur complement of the last diagonal entry gives (8.3). At $\xi = 0$, the derivatives of V in the base directions vanish and $\partial s = dw$, which gives the last assertion. $\square$

A rapid cutoff of a concentrated fiber potential can make the mixed derivative $V_{x\bar{w}}$ too large for this criterion. We therefore spread the concentration by the heat equation before cutting off, so that the fiber derivatives are already exponentially small in the cutoff region.

8.3 Heat potentials and the mixed derivative

The fiber potential will be built from the heat kernel of E . It has large vertical energy at small times and decays at large times, where it can be cut off, and a lower bound for its logarithmic Hessian controls vertical positivity. To control the radial-vertical block when the time varies, we also need an estimate relating the kernel to its logarithmic gradient.

For $t > 0$ define

$$k_t(w) = \frac{2}{t} \sum_{\lambda \in \Lambda} \exp\left(-\frac{|w - \lambda|^2}{t}\right). \quad (8.4)$$

This is a smooth positive Λ -periodic function of integral one: unfolding the integral reduces it to the Gaussian integral on $\mathbb{C}$, since $dA_E = da db / (2\pi)$ for $w = a + ib$. For $(p, q) \in \mathbb{Z}^2$ set

$$\nu_{p,q} = p + \frac{iq}{2\pi}, \quad \chi_{p,q}(w) = e^{2\pi i p \operatorname{Re} w + iq \operatorname{Im} w}.$$

These characters form an orthonormal basis of $L^2(E, dA_E)$. Computing the Fourier coefficients by the same unfolding gives

$$k_t = \sum_{p,q} e^{-\pi^2 |\nu_{p,q}|^2 t} \chi_{p,q}, \quad \partial_t k_t = \partial_w \partial_{\bar{w}} k_t. \quad (8.5)$$

All differentiated series converge locally uniformly for $t > 0$.

Lemma 8.3.1 *Let $0 < \eta < 1/10$ and define*

$$F_\eta(t, w) = -\eta \int_t^\infty (k_r(w) - 1) \, dr.$$

Then F_η is smooth and real, and

$$(F_\eta)_t = (F_\eta)_{w\bar{w}} = \eta(k_t - 1), \quad (8.6)$$

$$(\log k_t)_{w\bar{w}} \geq -1/t, \quad (8.7)$$

$$\int_E |(F_\eta)_w(t, w)|^2 dA_E = 2\eta^2 \log(1/t) + O(\eta^2) \quad (0 < t \leq 1). \quad (8.8)$$

The error term in (8.8) is uniform in t and η . For fixed nonnegative integers a, m there is also a uniform estimate

$$\|\partial_t^a F_\eta(t, \cdot)\|_{C^m(E)} \leq C_{a,m} \eta e^{-t/4} \quad (t \geq 1). \quad (8.9)$$

Proof Integrating the nonconstant Fourier modes gives

$$F_\eta(t, w) = -\frac{\eta}{\pi^2} \sum_{(p,q) \neq (0,0)} \frac{e^{-\pi^2 |v_{p,q}|^2 t}}{|v_{p,q}|^2} \chi_{p,q}(w).$$

This proves smoothness, reality and (8.6). The least nonzero value of $\pi^2 |v_{p,q}|^2$ is $1/4$, and any fixed number of differentiations introduces coefficients of polynomial growth in $|v_{p,q}|$. Factoring out $e^{-t/4}$ for $t \geq 1$ therefore leaves a convergent Gaussian series, which proves (8.9).

To prove (8.7), fix a lift of w and give Λ the probability weights

$$P_\lambda = \frac{e^{-|w-\lambda|^2/t}}{\sum_{\lambda'} e^{-|w-\lambda'|^2/t}}.$$

Logarithmic differentiation of the Gaussian sum yields

$$t \partial_{\bar{w}} \log k_t = - \sum_{\lambda} (w - \lambda) P_\lambda,$$

and one more derivative gives

$$(\log k_t)_{w\bar{w}} = -\frac{1}{t} + \frac{1}{t^2} \left(\sum_{\lambda} |w - \lambda|^2 P_\lambda - \left| \sum_{\lambda} (w - \lambda) P_\lambda \right|^2 \right).$$

The expression in parentheses is a variance and is nonnegative.

Finally, Parseval's identity gives, with $\mathcal{E}_\eta(t)$ denoting the energy in (8.8),

$$\mathcal{E}_\eta(t) = \frac{\eta^2}{\pi^2} \sum_{(p,q) \neq (0,0)} \frac{e^{-2\pi^2 |v_{p,q}|^2 t}}{|v_{p,q}|^2}, \quad \mathcal{E}'_\eta(t) = -2\eta^2 (k_{2t}(0) - 1).$$

The Gaussian formula at the origin implies

$$k_{2t}(0) = \frac{1}{t} + O\left(t^{-1}e^{-1/(4t)}\right) \quad (0 < t \leq 1).$$

To see this, isolate the zero lattice vector and use $e^{-|\lambda|^2/(2t)} \leq e^{-1/(4t)} e^{-|\lambda|^2/4}$ for $\lambda \neq 0$. The error term is integrable near $t = 0$, and $\mathcal{E}_\eta(1) = O(\eta^2)$. Integrating the derivative between t and 1 proves (8.8). $\square$

The Schur complement subtracts a square involving the mixed derivative. When the time parameter is allowed to vary, the heat equation produces a compensating positive square, and the following bound relating the heat kernel to its logarithmic gradient controls the region where that square is small.

Lemma 8.3.2 *For a constant $C_0 \geq 1$ depending only on E ,*

$$tk_t(w) \leq C_0 \exp\left(-\frac{|t\partial_{\bar{w}} \log k_t(w)|^2}{C_0 t}\right) \quad (0 < t \leq 1). \quad (8.10)$$

Proof Choose a nearest lattice point λ_0 , and put $d = |w - \lambda_0|$ and $s_\lambda = |w - \lambda|^2 - d^2 \geq 0$. The distance d is bounded by the diameter of a fundamental rectangle. By the triangle inequality, $s_\lambda \geq |\lambda - \lambda_0|^2/4 - C$, and outside a fixed finite set of λ we have $s_\lambda \geq |\lambda - \lambda_0|^2/8$. Consequently,

$$\sum_{\lambda} (1 + |w - \lambda|) e^{-s_\lambda/t} \leq C, \quad tk_t(w) \leq C e^{-d^2/t}.$$

The probability formula in the previous proof gives, with $G = |t\partial_{\bar{w}} \log k_t|$,

$$G \leq d + \sum_{\lambda \neq \lambda_0} |w - \lambda| e^{-s_\lambda/t}.$$

If $d \geq 1/4$, this is at most Cd . If $d < 1/4$, the nonzero lattice distances are at least one and

$$s_\lambda \geq |\lambda - \lambda_0|(|\lambda - \lambda_0| - 2d) \geq \frac{1}{2}|\lambda - \lambda_0|^2.$$

Summing the resulting Gaussian bound gives $G \leq C(d + e^{-c/t})$ in all cases. When $G > 2Ce^{-c/t}$, we have $d \geq G/(2C)$, and the bound $tk_t \leq Ce^{-d^2/t}$ gives (8.10). In the remaining case G^2/t is bounded, and (8.10) follows from $tk_t \leq C$ after increasing C_0 . $\square$

Lemma 8.3.3 *There is a constant C depending only on E with the following property. For $0 < \kappa < 1/(200C_0)$, $0 < \eta < 1/10$, $0 < t \leq 1$ and $1/2 \leq \mu \leq 1$, define $\sigma > 0$ and the functions h, ζ of $w \in E$ by*

$$\sigma^2 = \frac{2\kappa}{\eta} \log \frac{1}{\eta t}, \quad h = \eta k_t, \quad \zeta = \frac{\sigma}{\mu} t \partial_{\bar{w}} \log k_t.$$

Then

$$\kappa t k_t - \frac{\mu^2(1-\eta)h}{1-\eta+h} \left| \zeta - \frac{1}{1-\eta} \right|^2 \leq C\kappa \exp\left(-\frac{1}{C\sigma^2 t}\right). \quad (8.11)$$

Proof If $\sigma^2 t \geq 1/100$, the bound $t k_t \leq C_0$ gives (8.11) after enlarging C . Assume therefore that $\sigma^2 t < 1/100$. If $|\zeta - (1-\eta)^{-1}| \geq 1/4$, the subtracted expression is at least $h/[100(1+h)]$. Since $\log(1/(\eta t)) > 2$, the definition of σ gives

$$\kappa t(1+h) \leq \frac{\eta}{400} + C_0 \kappa \eta < \frac{\eta}{100}.$$

Multiplication by $k_t/(1+h)$ shows that the left side of (8.11) is nonpositive.

Otherwise $|\zeta| \geq 3/4$, so

$$|t \partial_{\bar{w}} \log k_t| = \frac{\mu |\zeta|}{\sigma} \geq \frac{3}{8\sigma}.$$

Discarding the nonnegative square and applying Lemma 8.3.2 gives (8.11) in this case as well. $\square$

8.4 Variation of the heat time

The heat time will remain small on a fixed base ball and then increase with the radial variable until the fiber potential can be cut off. We choose its rate of increase so that the negative part of the Schur complement has small integral in the radial variable. Fix κ as in Lemma 8.3.3.

All estimates below concern the limit $\eta \downarrow 0$, with κ fixed. Write

$$L = \log(1/\eta), \quad \varepsilon = \eta^{1/\eta^2}, \quad q_0 = \sqrt{\log \frac{1}{\eta \varepsilon}}, \quad a = \sqrt{\frac{\kappa}{2\eta}}.$$

Fix a smooth nondecreasing $\chi : \mathbb{R} \rightarrow [0, 1]$, independent of η , equal to zero on $(-\infty, 0]$ and one on $[1, +\infty)$, with $\int_0^1 \chi = 1/2$. Define

$$q(x) = q_0 - \int_0^{ax} \chi(s) ds, \quad t(x) = \eta^{-1} e^{-q(x)^2}. \quad (8.12)$$

Thus $t = \varepsilon$ on $x \leq 0$, and $q = q_0 + 1/2 - ax$ on $x \geq a^{-1}$. Put

$$b = \frac{q_0 + 1/2}{a}, \quad x_* = \frac{q_0 + 1/2}{a}.$$

For small η , we have $0 < a^{-1} < b < x_*$, with

$$q(b) = 1, \quad q(x_*) = 0, \quad b, x_* = O(\sqrt{L/\eta}), \quad \eta b = o(1). \quad (8.13)$$

Fix also a smooth cutoff $\vartheta : \mathbb{R} \rightarrow [0, 1]$, independent of η , zero on $(-\infty, 0]$ and one on $[1, +\infty)$, and define

$$W(x, w) = \vartheta(q(x))F_\eta(t(x), w).$$

This function equals $F_\eta(\varepsilon, w)$ for $x \leq 0$ and vanishes for $x \geq x_*$. Moreover, by (8.6),

$$1 + W_{w\bar{w}} = 1 + \vartheta(q)\eta(k_t - 1) > 1 - \eta. \quad (8.14)$$

Lemma 8.4.1 *For the functions just constructed, let*

$$d_\eta(x) = \max_{w \in E} \max\{-Q[W](x, w), 0\}.$$

For all sufficiently small η , the function d_η is continuous, supported in $[0, b]$, and

$$\int_{\mathbb{R}} d_\eta(x) dx = o(1), \quad \sup_{\mathbb{R} \times E} \max\{-W_x, 0\} = o(1). \quad (8.15)$$

On $[-2, -1] \times E$, one also has $Q[W] \geq 2/27$.

Proof We first derive an exact formula for $Q[W]$ on $[0, b]$, then bound its negative part separately on $[0, a^{-1}]$ and on $[a^{-1}, b]$, integrate these bounds, and finally examine the ends of the radial line.

Step 1: the Schur complement on $[0, b]$. Write $F = F_\eta$ for the heat potential. On $[0, b]$ we have $q \geq 1$, hence $\vartheta(q) = 1$ and $W = F(t(x), w)$. Set

$$h = \eta k_t, \quad \sigma = (\log t)_x, \quad \zeta = \frac{\sigma t}{\mu} \partial_{\bar{w}} \log k_t.$$

The heat equation gives $F_t = h - \eta$, and the chain rule gives

$$W_x = \sigma t F_t, \quad W_{xx} = (\sigma_x + \sigma^2)t F_t + \sigma^2 t^2 F_{tt}, \quad W_{x\bar{w}} = \sigma t F_{t\bar{w}}.$$

Substituting these in $Q[W]$, using $h_t = h((\log k_t)_{w\bar{w}} + |\partial_{\bar{w}} \log k_t|^2)$, and completing the square, we obtain the exact identity

$$\begin{aligned}
Q[W] = & \sigma^2 t \{h[1 + t(\log k_t)_{w\bar{w}}] - \eta\} + \sigma_x t F_t + \mu(1 - \mu) - \frac{\mu^2 \eta}{1 - \eta} \\
& + \frac{\mu^2(1 - \eta)h}{1 - \eta + h} \left| \zeta - \frac{1}{1 - \eta} \right|^2.
\end{aligned} \tag{8.16}$$

By (8.7), the part $\sigma^2 t h[1 + t(\log k_t)_{w\bar{w}}]$ is nonnegative.

Step 2: the initial interval $[0, a^{-1}]$. Here

$$\sigma = 2aq\chi(ax), \quad \sigma_x = -\frac{\kappa}{\eta}\chi(ax)^2 + \frac{\kappa}{\eta}q\chi'(ax).$$

Moreover $q_0 - 1/2 \leq q \leq q_0$ and $t \leq \varepsilon e^{q_0}$, and the latter tends to zero faster than any power of η . In particular,

$$\kappa q \chi'(ax)t \leq \eta, \quad \sigma^2 t \leq \eta^2.$$

At each point where $\chi(ax) > 0$, apply [Lemma 8.3.3](#) with $\kappa\chi(ax)^2$ in place of κ ; its constant is uniform in x . The positive square in (8.16) then absorbs the negative term $-\kappa\chi^2 t k_t$ coming from $\sigma_x t F_t$. The remaining part of $\sigma_x t F_t$, which involves χ' , is at least $-\eta$, because $F_t \geq -\eta$. The other negative terms in (8.16) are $O(\eta)$, and so is the exponential error of [Lemma 8.3.3](#), since $\sigma^2 t \leq \eta^2$. Thus $d_\eta \leq C\eta$ on this interval. At points where $\chi(ax) = 0$, the smooth nonnegative function χ has a minimum, so $\chi'(ax) = 0$ and directly

$$Q[W] = \mu - \frac{\mu^2}{1 - \eta + h} > 0,$$

since $\mu \leq \mu(a^{-1}) < 1 - \eta$ for small η .

Step 3: the interval $[a^{-1}, b]$. Here the formulas simplify to

$$\sigma = 2aq, \quad \sigma_x = -\kappa/\eta, \quad dx = -\frac{dq}{a} = \sqrt{\frac{\eta}{2\kappa}} \frac{dt}{tq}. \tag{8.17}$$

For $t \leq 1$, [Lemma 8.3.3](#) and (8.16) give

$$d_\eta(x) \leq 2\eta + 2\kappa q^2 t + C\kappa \exp\left(-\frac{\eta}{C\kappa q^2 t}\right). \tag{8.18}$$

Indeed, $-\eta\sigma^2 t = -2\kappa q^2 t$ and $\sigma_x t F_t = -\kappa t k_t + \kappa t$; these are the two terms for which the scale was chosen. When $t \geq 1$, we insert the exponential derivative estimates (8.9) directly in the definition of Q . The denominator stays above $1 - \eta$, and the chain rule gives

$$d_\eta(x) \leq C\kappa q^2 t^2 e^{-t/4}. \tag{8.19}$$

The perturbing derivatives are bounded by constants times $\eta e^{-t/4}$, $\eta\sigma t e^{-t/4}$ and $\eta[(|\sigma_x| + \sigma^2)t + \sigma^2 t^2]e^{-t/4}$. Since $q, t \geq 1$ here, each is bounded by a constant times the right side of (8.19). Since $1 + W_{w\bar{w}} \geq 1 - \eta$, subtracting the two quotients gives

$$|Q[W] - Q[0]| \leq |W_{xx}| + C(|W_{x\bar{w}}| + |W_{x\bar{w}}|^2 + |W_{w\bar{w}}|).$$

The square of the mixed derivative is at most $C\kappa\eta q^2 t^2 e^{-t/2}$, so it satisfies the same bound. Since $Q[0] > 0$, this proves (8.19).

Step 4: integration of the negative part. The constant 2η and the initial interval contribute $O(\eta b) = o(1)$, by (8.13). In the small-time region, $q \geq \sqrt{L}$ and $t = \eta^{-1}e^{-q^2}$. Therefore

$$\int 2\kappa q^2 t \, dx \leq \frac{2\kappa}{a\eta} \int_{\sqrt{L}}^{\infty} q^2 e^{-q^2} \, dq \leq C\sqrt{\eta L} = o(1).$$

For the exponential term the integral is at most

$$\frac{C\kappa}{a} \int_{\sqrt{L}}^{q_0} \exp\left(-\frac{\eta^2 e^{q^2}}{C\kappa q^2}\right) \, dq.$$

The interval $[\sqrt{L}, 2\sqrt{L}]$ has length $O(\sqrt{L})$. For $q \geq 2\sqrt{L}$ and sufficiently small η , $\eta^2 e^{q^2}/q^2 \geq e^{q^2/4}$. The integrand on this remaining interval is bounded by $\exp(-e^{q^2/4}/(C\kappa))$, which is integrable on $[1, +\infty)$. The prefactor is $O(\sqrt{\eta})$, and the initial interval contributes $O(\sqrt{\eta L})$, so the full expression is $o(1)$. In the large-time region, (8.17) gives

$$\int d_{\eta}(x) \, dx \leq C\sqrt{\eta} \int_1^{1/(e\eta)} q t e^{-t/4} \, dt \leq C\sqrt{\eta L} \int_1^{\infty} t e^{-t/4} \, dt = o(1).$$

This proves the integral assertion on $[0, b]$.

Step 5: the radial slope. The negative part of W_x is uniformly small as well. For $t \leq 1$, we have $F_t \geq -\eta$ and $0 \leq \sigma \leq 2aq$, so

$$\max\{-W_x, 0\} \leq \sqrt{2\kappa\eta} t \sqrt{\log \frac{1}{\eta t}} \leq C\sqrt{\eta L}.$$

The last inequality follows because $t\sqrt{L + \log(1/t)}$ is increasing on $(0, 1]$ when $L > 1$. For $t \geq 1$ and $q \geq 1$, use $|W_x| \leq C\sqrt{\eta} q t e^{-t/4}$ and $q \leq \sqrt{L}$.

Step 6: the ends. It remains to consider the two ends, including the cutoff region. If $b \leq x \leq x_*$, then $0 \leq q \leq 1$ and $1/(e\eta) \leq t \leq 1/\eta$. The derivatives of the cutoffs and scale have at most polynomial growth in η^{-1} . Thus (8.9) implies

$$\sup_w (|W_x| + |Q[W] - Q[0]|) \leq C e^{-1/(5e\eta)}.$$

But $Q[0] = \mu(1 - \mu) \geq e^{-x_*}/4$ on this interval, and (8.13) shows that the error is $o(e^{-x_*})$. Hence $Q[W] > 0$ there. For $x \geq x_*$, $W = 0$ and positivity is immediate. For $x \leq 0$, $W_x = 0$ and

$$Q[W] \geq \mu \left(1 - \frac{\mu}{1-\eta} \right) > 0,$$

since $\mu \leq 1/2$. On $[-2, -1]$, the bounds $1/9 \leq \mu \leq 3/10$ and $1 - \eta \geq 9/10$ give $Q[W] \geq 2/27$. Finally, $Q[W]$ is continuous, with positive denominator, so the maximum of its negative part over the compact fiber E is continuous in x . This proves the assertions about support and continuity, and completes the proof. $\square$

8.5 A base correction and unbounded mass

Adding a function of x alone changes $Q[W]$ by its second derivative and leaves the vertical energy unchanged. The integral bound for d_η lets us choose this second derivative larger than d_η and compensate its integral on an interval where $Q[W]$ is uniformly positive. The correction has small first derivative, so the remaining horizontal coefficient stays positive as well.

Proof (of Theorem 8.0.1) Choose a smooth function $r_\eta \geq 0$ supported in $(-1/2, b + 1/2)$ with

$$r_\eta > d_\eta \text{ on } [0, b], \quad m_\eta := \int_{\mathbb{R}} r_\eta \, dx \leq \int_{\mathbb{R}} d_\eta \, dx + \eta = o(1).$$

Such a majorant exists by uniform approximation of the compactly supported continuous function d_η , followed by adding a positive bump on $[0, b]$; for each fixed η the approximation error can be chosen small enough for the integral bound. Fix a smooth $\psi \geq 0$ supported in $(-2, -1)$ with integral one and set

$$g_\eta(x) = \int_{-\infty}^x (x-s)(r_\eta(s) - m_\eta\psi(s)) \, ds, \quad V_\eta = W + g_\eta.$$

The negative part of g_η'' lies to the left of its positive part, and their integrals agree. Consequently,

$$-m_\eta \leq g_\eta' \leq 0, \quad g_\eta' = 0 \text{ for } x \leq -2 \text{ and for } x \geq b + 1/2.$$

Thus g_η vanishes for $x \leq -2$ and is constant for $x \geq b + 1/2$, and V_η has the properties at the two ends required for smooth extension to X .

Since g_η is independent of w , the Schur complement changes by exactly its second derivative:

$$Q[V_\eta] = Q[W] + r_\eta - m_\eta\psi.$$

This is positive on $[0, b]$ because $r_\eta > d_\eta$ there. On $(-2, -1)$ it is at least $2/27 - m_\eta\|\psi\|_\infty > 0$ for small η . Elsewhere $Q[W] > 0$, $\psi = 0$ and $r_\eta \geq 0$. The vertical coefficient remains above $1 - \eta$ by (8.14). For the remaining coefficient, if $x \leq -2$, both W_x and g_η' vanish; if $-2 \leq x \leq 0$, then $W_x = 0$ and $\mu \geq \mu(-2) > 0$, while $|g_\eta'| \leq m_\eta = o(1)$; and if $x \geq 0$, then $\mu \geq 1/2$ and $W_x \geq -o(1)$. In all cases

$\mu + (V_\eta)_x > 0$ for sufficiently small η . Therefore Lemma 8.2.1 gives $\omega + \text{dd}^c V_\eta > 0$ on X .

On the fixed ball $B = \{|\xi|^2 < e^{-3}\} \Subset U_0$, one has $V_\eta = F_\eta(\varepsilon, w)$, including at $\xi = 0$. Thus

$$\int_{\pi^{-1}(y)} |(V_\eta)_w|^2 dA_E = 2\eta^2 \log(1/\varepsilon) + O(\eta^2) = 2\log(1/\eta) + O(\eta^2) \longrightarrow +\infty$$

uniformly for $y \in B$. Since $\int_B \omega_{\text{FS}}^2 > 0$, the mass identity (8.2) shows that $\int_X (\omega + \text{dd}^c V_\eta)^3 \rightarrow +\infty$, and the theorem follows by taking $V_j = V_{\eta_j}$ along any sequence $\eta_j \downarrow 0$. $\square$

8.6 Minimum mass and fiber averaging

Averaging along the elliptic fibers removes the variation measured by (8.2). The Poincaré inequality on the fibers bounds the distance from a potential to its average by the excess mass. Bounded regularization preserves this inequality, which therefore identifies all bounded potentials of minimal mass and shows that potentials of almost minimal mass are close to them.

Let E act on X by scalar multiplication: $\tau_a[z] = [e^a z]$ for $a \in E$. The action preserves α , β and ω , and dA_E is the Haar probability measure of E . For a bounded Borel function $u : X \rightarrow \mathbb{R}$, set

$$dv = \frac{\omega^3}{6} = \frac{1}{2} \alpha^2 \wedge \beta, \quad Au(p) = \int_E u(\tau_a(p)) dA_E(a) \quad (p \in X).$$

Thus Au is constant on each fiber, and v is the probability measure whose disintegration along π has fiber measures dA_E and base measure ω_{FS}^2 .

Proposition 8.6.1 *For every $u \in \text{PSH}(X, \omega) \cap L^\infty(X)$, the average Au is the pullback of a bounded ω_{FS} -plurisubharmonic function on $\mathbb{P}^2$, and*

$$\|u - Au\|_{L^2(X, v)}^2 \leq \frac{2}{3} \left(\int_X (\omega + \text{dd}^c u)^3 - 6 \right). \quad (8.20)$$

The coefficient 2/3 is optimal, even for smooth u with $\omega + \text{dd}^c u > 0$. Moreover,

$$\int_X (\omega + \text{dd}^c u)^3 = 6 \iff u = \pi^* v \text{ for some } v \in \text{PSH}(\mathbb{P}^2, \omega_{\text{FS}}) \cap L^\infty(\mathbb{P}^2).$$

Proof First suppose that u is smooth and $\omega + \text{dd}^c u > 0$. Averaging the positive forms $\tau_a^*(\omega + \text{dd}^c u)$ gives $\omega + \text{dd}^c Au > 0$. Since Au is smooth and constant on the fibers, $Au = \pi^* v$ for a smooth function v on $\mathbb{P}^2$. At each point, the kernel of ∂s maps isomorphically onto the tangent space of the base, and β vanishes on it. Restricting $\omega + \text{dd}^c Au = \pi^*(\omega_{\text{FS}} + \text{dd}^c v) + \beta$ to this kernel therefore shows that $\omega_{\text{FS}} + \text{dd}^c v > 0$.

For a smooth function $f : E \rightarrow \mathbb{R}$, the nonconstant Fourier characters in (8.5), indexed by $(p, q) \in \mathbb{Z}^2 \setminus \{(0, 0)\}$, have eigenvalues $\pi^2 p^2 + q^2/4 \geq 1/4$ for $-\partial_w \partial_{\bar{w}}$. Parseval's identity therefore gives

$$\int_E \left| f - \int_E f \, dA_E \right|^2 dA_E \leq 4 \int_E |f_w|^2 dA_E.$$

Applying this inequality on every fiber, integrating against ω_{FS}^2 and using the mass identity (8.2), we obtain (8.20).

For bounded u , choose uniformly bounded smooth functions $u_j \downarrow u$ with $\omega + \text{dd}^c u_j > 0$ by Theorem 1.11.1. Their averages decrease pointwise to Au by dominated convergence. The corresponding smooth base potentials v_j decrease to a bounded ω_{FS} -plurisubharmonic function v , so $Au = \pi^* v$. Dominated convergence gives $u_j \rightarrow u$ and $Au_j \rightarrow Au$ in $L^2(X, \nu)$, while bounded Bedford–Taylor continuity gives convergence of the total masses. Thus (8.20) passes to u .

If the mass is 6, the inequality gives $u = Au$ almost everywhere. Since both functions are bounded and quasi-plurisubharmonic, Lemma 1.3.4 gives equality everywhere. Conversely, if $u = \pi^* v$ with bounded $v \in \text{PSH}(\mathbb{P}^2, \omega_{\text{FS}})$, choose smooth $v_j \downarrow v$ with $\omega_{\text{FS}} + \text{dd}^c v_j > 0$ by Theorem 1.11.1. The pullbacks decrease to u and are uniformly bounded. They are strictly ω -plurisubharmonic because the base forms are positive and β is positive on the vertical line. Their vertical derivatives vanish, so (8.2) gives mass 6 for each of them. Bounded Bedford–Taylor continuity gives the same mass for u .

It remains to prove that the constant $2/3$ is optimal. Choose a nonzero real $\rho \in C_c^\infty(U_0)$. For $\delta \in \mathbb{R}$, the function

$$u(\xi, w) = \delta \rho(\xi) \cos(\text{Im } w)$$

extends by zero to a smooth function on X . For sufficiently small nonzero real δ , it satisfies $\omega + \text{dd}^c u > 0$. Its fiber average is zero, and its only fiber frequencies are $(p, q) = (0, \pm 1)$, with eigenvalue $1/4$. Hence equality holds in the fiber inequality, and therefore in (8.20), with nonzero left-hand side. No smaller coefficient can hold. $\square$

Corollary 8.6.1 *The Hopf metric satisfies*

$$v_-(\omega) = 6, \quad v_+(\omega) = +\infty.$$

Proof The lower bound $v_-(\omega) \geq 6$ follows from (8.20), and it is attained by constants. Theorem 8.0.1 gives $v_+(\omega) = +\infty$. $\square$

In particular, for any sequence of bounded potentials whose masses tend to 6, the differences from their fiber averages tend to zero in $L^2(X, \nu)$. This controls only the variation along the fibers; the averaged potentials can still be arbitrary bounded potentials on the base.

For nonpositive $u \in \text{PSH}(X, \omega)$ on this threefold, Theorem 7.3.1 gives finite damped measures for the weight $(1 - u)^{-1} [\log(e - u)]^{-a}$, $a > 1$, at the threshold

$r_3 = 1$, with uniform tails and capacity continuity. We do not know the optimal damping rate on this threefold.

8.7 Limits of shrinking smooth potentials

When the bounded mass property fails, [Corollary 7.5.1](#) produces smooth potentials converging to zero whose Monge–Ampère measures keep an excess mass in the limit. On the Hopf threefold we can determine exactly which excess measures occur: they are the lifts of arbitrary base measures by the fiber probability measures. The proof combines the intermediate currents of [Proposition 7.5.1](#) with averaging over the automorphism group.

We keep the Hopf threefold X , its projection $\pi : X \rightarrow \mathbb{P}^2$, and the forms $\omega = \alpha + \beta$ of the previous sections. For $p \in \mathbb{P}^2$, let h_p be the Haar probability measure on the elliptic fiber $\pi^{-1}(p)$, that is, the measure dA_E transported by the action of E . For a finite positive measure μ on the base, define its *fiberwise lift* $\mathcal{L}\mu$ by

$$\int_X \varphi d\mathcal{L}\mu = \int_{\mathbb{P}^2} \left(\int_{\pi^{-1}(p)} \varphi dh_p \right) d\mu(p), \quad \varphi \in C(X).$$

Since fiber integrals of continuous functions are continuous in p , the map $\mathcal{L}$ is weakly continuous. The normalization $\int_{\pi^{-1}(p)} \beta = 2$ gives

$$\mathcal{L}\mu = \frac{1}{2}\beta \wedge \pi^*\mu, \quad \mathcal{L}(\omega_{\text{FS}}^2) = \frac{1}{6}\omega^3. \quad (8.21)$$

Here $\pi^*\mu$ denotes the pullback of a top-degree current by the submersion π ; locally it is the base measure with constant coefficients in the fiber directions.

For a Hermitian form Ω on X , put

$$M_\Omega(f) = \int_X (\Omega + dd^c f)^3, \quad V_\Omega = \int_X \Omega^3$$

for smooth real f , and let b be a real number. A positive measure σ on X is called a *shrinking defect* for (Ω, b) if, for every sequence $0 < \varepsilon_j < 1$ tending to zero, there are smooth $U_j \in \text{PSH}(X, \Omega)$ and numbers $0 < r_j < \varepsilon_j$ such that

$$\sup_X U_j = 0, \quad w_j = r_j U_j, \quad M_\Omega(w_j) = b, \quad (\Omega + dd^c w_j)^3 \rightharpoonup \Omega^3 + \sigma. \quad (8.22)$$

Here weak convergence means convergence against every continuous function on X . We first classify the shrinking defects for the metric ω , for which $V_\omega = 6$; we then write $m = b - 6 > 0$. Afterwards we pass to an arbitrary Hermitian form.

8.7.1 Positive quadratic measures

The mass formula of [Proposition 8.1.1](#) gives

$$M_\omega(\lambda f) - 6 = \lambda^2(M_\omega(f) - 6)$$

for every smooth real f and real λ . To use this scalar identity in a weak limit, we also need a positive measure that represents the quadratic term.

Lemma 8.7.1 *Let f be smooth, $0 < t < 1$, and $\text{dd}^c f \geq -t\omega$. Set $H = \text{dd}^c f + t\omega$, $d = M_\omega(f) - 6$, and $\nu = 3\omega \wedge H^2$. Then $d \geq 0$ and*

$$\begin{aligned} \int_X \omega^2 \wedge H &= 6t, & \int_X \omega \wedge H^2 &= d/3 + 6t^2, & \int_X H^3 &= td + 6t^3, \\ \|(\omega + \text{dd}^c f)^3 - \omega^3 - \nu\|_{\text{TV}} &\leq 36t + 2td + 24t^3. \end{aligned}$$

Proof The Gauduchon identity $\text{dd}^c \omega^2 = 0$ gives $\int_X \omega^2 \wedge \text{dd}^c f = 0$, and Stokes' formula gives $\int_X (\text{dd}^c f)^3 = 0$. Expanding the three integrals with these identities proves the asserted values, and [Proposition 8.1.1](#) gives $d \geq 0$. The identity of measures

$$(\omega + \text{dd}^c f)^3 = (1-t)^3 \omega^3 + 3(1-t)^2 \omega^2 \wedge H + (1-t)\nu + H^3$$

has four positive terms. After subtracting $\omega^3 + \nu$, the total masses of the remaining terms bound the total variation by $18t + 18t + t(d + 18t^2) + td + 6t^3$, as asserted. $\square$

8.7.2 Orbital mixtures

Averaging a shrinking defect over automorphisms of X produces new shrinking defects. The compact group $G = U(3) \times (\mathbb{R}/\mathbb{Z})$ acts transitively on X by the holomorphic maps $g[z] = [e^t A z]$, $g = (A, t)$, and preserves ω . Let h_G be its Haar probability measure. For a probability measure ρ on G and a finite measure σ on X , write

$$\mathcal{A}_\rho \sigma = \int_G g^* \sigma \, d\rho(g).$$

Here the pullback of a measure is defined by $\int_X \varphi \, d(g^* \sigma) = \int_X \varphi \circ g^{-1} \, d\sigma$. In particular, transitivity gives

$$\int_G g^* \zeta \, dh_G(g) = \frac{\zeta(X)}{6} \omega^3$$

for every finite measure ζ on X .

Proposition 8.7.1 *If σ is a shrinking defect for $(\omega, 6 + m)$, then so is $\mathcal{A}_\rho \sigma$ for every probability measure ρ on G .*

Proof Fix a sequence ε_j as in the definition. Take a sequence $f_k = t_k u_k$ realizing σ as in (8.22), so that f_k has mass $6 + m$, and put $H_k = \text{dd}^c f_k + t_k \omega$. By Lemma 8.7.1, the positive measures $\nu_k = 3\omega \wedge H_k^2$ have masses $m + 18t_k^2$ and converge weakly to σ .

The idea is to replace f_k by a normalized sum of N random translates. First suppose that ρ has density at most L relative to h_G . Choose N independent random group elements $g_1, \dots, g_N$ with law ρ , and set

$$W = N^{-1/2} \sum_{a=1}^N f_k \circ g_a, \quad \tau = t_k \sqrt{N}, \quad K = \text{dd}^c W + \tau \omega = N^{-1/2} \sum_{a=1}^N g_a^* H_k \geq 0.$$

The quadratic measure of W is

$$3\omega \wedge K^2 = D + C, \quad D = N^{-1} \sum_{a=1}^N g_a^* \nu_k, \quad C = \frac{6}{N} \sum_{a < c} \omega \wedge g_a^* H_k \wedge g_c^* H_k \geq 0.$$

Averaging $u_k \circ g$ against h_G gives a constant, hence $\int_G g^* H_k \, dh_G = t_k \omega$. Consequently $B = \int_G g^* H_k \, d\rho \leq L t_k \omega$, and independence gives

$$\mathbb{E}[C(X)] = 3(N-1) \int_X \omega \wedge B^2 \leq 18(N-1) L^2 t_k^2.$$

For any real $\varphi \in C(X)$ with $\|\varphi\|_\infty \leq 1$, the variance of $D(\varphi)$ is at most $(m + 18t_k^2)^2 / N$.

For general ρ , convolve it with the normalized restrictions of h_G to shrinking neighborhoods of the identity, which have positive Haar measure. This gives probability measures $\rho_j \rightarrow \rho$ with bounded densities L_j . Fix a countable dense set (φ_l) in the real unit ball of $C(X)$ and numbers $0 < \delta_j < \min(1, m/4)$ tending to zero. Choose N_j large enough that

$$\frac{j(m+18)^2}{N_j \delta_j^2} < \frac{1}{4}.$$

Next choose k_j large enough that $t_{k_j} < 1$, $\tau_j = t_{k_j} \sqrt{N_j} < \min(\varepsilon_j/4, 1/j, 1/4)$, $18N_j t_{k_j}^2 < m/4$, and the expected cross-term mass is less than $\delta_j/4$. Chebyshev's inequality for the first j test functions and Markov's inequality for $C(X)$ show that some choice of N_j group elements satisfies

$$|D_j(\varphi_l) - (\mathcal{A}_{\rho_j} \nu_{k_j})(\varphi_l)| < \delta_j \quad (l \leq j), \quad C_j(X) < \delta_j.$$

We may also arrange $k_j \rightarrow \infty$. For each fixed test function φ , the family $\{\varphi \circ g^{-1} : g \in G\}$ is compact in $C(X)$, so a finite uniform net and the bounded masses of ν_k show that $\int \varphi \circ g^{-1} \, d\nu_k \rightarrow \int \varphi \circ g^{-1} \, d\sigma$ uniformly in g . It follows that $\mathcal{A}_{\rho_j} \nu_{k_j} \rightarrow \mathcal{A}_\rho \sigma$. The dense test functions and the bounded masses now imply $D_j \rightarrow \mathcal{A}_\rho \sigma$, while $C_j \rightarrow 0$ in total variation.

By the integral identity of [Lemma 8.7.1](#),

$$d_j = M_\omega(W_j) - 6 = m + C_j(X) - 18(N_j - 1)t_{k_j}^2 \longrightarrow m, \quad d_j > 3m/4.$$

Put $\lambda_j = \sqrt{m/d_j}$, so $\lambda_j \rightarrow 1$ and $\lambda_j < 2$. The average $a_j = N_j^{-1} \sum_a u_{k_j} \circ g_a$ is smooth and ω -plurisubharmonic. With

$$U_j = a_j - \sup_X a_j, \quad r_j = \lambda_j \tau_j < \varepsilon_j,$$

the potential $r_j U_j$ differs from $\lambda_j W_j$ by a constant and has exact mass $6+m$. Its positive quadratic measure is $\lambda_j^2(D_j + C_j)$. The total-variation estimate of [Lemma 8.7.1](#), with parameter r_j , proves the required weak limit. $\square$

Since $v_+(\omega) = +\infty$, [Corollary 7.5.1](#) gives a sequence with some defect of mass m . Passing to a further subsequence meets any prescribed bounds ε_j without changing the defect, so a shrinking defect of mass m exists. Applying [Proposition 8.7.1](#) with $\rho = h_G$ shows that $(m/6)\omega^3$ is a shrinking defect. In particular, the excess mass can persist as a smooth limiting density.

8.7.3 Fiber measures

The intermediate currents force every shrinking defect to be a lift of a base measure, and the automorphisms of X realize all such lifts.

Lemma 8.7.2 *Let $f_j = t_j u_j$, where $u_j \in \text{PSH}(X, \omega)$ are smooth, $\sup_X u_j = 0$ and $0 < t_j \rightarrow 0$. Suppose that $M_\omega(f_j) = 6 + m$ and $(\omega + \text{dd}^c f_j)^3 \rightarrow \omega^3 + \sigma$. Then there is a unique positive measure μ on $\mathbb{P}^2$, of mass m , such that*

$$\sigma = \mathcal{L}\mu, \quad (\text{dd}^c f_j + t_j \omega)^2 \rightarrow \frac{1}{6} \pi^* \mu.$$

Proof Put $H_j = \text{dd}^c f_j + t_j \omega$. By [Proposition 7.5.1](#), applied with $h = \omega$ and $n = 3$, every convergent subsequence of H_j^2 has a positive closed limit K with $\sigma = 3\omega \wedge K$; moreover $\alpha \wedge K = 0$, because α is closed and semipositive, so that $\alpha \wedge K$ is a positive measure with $\int_X \alpha \wedge K = 0$. In holomorphic coordinates (ξ_1, ξ_2, w) on a local trivialization of the elliptic bundle, the coefficient matrix of K on the three exterior pairs is positive semidefinite as a matrix of measures. To see this directly, note that positivity of the matrices of H_j^2 passes to the limit when they are tested against constant vectors, and take Radon–Nikodym derivatives with respect to the diagonal trace. Since α is strictly positive in the horizontal directions, the identity $\alpha \wedge K = 0$ makes both diagonal entries containing dw vanish. Positivity then makes their rows and columns vanish, so only the horizontal top-degree coefficient remains.

Since K is closed, both real fiber derivatives of that coefficient vanish in the sense of distributions. Testing against a compactly supported base function times a nonconstant Fourier mode on $E = \mathbb{C}/(\mathbb{Z} + 2\pi i\mathbb{Z})$ shows that every such mode

vanishes. By density of trigonometric polynomials in $C(E)$, the coefficient is a base measure times the constant fiber area. Changes of bundle coordinates translate w by a holomorphic function of the base and preserve that area. Thus $K = \pi^* \tau$ for a positive measure τ on $\mathbb{P}^2$.

Since $\alpha \wedge K = 0$, (8.21) gives $\sigma = 3\beta \wedge \pi^* \tau = \mathcal{L}(6\tau)$. Therefore $\mu = 6\tau = \pi_* \sigma$ is uniquely determined by σ , and it has mass m . In particular, every subsequential limit of H_j^2 is the same, which proves convergence of the entire sequence. $\square$

Lemma 8.7.3 *For every $p \in \mathbb{P}^2$, the measure mh_p is a shrinking defect for $(\omega, 6+m)$.*

Proof Start with smooth $f_j = t_j u_j$ realizing the shrinking defect $(m/6)\omega^3 = \mathcal{L}(m\omega_{\text{FS}}^2)$, and put $H_j = \text{dd}^c f_j + t_j \omega$. By Lemma 8.7.2, $H_j^2 \rightarrow (m/6)\alpha^2$, while H_j has trace mass $O(t_j)$. Fix $A \in GL(3, \mathbb{C})$, regarded as an automorphism of X , and let a be the induced projective transformation of $\mathbb{P}^2$. Choose $C_A \geq 1$ with $A^* \omega \leq C_A \omega$, and put

$$R_A = C_A \omega - A^* \omega \geq 0, \quad H_j^A = \text{dd}^c(f_j \circ A) + C_A t_j \omega = A^* H_j + t_j R_A.$$

For this fixed A , the trace mass of $A^* H_j$ is $O_A(t_j)$, and the positive difference $(H_j^A)^2 - A^*(H_j^2)$ has trace mass $O_A(t_j^2)$. Since $\alpha = \pi^* \omega_{\text{FS}}$, it follows that

$$(H_j^A)^2 \rightarrow \frac{m}{6} \pi^*(a^* \omega_{\text{FS}}^2), \quad 3\omega \wedge (H_j^A)^2 \rightarrow \mathcal{L}(ma^* \omega_{\text{FS}}^2).$$

The limiting measure has mass m , so the integral identity of Lemma 8.7.1, applied with the parameter $C_A t_j$, gives $d_j^A = M_\omega(f_j \circ A) - 6 \rightarrow m$. For large j , multiply $f_j \circ A$ by $\sqrt{m/d_j^A} \rightarrow 1$. The mass is then exactly $6+m$, and the weak limit is unchanged. The underlying normalized potential is $u_j \circ A/C_A \in \text{PSH}(X, \omega)$, with parameter $C_A t_j \sqrt{m/d_j^A} \rightarrow 0$. The total-variation estimate of Lemma 8.7.1 therefore shows that $\mathcal{L}(ma^* \omega_{\text{FS}}^2)$ is a shrinking defect; any prescribed bounds ε_j are met by passing to a sufficiently late subsequence.

Now take $A_l = \text{diag}(R_l^{-1}, 1, 1)$, $R_l \rightarrow +\infty$. Since

$$a_l^* \omega_{\text{FS}}^2 = (a_l^{-1})_* \omega_{\text{FS}}^2,$$

and $a_l^{-1}[q_0 : q_1 : q_2] = [R_l q_0 : q_1 : q_2] \rightarrow [1 : 0 : 0]$ outside the hyperplane $\{q_0 = 0\}$, which has zero volume, dominated convergence gives $a_l^* \omega_{\text{FS}}^2 \rightarrow \delta_{[1:0:0]}$. By weak continuity of $\mathcal{L}$, the shrinking defects $\mathcal{L}(ma_l^* \omega_{\text{FS}}^2)$ converge to $mh_{[1:0:0]}$. For each l , choose one corrected potential for A_l , sufficiently late in its sequence that its parameter is less than ε_l and its measure differs from the corresponding limit by less than $1/l$ on the first l functions of a fixed dense sequence of test functions. This diagonal sequence has the exact mass $6+m$ and the limit $\omega^3 + mh_{[1:0:0]}$. Unitary automorphisms move this fiber to any prescribed fiber. $\square$

Theorem 8.7.1 *For $b > 6$, the shrinking defects for (ω, b) are exactly $\mathcal{L}\mu$, where μ ranges over all positive measures on $\mathbb{P}^2$ of mass $b-6$. Each such defect has support*

$\pi^{-1}(\text{supp } \mu)$ and has no point atoms. It charges no pluripolar sets if and only if μ charges no pluripolar sets on $\mathbb{P}^2$.

Proof Put $m = b - 6$. Necessity follows from [Lemma 8.7.2](#). Finite convex combinations of the measures mh_p are shrinking defects by [Lemma 8.7.3](#) and [Proposition 8.7.1](#), the latter applied to an atomic measure ρ supported on unitary maps that move a fixed fiber to the desired fibers. Approximate an arbitrary base measure of mass m by finite atomic measures of the same mass, using finite partitions of diameter tending to zero. Weak continuity of $\mathcal{L}$ and the diagonal choice on dense test functions used in the preceding proof give a realizing sequence for every prescribed sequence ε_j .

Every nonempty open subset of a fiber has positive Haar measure. Local trivializations therefore show that $\mathcal{L}\mu$ has support $\pi^{-1}(\text{supp } \mu)$, and the fiber measures have no point atoms. If B is a pluripolar subset of the base, local plurisubharmonic functions whose pole sets contain B pull back by the submersion to such functions on X . Hence $\pi^{-1}(B)$ is pluripolar, and $\mathcal{L}\mu(\pi^{-1}(B)) = \mu(B)$; thus $\mathcal{L}\mu$ charges a pluripolar set whenever μ does.

Conversely, suppose that μ charges no pluripolar subset of the base. Cover a pluripolar set in X by countably many local product charts, each carrying a plurisubharmonic function $q(\xi, w) \not\equiv -\infty$ whose pole set contains the part of the set in that chart. For a relatively compact disk D in the fiber direction, the function

$$F(\xi) = \frac{1}{|D|} \int_D q(\xi, w) dA(w)$$

is plurisubharmonic and not identically $-\infty$ on a smaller base chart. Indeed, local integrability of q and Fubini's theorem show that F is locally integrable, and in particular finite almost everywhere; a common upper bound and the reverse Fatou lemma give upper semicontinuity; and integrating the submean inequalities in the base directions gives the submean property. The restriction of q to a fiber is either subharmonic with a pole set of zero area or identically $-\infty$. The fibers of the second kind lie over the pluripolar set $\{F = -\infty\}$, which has zero μ -measure. Integrating the Haar measures of the fibers against μ therefore shows that each local pole set has zero $\mathcal{L}\mu$ -measure, and the countable cover proves the assertion for this pluripolar set. For arbitrary pluripolar subsets, the same argument applies to Borel pole sets containing them, with outer measure. Similarly, for the first implication, a Borel $\mathcal{L}\mu$ -null set containing $\pi^{-1}(B)$ has a measurable fiber-mass function equal to one on B , which gives the corresponding outer-measure statement. $\square$

For every nonempty closed set $F \subseteq \mathbb{P}^2$, a measure $m \sum_{l \geq 1} 2^{-l} \delta_{p_l}$ carried by a countable dense subset $\{p_l\}$ of F has support F . Thus every closed set of the form $\pi^{-1}(F)$ is the support of a shrinking defect. The fibers themselves are pluripolar in a global sense: for the fiber over $[1 : 0 : 0]$, the function

$$\psi = \log \frac{|z_1|^2 + |z_2|^2}{|z|^2}, \quad \text{dd}^c \psi \geq -\alpha, \quad \omega + \text{dd}^c \psi \geq \beta \geq 0.$$

is ω -plurisubharmonic, and its pole set is exactly that fiber; unitary maps give the other fibers. In particular, for $0 \leq \lambda \leq 1$ and $p \in \mathbb{P}^2$, the measure

$$m\lambda h_p + \frac{m(1-\lambda)}{6}\omega^3$$

is a shrinking defect. It gives mass $m\lambda$ to the pluripolar fiber $\pi^{-1}(p)$, while every pluripolar set has mass at most $m\lambda$. For $0 < \lambda < 1$ its support is all of X , despite this positive mass on a pluripolar set.

8.7.4 Changing the Hermitian metric

For a general Hermitian form, the fiber Haar measures are replaced by the normalized area measures of the form. Let Ω be any Hermitian form on the Hopf threefold X . Its restriction to each elliptic fiber has positive area

$$A_\Omega(p) = \int_{\pi^{-1}(p)} \Omega.$$

These areas depend smoothly on p and are bounded above and below by positive constants. Define the probability measures $h_p^\Omega = \Omega|_{\pi^{-1}(p)} / A_\Omega(p)$ on the fibers, and define the lift $\mathcal{L}_\Omega \mu$ of a finite positive measure μ on $\mathbb{P}^2$ by the formula defining $\mathcal{L}\mu$, with h_p^Ω in place of h_p .

Theorem 8.7.2 *For every Hermitian form Ω on X and every $b > V_\Omega$, the shrinking defects for (Ω, b) are exactly*

$$\mathcal{L}_\Omega \mu, \quad \mu \geq 0, \quad \mu(\mathbb{P}^2) = b - V_\Omega.$$

Their supports are $\pi^{-1}(\text{supp } \mu)$, they have no point atoms, and they charge no pluripolar sets exactly when μ charges no base pluripolar sets. Moreover, $v_+(\Omega) = +\infty$.

Proof Put $m = b - V_\Omega > 0$. For necessity, let σ be a shrinking defect for (Ω, b) . **Proposition 7.5.1**, applied with $h = \Omega$, gives a positive closed limit K of the squares of the intermediate forms with $\sigma = 3\Omega \wedge K$, and $\alpha \wedge K = 0$ as in the proof of **Lemma 8.7.2**. The local coefficient and Fourier argument of that proof gives $K = \pi^* \tau$ for a positive measure τ on $\mathbb{P}^2$. Consequently

$$\sigma = \mathcal{L}_\Omega \mu, \quad \mu = 3A_\Omega \tau = \pi_* \sigma,$$

and μ has mass m .

Conversely, fix such a μ and set $\tau = \mu / (3A_\Omega)$. By **Theorem 8.7.1**, choose a sequence $f_j = t_j u_j$ realizing the shrinking defect $\mathcal{L}(6\tau)$ for ω . The positive forms $H_j = \text{dd}^c f_j + t_j \omega$ have trace mass $O(t_j)$, and $H_j^2 \rightharpoonup \pi^* \tau$ by **Lemma 8.7.2**. Choose $C \geq 1$ with $\omega \leq C\Omega$, and put

$$R = C\Omega - \omega \geq 0, \quad G_j = \text{dd}^c f_j + Ct_j\Omega = H_j + t_j R \geq 0.$$

The trace mass of G_j is $O(t_j)$, and $G_j^2 - H_j^2$ has trace mass $O(t_j^2)$. Thus $G_j^2 \rightharpoonup \pi^*\tau$ and $3\Omega \wedge G_j^2 \rightharpoonup \mathcal{L}_\Omega\mu$.

Unlike ω , the form Ω need not be Gauduchon, so the mass polynomial may have a linear term. Define

$$\ell_j = 3 \int_X \Omega^2 \wedge \text{dd}^c f_j = O(t_j), \quad q_j = 3 \int_X \Omega \wedge (\text{dd}^c f_j)^2 \longrightarrow m.$$

These estimates follow by expanding $\text{dd}^c f_j = G_j - Ct_j\Omega$ and using the preceding trace bounds. Stokes' formula removes the cubic integral, so

$$M_\Omega(\lambda f_j) = V_\Omega + \lambda \ell_j + \lambda^2 q_j.$$

For large j , $q_j > 0$. The positive root

$$\lambda_j = \frac{-\ell_j + \sqrt{\ell_j^2 + 4mq_j}}{2q_j} \longrightarrow 1 \quad (8.23)$$

gives $M_\Omega(\lambda_j f_j) = b$. The normalized function $U_j = u_j/C$ is Ω -plurisubharmonic, and $w_j = \lambda_j f_j = r_j U_j$ with $r_j = \lambda_j Ct_j \rightarrow 0$.

To identify the full weak limit, first note that expanding $G_j = \text{dd}^c f_j + Ct_j\Omega$ gives

$$\int_X G_j^3 = Ct_j q_j + (Ct_j)^2 \ell_j + (Ct_j)^3 V_\Omega = O(t_j).$$

Hence $G_j^3 \rightarrow 0$ in total variation. The positive expansion

$$(\Omega + \text{dd}^c w_j)^3 = (1 - r_j)^3 \Omega^3 + 3(1 - r_j)^2 \lambda_j \Omega^2 \wedge G_j + 3(1 - r_j) \lambda_j^2 \Omega \wedge G_j^2 + \lambda_j^3 G_j^3$$

converges weakly to $\Omega^3 + \mathcal{L}_\Omega\mu$, since the second and fourth terms tend to zero in total variation. Given prescribed bounds ε_j , pass to a sufficiently late subsequence with $r_j < \varepsilon_j$ at every index. This preserves the normalization, the exact mass and the weak limit.

The fiber probabilities h_p^Ω have smooth densities relative to h_p that are bounded above and below by positive constants, uniformly in p . Thus $\mathcal{L}_\Omega\mu$ and $\mathcal{L}\mu$ are bounded by fixed positive multiples of each other, and the assertions about support, point atoms and pluripolar sets follow from [Theorem 8.7.1](#). The global functions with fiber poles also remain available: if $\Omega \geq c\omega$, then $c\psi \in \text{PSH}(X, \Omega)$.

Finally, for smooth $u \in \text{PSH}(X, \omega)$ and $c > 0$ with $\Omega \geq c\omega$,

$$\Omega + \text{dd}^c(cu) \geq c(\omega + \text{dd}^c u), \quad M_\Omega(cu) \geq c^3 M_\omega(u).$$

Since $v_+(\omega) = +\infty$ by [Corollary 8.6.1](#) and the supremum may be computed over smooth potentials ([Proposition 6.5.1](#)), it follows that $v_+(\Omega) = +\infty$. $\square$

The classification uses the elliptic bundle and its automorphisms to realize every admissible base measure. On a general Hermitian manifold, the restrictions on the intermediate currents in [Proposition 7.5.1](#) are still necessary; we do not know whether they are sufficient, or what the support and pluripolar behavior of shrinking defects can be in general.

Part II
Monge–Ampère equations

Chapter 9

Smooth Monge–Ampère equations

Throughout this chapter, ω is a Hermitian form on X and dV is a smooth positive volume form. Given $F \in C^\infty(X, \mathbb{R})$, we seek a smooth real potential u and a scalar $b \in \mathbb{R}$ satisfying

$$\omega_u^n = e^{F+b} dV, \quad \omega_u > 0. \quad (9.1)$$

Here $\omega_u = \omega + dd^c u$, and adding a constant to u does not change the equation. For a closed background, integration determines b from the prescribed density. For a Hermitian background, the total mass can depend on u , so the potential and the scalar must be found together. The adjoint probability measure of [Proposition 4.7.1](#) gives the compatibility condition for the linearized problem. Weighted integration and an estimate for the trace of the complex Hessian give the compactness needed to deform solutions from the background density by the continuity method, and the same adjoint probability governs the variation of b with F .

For $n \geq 2$, prescribing the volume form of a Gauduchon metric requires a different variation of the metric: we deform its $(n-1)$ st power within its Aeppli class. The resulting equation contains first-order torsion terms with a specific matrix structure. This structure makes the second-derivative estimate possible, and a rescaling argument reduces the gradient bound to a Liouville theorem on $\mathbb{C}^n$.

9.1 Scalar bounds and uniqueness

Evaluating the equation at the extrema of the potential bounds the normalization scalar in terms of the prescribed data. Applied to the difference of two solutions, the same argument shows that their scalars agree, and ellipticity then determines the potential up to a constant. The scalar bounds will also give uniform control along the continuity path.

Theorem 9.1.1 (Tosatti–Weinkove) *For every smooth real F , (9.1) has a unique pair $(u, b) \in C^\infty(X, \mathbb{R}) \times \mathbb{R}$ with $\sup_X u = 0$.*

In dimension one, integration determines $e^b = \int_X \omega / \int_X e^F dV$, and the remaining equation $dd^c u = e^{F+b} dV - \omega$ is a Poisson equation whose right-hand side has integral zero, so it has a smooth solution, unique up to a constant; positivity of ω_u is automatic. Thus the theorem holds in that dimension, and we prove it for $n \geq 2$ at the end of [Section 9.5](#).

Proposition 9.1.1 *Every solution of (9.1) satisfies*

$$\inf_X \left(\log \frac{\omega^n}{dV} - F \right) \leq b \leq \sup_X \left(\log \frac{\omega^n}{dV} - F \right).$$

Proof At a maximum point x_+ of u , the real $(1, 1)$ -form $dd^c u$ is nonpositive, so $0 < \omega_u \leq \omega$ there. Hence $\omega_u^n(x_+) \leq \omega^n(x_+)$, and $b \leq \log(\omega^n/dV)(x_+) - F(x_+)$. At a minimum point the reverse argument gives the lower bound. $\square$

When $d\omega = 0$, integration gives the familiar explicit formula

$$b = \log \frac{\int_X \omega^n}{\int_X e^F dV}. \quad (9.2)$$

The same formula holds whenever the mass-invariance criterion of [Theorem 2.2.2](#) is satisfied. In general, integrating the equation gives only

$$e^b = \frac{M_\omega(u)}{\int_X e^F dV},$$

where $M_\omega(u) = \int_X \omega_u^n$ is the mass of [Theorem 2.2.1](#); the numerator depends on the unknown potential.

Proposition 9.1.2 *Suppose (u, b) and (v, c) are smooth solutions of (9.1) with the same F and dV . Then $b = c$ and $u - v$ is constant.*

Proof At a maximum of $u - v$, one has $\omega_u \leq \omega_v$, so the equations give $e^b \leq e^c$. At a minimum one obtains $e^b \geq e^c$. Therefore $b = c$.

Put $h = u - v$ and $\eta_t = \omega_v + t dd^c h = (1 - t)\omega_v + t\omega_u$ for $0 \leq t \leq 1$. These forms are strictly positive. Subtracting the logarithms of the two equations and writing the difference as the integral of its derivative along the segment, we obtain

$$0 = \int_0^1 n \frac{dd^c h \wedge \eta_t^{n-1}}{\eta_t^n} dt.$$

The right-hand side is a linear second-order operator applied to h . Its coefficients are smooth, its principal part is uniformly elliptic on the compact manifold, and it has no zeroth-order term. The strong maximum principle therefore implies that h is constant. $\square$

9.2 The potential bound from weighted integration

We now show that an upper bound for the density controls the normalized potential, following the method of Cherrier. Integrating the equation against e^{-pu} produces a gradient term and mixed weighted masses; a finite recurrence absorbs the latter together with the torsion error. Moser iteration then gives a set of uniformly positive volume near the minimum, and normalized L^1 compactness bounds that minimum. Norms below are computed with respect to the fixed metric ω .

Lemma 9.2.1 *There is a constant C depending on ω such that, for every positive $(1, 1)$ -form η , every smooth real f , every $\delta > 0$, and $0 \leq k \leq n-2$,*

$$|d^c f \wedge d\omega \wedge \eta^k \wedge \omega^{n-k-2}| \leq \frac{C}{\delta} df \wedge d^c f \wedge \eta^k \wedge \omega^{n-k-1} + C\delta \eta^k \wedge \omega^{n-k}.$$

Here the absolute value of a top-degree form is the absolute value of its coefficient relative to the positive volume form ω^n .

Proof At a given point, choose an ω -unitary frame in which η is diagonal, with positive eigenvalues $\lambda_1, \dots, \lambda_n$. Expand η^k as a sum over k -element subsets I of $\{1, \dots, n\}$, with coefficients that are positive dimensional multiples of $\lambda_I = \prod_{i \in I} \lambda_i$. After wedging with $d^c f \wedge d\omega \wedge \omega^{n-k-2}$, each surviving term is a bounded coefficient of $d\omega$ times λ_I times one first derivative f_a with $a \notin I$. Young's inequality bounds its absolute value by

$$C\lambda_I |f_a| \leq (C/\delta)\lambda_I |f_a|^2 + C\delta\lambda_I.$$

The sum of the first terms is bounded by a fixed multiple of the first form on the right of the assertion, whose diagonal expansion consists of the terms $\lambda_I |f_a|^2$ with $a \notin I$. The second form on the right contains all the λ_I . Since there are finitely many indices and $d\omega$ is bounded, the constant C is uniform. $\square$

Lemma 9.2.2 *Suppose u is smooth, $\eta = \omega + dd^c u > 0$, and $\eta^n \leq \Lambda\omega^n$ for a fixed $\Lambda > 0$. There are constants $p_0 \geq 1$ and C depending only on ω and Λ such that*

$$\int_X d(e^{-pu/2}) \wedge d^c(e^{-pu/2}) \wedge \omega^{n-1} \leq Cp \int_X e^{-pu} \omega^n \quad (p \geq p_0).$$

Proof For a fixed real $p \geq 1$, define M_k for $0 \leq k \leq n$ and J_k for $0 \leq k \leq n-1$ by

$$M_k = \int_X e^{-pu} \eta^k \wedge \omega^{n-k}, \quad J_k = \int_X e^{-pu} du \wedge d^c u \wedge \eta^k \wedge \omega^{n-k-1}, \quad J = \sum_{k=0}^{n-1} J_k.$$

All these numbers are nonnegative. The proof first bounds pJ in terms of the masses M_k , and then bounds these masses by a recurrence. Let $T = \sum_{k=0}^{n-1} \eta^k \wedge \omega^{n-k-1}$, so that $\eta^n - \omega^n = dd^c u \wedge T$. Since $d\eta = d\omega$, differentiation gives

$$dT = n \sum_{k=0}^{n-2} \eta^k \wedge \omega^{n-k-2} \wedge d\omega.$$

The sum is empty when $n = 1$. Stokes' theorem gives the exact identity

$$\begin{aligned} \int_X e^{-pu} (\eta^n - \omega^n) &= \int_X e^{-pu} dd^c u \wedge T \\ &= pJ + \int_X e^{-pu} d^c u \wedge dT. \end{aligned}$$

The density assumption bounds the left-hand side above by $(\Lambda + 1)M_0$. Apply [Lemma 9.2.1](#) to the last integral, with $\delta = K/p$ for a sufficiently large fixed K . The contribution proportional to J/δ is then at most $pJ/2$, and after absorbing it we obtain

$$pJ \leq CM_0 + \frac{C}{p} \sum_{k=0}^{n-2} M_k. \quad (9.3)$$

This estimate alone does not suffice, because the mixed weighted masses on the right have not yet been bounded.

For $1 \leq k \leq n-2$, a second integration by parts gives

$$M_k - M_{k-1} = pJ_{k-1} + R_k, \quad R_k = \int_X e^{-pu} d^c u \wedge d(\eta^{k-1} \wedge \omega^{n-k}). \quad (9.4)$$

The derivative in R_k has two terms, with coefficients $k-1$ and $n-k$. Applying the pointwise estimate with $\delta = 1/p$ to each of them, and omitting terms with negative indices, we obtain

$$|R_k| \leq Cp(J_{k-2} + J_{k-1}) + \frac{C}{p}(M_{k-2} + M_{k-1}), \quad M_{-1} = J_{-1} = 0.$$

Consequently, for $p \geq 1$,

$$M_k \leq C(M_{k-1} + M_{k-2} + pJ).$$

Induction over the finitely many values of k proves

$$\sum_{k=0}^{n-2} M_k \leq C(M_0 + pJ).$$

For $n = 2$ this is immediate, and for $n = 1$ the sum is empty. Inserting this bound in (9.3) gives $pJ \leq CM_0 + C'J$. For $p \geq 2C'$ the last term can be absorbed, and $pJ \leq CM_0$.

Finally,

$$\int_X d(e^{-pu/2}) \wedge d^c(e^{-pu/2}) \wedge \omega^{n-1} = \frac{p^2}{4} J_0 \leq \frac{p^2}{4} J \leq CpM_0.$$

This proves the claimed estimate for all $p \geq p_0$. $\square$

Theorem 9.2.1 *For each $\Lambda > 0$ there is C_Λ such that every smooth u with*

$$\omega + \text{dd}^c u > 0, \quad \sup_X u = 0, \quad (\omega + \text{dd}^c u)^n \leq \Lambda \omega^n$$

satisfies $\|u\|_\infty \leq C_\Lambda$.

Proof Let $d\mu = \omega^n / \int_X \omega^n$. The Sobolev inequality for the Riemannian metric of ω gives, for some $\beta > 1$ and every smooth real function w ,

$$\left(\int_X |w|^{2\beta} d\mu \right)^{1/\beta} \leq C \left(\int_X dw \wedge d^c w \wedge \omega^{n-1} + \int_X |w|^2 d\mu \right).$$

We may take $\beta = n/(n-1)$ if $n \geq 2$, and for example $\beta = 2$ if $n = 1$. Choose p_0 as in [Lemma 9.2.2](#). Applying the Sobolev inequality to $w = e^{-pu/2}$ and using that lemma, we obtain, with $Z = e^{-u}$,

$$\|Z\|_{L^{p\beta}(\mu)} \leq (Cp)^{1/p} \|Z\|_{L^p(\mu)} \quad (p \geq p_0).$$

Iterating with $p = p_0 \beta^j$, $j = 0, 1, 2, \dots$, we obtain a bound for $\sup_X Z$; the product of the constants is finite because $\sum_j (1 + \log(p_0 \beta^j)) / (p_0 \beta^j) < \infty$. Hence, for a uniform $C_1 \geq 1$ and $m = \inf_X u$,

$$e^{-p_0 m} \leq C_1 \int_X e^{-p_0 u} d\mu. \quad (9.5)$$

The right-hand side still involves the unknown potential. Divide by $e^{-p_0 m}$ and set $A = p_0^{-1} \log(2C_1)$. The integrand $e^{-p_0(u-m)}$ is at most one everywhere and at most $(2C_1)^{-1}$ outside $S = \{u \leq m + A\}$. Therefore (9.5) implies

$$\mu(S) \geq \frac{1}{2C_1} =: \delta > 0.$$

Since $\sup_X u = 0$, [Theorem 1.4.1](#) gives $\int_X (-u) d\mu \leq C_0$. On S we have $-u \geq -m - A$, so

$$C_0 \geq \int_X (-u) d\mu \geq \delta(-m - A)$$

when $-m \geq A$; otherwise the desired bound is immediate. Thus $-m \leq A + C_0/\delta$, proving the theorem. $\square$

9.3 The linearized equation and smooth dependence

Recall from (4.8) that the linearization of $u \mapsto \log(\omega_u^n/dV)$ at u is $L_u v = n \text{dd}^c v \wedge \omega_u^{n-1}/\omega_u^n$. This operator annihilates constants, and by [Proposition 4.7.1](#) its range

consists of the functions with zero mean under the adjoint probability measure μ_u . Including the scalar b as an unknown removes this obstruction. In dimension one, $\mu_u = \omega_u / \int_X \omega_u$, and the compatibility condition follows from Stokes' theorem.

The normalization $\sup_X u = 0$ is convenient for compactness, but it need not depend differentiably on the data. To differentiate solutions, we use instead the linear normalization

$$\int_X u \, dV = 0.$$

Passing from one normalization to the other only adds a constant to u and leaves b unchanged.

Proposition 9.3.1 *With this linear normalization, the solution (u, b) of (9.1) depends smoothly on F in Hölder spaces, and hence smoothly on the parameters of every smooth finite-dimensional family of smooth data.*

Proof Fix an integer $k \geq 0$ and a real exponent $0 < \alpha < 1$. Consider the map

$$(u, b, F) \mapsto \log \frac{(\omega + \text{dd}^c u)^n}{dV} - F - b$$

on the open set of potentials in $C^{k+2, \alpha}$ with $\omega_u > 0$, restricted to $\int_X u \, dV = 0$. Its derivative in (u, b) is

$$(v, a) \mapsto L_u v - a.$$

Given $h \in C^{k, \alpha}$, integrating $L_u v - a = h$ against μ_u forces $a = -\int_X h \, d\mu_u$. For this value, the equation for v satisfies the compatibility condition of [Proposition 4.7.1](#), and it has a unique solution with zero dV -mean. Schauder estimates show that this inverse is bounded. The implicit function theorem in Banach spaces therefore gives a smooth local solution map around any given solution; this step does not use the global existence theorem. Uniqueness identifies the local maps wherever they overlap, and elliptic regularity allows arbitrary k for smooth data. $\square$

9.4 Second derivatives and ellipticity

The equation controls the product of the eigenvalues of ω_u relative to ω , so an upper bound for their sum gives uniform ellipticity. We obtain this trace bound by completing a square in the differentiated equation. The remaining torsion term is of first order in the trace, and it can be absorbed at the maximum of a suitable function of the trace and the potential.

In holomorphic coordinates $(z^1, \dots, z^n)$, subscripts denote coordinate derivatives, inverse matrices carry upper indices, and repeated indices run from 1 to n . Write

$$\omega = \frac{i}{2\pi} g_{i\bar{j}} \, dz^i \wedge d\bar{z}^j, \quad \omega_u = \frac{i}{2\pi} h_{i\bar{j}} \, dz^i \wedge d\bar{z}^j, \quad h_{i\bar{j}} = g_{i\bar{j}} + u_{i\bar{j}}.$$

For a smooth real function v , set $\Delta_g v = g^{i\bar{j}} v_{i\bar{j}}$ and $\Delta_h v = h^{i\bar{j}} v_{i\bar{j}}$. Thus $\Delta_h = L_u$ and $\Delta_h u = n - \text{tr}_h g$. Write also $|\partial v|_h^2 = h^{i\bar{j}} v_i v_{\bar{j}}$. Let ∇ be the Chern connection of the fixed metric g , with

$$\Gamma_{ik}^p = g^{p\bar{q}} \partial_i g_{k\bar{q}}, \quad T_{ik}^p = \Gamma_{ik}^p - \Gamma_{ki}^p, \quad \tau_k = \sum_i T_{ik}^i.$$

Here T is the torsion of ∇ and τ its trace; all bounds for this connection, its torsion and its curvature depend only on g .

Lemma 9.4.1 *Suppose $h = g + (u_{i\bar{j}}) > 0$, and put*

$$S = \text{tr}_g h, \quad B = \text{tr}_h g, \quad G = \log \frac{\det h}{\det g}.$$

There is C_g such that, at every point where $S \geq 1$,

$$\Delta_h \log S \geq \frac{2}{S^2} \text{Re}(h^{k\bar{q}} \tau_k S_{\bar{q}}) + \frac{\Delta_g G}{S} - C_g B. \quad (9.6)$$

Proof The identity $d\omega_u = d\omega$ is equivalent to

$$\nabla_i h_{k\bar{j}} - \nabla_k h_{i\bar{j}} = T_{ik}^p (g_{p\bar{j}} - h_{p\bar{j}}), \quad (9.7)$$

together with its complex conjugate; this can also be checked directly, since the third derivatives of u cancel.

For tensors with two holomorphic and one antiholomorphic lower index, we use the norm

$$\|A\|^2 = g^{i\bar{\ell}} h^{k\bar{q}} h^{p\bar{j}} A_{ik\bar{j}} \overline{A_{\ell q\bar{p}}}.$$

Set $A_{ik\bar{j}} = \nabla_i h_{k\bar{j}}$ and $D_{ik\bar{j}} = T_{ik}^p h_{p\bar{j}}$. We first claim

$$\Delta_h S = \|A + D\|^2 + \Delta_g G + E, \quad |E| \leq C_g (1 + S) B. \quad (9.8)$$

To prove this, start with $\Delta_h S = h^{i\bar{j}} g^{k\bar{\ell}} \nabla_i \nabla_{\bar{j}} h_{k\bar{\ell}}$. Switch $\bar{j}, \bar{\ell}$ by the conjugate of (9.7), commute $\nabla_i, \nabla_{\bar{\ell}}$, and then switch i, k by (9.7). The terms with a derivative of h are

$$h^{i\bar{j}} g^{k\bar{\ell}} \nabla_{\bar{\ell}} \nabla_k h_{i\bar{j}} - 2 \text{Re}(h^{i\bar{j}} g^{k\bar{\ell}} T_{ik}^p \nabla_{\bar{\ell}} h_{p\bar{j}}).$$

The first switch also produces the term $-h^{i\bar{j}} g^{k\bar{\ell}} \overline{T_{j\bar{\ell}}^q} \nabla_i h_{k\bar{q}}$. Applying (9.7) to it gives one of the two conjugate derivative terms displayed above, together with

$$h^{i\bar{j}} g^{k\bar{\ell}} T_{ik}^p \overline{T_{j\bar{\ell}}^q} (h_{p\bar{q}} - g_{p\bar{q}}).$$

The part of this expression containing $h_{p\bar{q}}$ is $\|D\|^2$. Differentiating the logarithmic determinant twice gives

$$\Delta_g G = h^{i\bar{j}} g^{k\bar{\ell}} \nabla_{\bar{\ell}} \nabla_k h_{i\bar{j}} - \|A\|^2.$$

By the antisymmetry of T , the two remaining derivative terms combine to $2 \operatorname{Re}\langle A, D \rangle$, where $\langle \cdot, \cdot \rangle$ is the inner product of the norm above. These identities give (9.8).

To bound the remainder E explicitly, let

$$C_{i\bar{\ell}k\bar{j}} = (\nabla_i \nabla_{\bar{\ell}} - \nabla_{\bar{\ell}} \nabla_i) h_{k\bar{j}}.$$

The remainder is the contraction by $h^{i\bar{j}} g^{k\bar{\ell}}$ of

$$\begin{aligned} & (\nabla_i \overline{T_{j\bar{\ell}}^q})(g_{k\bar{q}} - h_{k\bar{q}}) + (\nabla_{\bar{\ell}} T_{ik}^p)(g_{p\bar{j}} - h_{p\bar{j}}) \\ & + C_{i\bar{\ell}k\bar{j}} - T_{ik}^p \overline{T_{j\bar{\ell}}^q} g_{p\bar{q}}. \end{aligned}$$

The commutator C is the curvature of ∇ acting linearly on h , as one sees by inserting $\nabla = \partial + \Gamma$ and canceling the derivatives of h . In a g -unitary frame diagonalizing h , every coefficient in this remainder is bounded by $C_g(1+S)$, so the contraction is bounded by $C_g(1+S) \sum_i h^{i\bar{i}} = C_g(1+S)B$, as asserted. In particular, no derivative of h remains in E .

It remains to control the gradient term introduced by the logarithm. Define

$$H_{ik\bar{j}} = h_{i\bar{j}} \frac{S_k}{S}, \quad K = \|A + D - H\|^2 \geq 0.$$

By (9.7),

$$g^{i\bar{\ell}}(A + D)_{ik\bar{\ell}} = S_k + \tau_k.$$

Moreover $\|H\|^2 = |\partial S|_h^2 / S$. Expanding the square therefore gives

$$K = \|A + D\|^2 - \frac{|\partial S|_h^2}{S} - \frac{2}{S} \operatorname{Re}(h^{k\bar{q}} \tau_k S_{\bar{q}}).$$

Combining this with (9.8) and with $\Delta_h \log S = \Delta_h S / S - |\partial S|_h^2 / S^2$, we obtain the exact identity

$$\Delta_h \log S = \frac{K}{S} + \frac{2}{S^2} \operatorname{Re}(h^{k\bar{q}} \tau_k S_{\bar{q}}) + \frac{\Delta_g G}{S} + \frac{E}{S}.$$

Since $K \geq 0$ and $S \geq 1$, and since $E/S \geq -2C_g B$, enlarging the constant proves the lemma. $\square$

Theorem 9.4.1 Fix $D, K > 0$ and a smooth real function G on X . Suppose u is smooth, $\omega_u > 0$, and

$$\operatorname{osc}_X u \leq D, \quad \omega_u^n = e^G \omega^n, \quad |G| \leq K, \quad \Delta_g G \geq -K.$$

There is a constant $C = C(\omega, D, K)$ such that

$$C^{-1}\omega \leq \omega_u \leq C\omega.$$

Proof Use $h = g + (u_{i\bar{j}})$, $S = \operatorname{tr}_g h$, and $B = \operatorname{tr}_h g$ as in Lemma 9.4.1. Write $s = u - \inf_X u + 1$, so that $1 \leq s \leq D + 1$, and consider the maximum of

$$Q = \log S - Au + s^{-1}$$

on X , where $A \geq 1$ will be fixed below. Let x be a maximum point. If $S(x) < 1$, an upper bound for S on X already follows from the oscillation bound and the definition of Q , as at the end of the proof. We may therefore assume $S(x) \geq 1$ and use Lemma 9.4.1.

Since the eigenvalues of h relative to g are positive, $SB \geq n^2$, and hence $\Delta_g G/S \geq -KB/n^2$. Moreover, $\partial Q = 0$ at x gives

$$\frac{S_k}{S} = (A + s^{-2})u_k.$$

Because $|\tau|_h^2 \leq C_g B$, the absolute value of the torsion term is bounded by

$$\begin{aligned} \left| \frac{2}{S^2} \operatorname{Re}(h^{k\bar{q}} \tau_k S_{\bar{q}}) \right| &\leq \frac{C_g(A+1)}{S} \sqrt{B} |\partial u|_h \\ &\leq \frac{|\partial u|_h^2}{s^3} + \frac{C_g(A+1)^2 s^3}{S^2} B. \end{aligned} \tag{9.9}$$

If $S(x)^2 \leq (A+1)^2(D+1)^3$, then $S(x)$ is bounded once A is fixed, and again so is S on X . In the remaining case the coefficient of B in the last term is at most C_g .

On the other hand, direct computation gives

$$\Delta_h Q = \Delta_h \log S + (A + s^{-2})(B - n) + 2s^{-3} |\partial u|_h^2.$$

The trace inequality and (9.9) imply at x

$$0 \geq \Delta_h Q \geq (A - C_g - K/n^2)B - n(A + 1),$$

after a fixed enlargement of C_g . Choosing $A > C_g + K/n^2 + 1$, we conclude that $B(x)$ is bounded. If $\lambda_1, \dots, \lambda_n$ are the eigenvalues of h relative to g , then $\prod_i \lambda_i = e^G$, and for $n \geq 2$

$$S = \sum_i \lambda_i = e^G \sum_i \prod_{j \neq i} \lambda_j^{-1} \leq n e^K B^{n-1}.$$

For $n = 1$, directly $S = e^G$. Thus $S(x)$ is bounded in all cases. For every $y \in X$, the maximality of Q at x gives

$$\log S(y) \leq \log S(x) + A(u(y) - u(x)) + s(x)^{-1} - s(y)^{-1} \leq \log S(x) + AD + 1.$$

This proves $S \leq C$ on X . The lower bound for the determinant then gives $\lambda_i \geq e^{-K} C^{-(n-1)}$, which proves the uniform equivalence. $\square$

Corollary 9.4.1 *Fix ω . For smooth solutions of*

$$(\omega + \text{dd}^c u)^n = e^G \omega^n, \quad \omega + \text{dd}^c u > 0,$$

a uniform C^0 bound for u and uniform bounds for the smooth real logarithmic density G in every C^k norm imply uniform bounds for u in every C^k norm.

Proof **Theorem 9.4.1** gives uniform ellipticity and a bound for $\Delta_g u = S - n$. The linear elliptic $W^{2,p}$ estimates for the fixed operator Δ_g first bound u in $C^{1,\alpha}$ for every $0 < \alpha < 1$. The local Evans–Krylov estimate for the concave logarithmic determinant then gives a uniform $C^{2,\beta}$ bound for some $0 < \beta < 1$. To apply it in its real form, project real symmetric Hessians to their complex Hermitian part and extend the logarithmic determinant concavely from the compact set of positive matrices given by the preceding theorem. The extension is uniformly elliptic on real symmetric matrices because the projection preserves positivity and the trace, so the usual Evans–Krylov theorem applies. Finally, differentiating the equation gives linear uniformly elliptic equations with Hölder coefficients, and Schauder estimates and induction give all higher bounds. No regularity results beyond these standard local elliptic estimates are needed. $\square$

The same conclusion holds for equations $\omega_u^n = e^{au+F} \omega^n$ with a in a fixed bounded interval of nonnegative numbers, u uniformly bounded, and F uniformly bounded in every C^k norm. Indeed, with $G = au + F$,

$$\Delta_g(au + F) = a(S - n) + \Delta_g F \geq -an + \Delta_g F,$$

so **Theorem 9.4.1** applies without any prior bound for derivatives of u . The estimate for the fixed operator Δ_g then gives a $C^{1,\alpha}$ bound, after which the same local regularity and bootstrapping apply.

9.5 The continuity method

We join the background density to the prescribed one by a path of equations. The local inverse of **Proposition 9.3.1** shows that the set of solvable parameters is open. The extremum bound for the scalar, the potential estimate and the derivative estimates give compactness along the path, and uniform ellipticity preserves positivity at a limiting parameter.

Proof (of Theorem 9.1.1) The case $n = 1$ was treated after the statement of the theorem. For $n \geq 2$ put $G = F + \log(dV/\omega^n)$ and consider

$$(\omega + \text{dd}^c u_t)^n = e^{tG+b_t} \omega^n, \quad \sup_X u_t = 0, \quad 0 \leq t \leq 1.$$

At $t = 0$, take $u_0 = 0$ and $b_0 = 0$. The local implicit-function argument in Proposition 9.3.1, with the additive constant temporarily fixed by a linear mean, shows that the set of solvable parameters is open.

At every solvable parameter, Proposition 9.1.1 gives

$$-\sup_X(tG) \leq b_t \leq -\inf_X(tG), \quad e^{tG+b_t} \leq e^{\text{osc}_X G}.$$

The constants b_t are therefore uniformly bounded, and Theorem 9.2.1 bounds u_t in C^0 . By Corollary 9.4.1, the solutions are bounded in every C^k norm. Along any sequence of solvable parameters converging in $[0, 1]$, a subsequence of (u_t, b_t) therefore converges smoothly to a solution; uniform equivalence of the metrics preserves strict positivity, and the supremum normalization passes to the limit. Thus the solvable set is closed. Since it is nonempty, open and closed, connectedness of $[0, 1]$ gives a solution at $t = 1$, and Proposition 9.1.2 gives uniqueness. $\square$

9.6 The smooth exponential equation

When the logarithmic density contains a positive multiple of the potential, the extrema of the potential are bounded directly, and the linearization acquires a negative zeroth-order term. The continuity method then needs neither an additive normalization nor an extra scalar unknown.

Proposition 9.6.1 *Let $\lambda > 0$, let F be smooth, and let v, w be smooth strictly ω -plurisubharmonic functions. If*

$$\omega_v^n \geq e^{\lambda v + F} \omega^n, \quad \omega_w^n \leq e^{\lambda w + F} \omega^n,$$

then $v \leq w$. In particular, two smooth solutions coincide.

Proof Suppose that $v - w$ has a positive maximum at a point x . Then $\omega_v(x) \leq \omega_w(x)$, and taking determinants and applying the two assumptions gives $e^{\lambda v(x) + F(x)} \leq e^{\lambda w(x) + F(x)}$, which contradicts $v(x) > w(x)$. For two solutions, apply the comparison in both orders. $\square$

Theorem 9.6.1 *For every $\lambda > 0$ and every smooth real F , there is a unique smooth u with $\omega_u > 0$ such that*

$$\omega_u^n = e^{\lambda u + F} \omega^n.$$

The solution satisfies

$$-\lambda^{-1} \sup_X F \leq u \leq -\lambda^{-1} \inf_X F.$$

Proof At a minimum of u , the equation gives $\lambda u + F \geq 0$; at a maximum it gives $\lambda u + F \leq 0$. These inequalities prove the stated bounds.

Consider the equations

$$\omega_{u_t}^n = e^{\lambda u_t + tF} \omega^n, \quad 0 \leq t \leq 1.$$

At $t = 0$, $u_0 = 0$ is a solution. The linearization in u is $L_u - \lambda$, whose kernel is zero by the maximum principle. Its Fredholm index is zero: deform its principal coefficients to those of a fixed Laplacian while keeping the negative zeroth-order term; the latter operator is invertible, and the index is constant along this deformation of elliptic operators. Thus $L_u - \lambda$ is an isomorphism between the usual Hölder spaces, with bounded inverse by Schauder theory, and the implicit function theorem proves that the set of solvable parameters is open.

The extremum bounds give $\|u_t\|_\infty \leq \lambda^{-1} \|F\|_\infty$. The semilinear version of [Theorem 9.4.1](#) and [Corollary 9.4.1](#), stated in the remark following that corollary, then gives uniform ellipticity and bounds in every C^k norm. Along any convergent sequence of solvable parameters, a subsequence of the solutions therefore converges smoothly to a strictly positive solution at the limit parameter. This proves closedness, and hence existence at $t = 1$. Uniqueness is [Proposition 9.6.1](#). $\square$

For a fixed smooth real obstacle f on X and a parameter $\beta > 0$, the choice $\lambda = \beta$ and $F = -\beta f$ gives

$$\omega_{u_\beta}^n = e^{\beta(u_\beta - f)} \omega^n.$$

These equations penalize values above the obstacle. In [Proposition 12.1.1](#) we use them to construct the envelope of f and to show that its Monge–Ampère measure is supported on the contact set. The convergence argument there uses only bounded regularization and the comparison just proved.

9.7 Variation of the normalization scalar

Integration against the adjoint probability measure eliminates the derivatives of the potential from the first variation of b . In the second variation, the second derivative of the logarithmic determinant contributes a nonnegative square with a minus sign. This gives concavity of b and identifies the equality case.

Write $b(F)$ for the scalar in [\(9.1\)](#), and use the linear normalization $\int_X u \, dV = 0$. For a smooth family F_t , with t in an open interval $I \subset \mathbb{R}$, write (u_t, b_t) for the corresponding solutions and put $\eta_t = \omega_{u_t}$. By [Proposition 9.3.1](#) these depend smoothly on t ; a dot denotes differentiation in t .

Theorem 9.7.1 *Let $A_t = \eta_t^{-1} \text{dd}^c \dot{u}_t$ be the endomorphism of the tangent bundle that represents the real $(1, 1)$ -form $\text{dd}^c \dot{u}_t$ with respect to η_t ; it is Hermitian with respect to η_t . The normalization constant satisfies*

$$\dot{b}_t = - \int_X \dot{F}_t \, d\mu_{u_t}, \quad (9.10)$$

$$\ddot{b}_t = - \int_X \ddot{F}_t \, d\mu_{u_t} - \int_X \operatorname{tr}(A_t^2) \, d\mu_{u_t}. \quad (9.11)$$

In particular, for smooth real functions F_0, G on X and the affine family $F_t = F_0 + tG$, the function b_t is concave. Its second derivative vanishes at a parameter value if and only if G is constant on X .

Proof Differentiating the logarithm of (9.1) gives

$$L_{u_t} \dot{u}_t = \dot{F}_t + \dot{b}_t.$$

Integration against μ_{u_t} proves (9.10).

For a smooth family of positive Hermitian matrices H_t , differentiation of the inverse matrix gives

$$\frac{d^2}{dt^2} \log \det H_t = \operatorname{tr}(H_t^{-1} \ddot{H}_t) - \operatorname{tr}((H_t^{-1} \dot{H}_t)^2).$$

Apply this pointwise to the matrices of η_t , using $\dot{\eta}_t = dd^c \dot{u}_t$ and $\ddot{\eta}_t = dd^c \ddot{u}_t$. The second derivative of the logarithmic equation is

$$L_{u_t} \ddot{u}_t - \operatorname{tr}(A_t^2) = \ddot{F}_t + \ddot{b}_t.$$

Integrating against μ_{u_t} at this fixed parameter proves (9.11); there is no need to differentiate the measure.

The eigenvalues of the Hermitian endomorphism A_t are real, so $\operatorname{tr}(A_t^2) \geq 0$. For affine F_t we have $\ddot{F}_t = 0$, so the second derivative of b_t is nonpositive. If it vanishes, strict positivity of the smooth density of μ_{u_t} implies $A_t = 0$ everywhere. Thus $dd^c \dot{u}_t = 0$, and the maximum principle shows that $\dot{u}_t$ is constant. The first differentiated equation then gives $G = -\dot{b}_t$, a constant. Conversely, if G is constant, the solution metric is independent of t and $b_t = b_0 - tG$. $\square$

Corollary 9.7.1 *For two smooth functions F, G , the normalization constants satisfy*

$$-\sup_X (G - F) \leq b(G) - b(F) \leq -\inf_X (G - F).$$

In particular, $|b(G) - b(F)| \leq \|G - F\|_\infty$. If $G - F$ is nonconstant, both inequalities in the first display are strict.

Proof Apply (9.10) along $F_t = F + t(G - F)$ and integrate over $0 \leq t \leq 1$. Each μ_{u_t} is a probability measure with strictly positive smooth density, so the integral of a nonconstant continuous function against it lies strictly between the minimum and the maximum of that function. $\square$

Thus b is a decreasing, concave, Lipschitz functional of the logarithmic density, with $b(F + a) = b(F) - a$ for every real constant a . By uniform approximation, it

extends uniquely to a Lipschitz functional of continuous F . This extension concerns the scalar functional only; the existence and regularity of corresponding potentials require further estimates.

9.8 Normalization on the Hopf threefold

On the Hopf threefold of [Chapter 8](#), the deviation of b from the closed-background formula (9.2) can be computed: it is the energy of the solution along the elliptic fibers. In this section, X is that threefold and ω its Gauduchon metric; we use the projection $\pi : X \rightarrow \mathbb{P}^2$, the probability measure $\nu = \omega^3/6$ and the averaging operator A of [Proposition 8.6.1](#), and we write $\beta = \omega - \pi^* \omega_{\text{FS}}$ for the rank-one form of that construction. As in [Chapter 8](#), the fiber derivative u_w does not depend on the local trivialization of the elliptic bundle.

For $F \in C^\infty(X, \mathbb{R})$, let $(u_F, b(F))$ be the solution of

$$(\omega + \text{dd}^c u_F)^3 = e^{F+b(F)} \omega^3, \quad \omega + \text{dd}^c u_F > 0, \quad \int_X u_F \, d\nu = 0.$$

Define

$$D(F) = b(F) + \log \int_X e^F \, d\nu.$$

For a closed background, the corresponding quantity vanishes by (9.2).

Proposition 9.8.1 *For every smooth real F on this threefold,*

$$e^{D(F)} = 1 + \int_X |(u_F)_w|^2 \, d\nu, \quad (9.12)$$

$$\|u_F - Au_F\|_{L^2(X, \nu)}^2 \leq 4(e^{D(F)} - 1). \quad (9.13)$$

Thus $D(F) \geq 0$, with equality if and only if $F = \pi^* H$ for some $H \in C^\infty(\mathbb{P}^2, \mathbb{R})$.

Proof Integration of the equation and (8.2) give

$$e^{D(F)} = \frac{1}{6} \int_X (\omega + \text{dd}^c u_F)^3 = 1 + \int_X |(u_F)_w|^2 \, d\nu.$$

Substituting the first equality into (8.20) proves (9.13).

If $D(F) = 0$, then $(u_F)_w = 0$ everywhere, because u_F is smooth. Since u_F is real, it is constant on each connected fiber, so it descends to a smooth real function q on $\mathbb{P}^2$, and $\omega_{\text{FS}} + \text{dd}^c q > 0$ as in the proof of [Proposition 8.6.1](#). Since $\beta^2 = 0$ and $\omega = \pi^* \omega_{\text{FS}} + \beta$, we have

$$(\omega + \text{dd}^c \pi^* q)^3 = 3\pi^*(\omega_{\text{FS}} + \text{dd}^c q)^2 \wedge \beta.$$

Dividing by $\omega^3 = 3\pi^*\omega_{\text{FS}}^2 \wedge \beta$ and taking logarithms proves that F is a smooth base pullback.

Conversely, suppose $F = \pi^*H$. Apply [Theorem 9.1.1](#) on $(\mathbb{P}^2, \omega_{\text{FS}})$ to obtain a smooth real q and a scalar c with

$$\omega_{\text{FS}} + \text{dd}^c q > 0, \quad (\omega_{\text{FS}} + \text{dd}^c q)^2 = e^{H+c} \omega_{\text{FS}}^2.$$

Since the base form is closed, Stokes' theorem gives $e^c \int_{\mathbb{P}^2} e^H \omega_{\text{FS}}^2 = 1$. The preceding cube identity shows that π^*q , after subtraction of its ν -mean, solves the equation on X with scalar c , and uniqueness gives $b(F) = c$. Since the base measure of ν is ω_{FS}^2 , it follows that $D(F) = 0$. $\square$

In particular, if a smooth positive density f satisfies $\int_X f \, d\nu = 1$, the equation $(\omega + \text{dd}^c u)^3 = e^b f \omega^3$ has $b \geq 0$, with equality if and only if f is the pullback of a function on the base. Fixing the total integral of the density therefore does not determine the scalar on this nonclosed background.

Corollary 9.8.1 *Let $G \in C^\infty(X, \mathbb{R})$, let $L_0 v = 3 \text{dd}^c v \wedge \omega^2 / \omega^3$ be the linearized operator at $u = 0$, and let ν be the unique smooth real function satisfying*

$$L_0 v = G - \int_X G \, d\nu, \quad \int_X v \, d\nu = 0.$$

Then

$$\left. \frac{d}{dt} D(tG) \right|_{t=0} = 0, \quad \left. \frac{d^2}{dt^2} D(tG) \right|_{t=0} = 2 \int_X |\nu_w|^2 \, d\nu.$$

The second derivative vanishes if and only if G is a smooth base pullback.

Proof For real t near zero put $u_t = u_{tG}$ and $b_t = b(tG)$. By [Proposition 9.3.1](#), this is a smooth family, with $u_0 = b_0 = 0$. Differentiating the logarithmic equation at $t = 0$ gives $L_0 \dot{u}_0 = G + \dot{b}_0$. Since ω is Gauduchon, ν is the adjoint probability measure of L_0 , and integration gives $\dot{b}_0 = -\int_X G \, d\nu$. Hence $\dot{u}_0 = \nu$; this also proves the existence and uniqueness of ν .

Smooth dependence gives $(u_t)_w = t\nu_w + O(t^2)$ uniformly on X , so [\(9.12\)](#) gives

$$e^{D(tG)} = 1 + t^2 \int_X |\nu_w|^2 \, d\nu + O(t^3).$$

Taking logarithms proves the derivative formulas.

If the second derivative vanishes, then $\nu_w = 0$, so $\nu = \pi^*q$ for a smooth real function q on the base. Expanding $\omega^2 = \pi^*\omega_{\text{FS}}^2 + 2\pi^*\omega_{\text{FS}} \wedge \beta$ gives

$$L_0(\pi^*q) = \pi^* \left(\frac{2\text{dd}^c q \wedge \omega_{\text{FS}}}{\omega_{\text{FS}}^2} \right).$$

Hence $G = L_0 v + \int_X G \, d\nu$ is a base pullback. Conversely, when G is a base pullback, [Proposition 9.8.1](#) gives $D(tG) = 0$ for every real t . $\square$

This is a second-variation formula at the background density only. It does not determine whether D is convex globally, because the second derivatives of b and of the logarithmic integral have opposite signs.

9.9 Prescribing a Gauduchon volume form

We now return to a general connected compact complex manifold X , of dimension $n \geq 2$. To stay in a fixed Aeppli class of Gauduchon metrics, we vary the $(n-1)$ st power of the metric by a term of the form $\partial\xi + \bar{\partial}\bar{\xi}$. The resulting scalar ansatz contains first derivatives of the potential as well as its complex Hessian.

Theorem 9.9.1 (Székelyhidi–Tosatti–Weinkove) *Fix a Hermitian form γ_0 , a Gauduchon form γ , and a smooth real function F . There is a unique pair $(u, b) \in C^\infty(X, \mathbb{R}) \times \mathbb{R}$ with $\sup_X u = 0$ such that the $(n-1, n-1)$ -form*

$$\Gamma_u = \gamma_0^{n-1} + dd^c u \wedge \gamma^{n-2} + \operatorname{Re} \left(\frac{i}{2\pi} \partial u \wedge \bar{\partial}(\gamma^{n-2}) \right)$$

is strictly positive, and the Hermitian form η_u with $\eta_u^{n-1} = \Gamma_u$ satisfies

$$\eta_u^n = e^{F+b} \gamma^n.$$

Here we use the linear-algebra fact that a real $(n-1, n-1)$ -form is strictly positive if and only if it is the $(n-1)$ st power of a Hermitian form, and that this Hermitian form is unique; the matrix form of this correspondence is described in [Section 9.12](#). Keep γ_0 and γ fixed for the remainder of the chapter, and write $\mathcal{D}_\gamma u = \Gamma_u - \gamma_0^{n-1}$ for the part of the ansatz that is linear in u .

To see which geometry is preserved, set $\xi_u = i \bar{\partial} u \wedge \gamma^{n-2} / (4\pi)$. The Leibniz rule gives $\Gamma_u - \gamma_0^{n-1} = \partial\xi_u + \bar{\partial}\bar{\xi}_u$. Since $dd^c(\partial\xi_u + \bar{\partial}\bar{\xi}_u) = 0$, if γ_0 is Gauduchon then so is η_u , and the $(n-1)$ st powers of γ_0 and η_u have the same Aeppli class. The uniqueness in [Theorem 9.9.1](#) concerns this scalar ansatz; it does not assert uniqueness among all Gauduchon metrics in the Aeppli class.

9.10 Bounds for the Gauduchon potential

Taking the trace of the positive form Γ_u gives a lower bound for a fixed linear elliptic operator applied to the potential, and its Green kernel then gives an L^1 bound. Near a minimum, supporting affine functions select a contact set on which the gradient is small and the real Hessian is bounded below; the determinant equation forces this set to have uniformly positive volume. Combining the two estimates bounds the minimum. This is an Alexandrov–Bakelman–Pucci type argument.

Proposition 9.10.1 *Every smooth solution (u, b) of the equation in [Theorem 9.9.1](#) with $\sup_X u = 0$ satisfies*

$$|b| + \|u\|_{L^\infty(X)} \leq C.$$

The constant depends only on X , γ_0 , γ and an upper bound for $\|F\|_\infty$; in particular, it does not depend on derivatives of F .

Proof We first bound the scalar. At a maximum of u , the first derivatives of u vanish and $\text{dd}^c u \leq 0$, so $\Gamma_u \leq \gamma_0^{n-1}$; at a minimum the reverse inequality holds. The determinant is monotone with respect to the order of positive matrices, and $(\eta_u^n / \gamma^n)^{n-1}$ is the determinant of the coefficient matrix of Γ_u relative to γ (see (9.18) below). Evaluating the equation at these two points gives

$$\inf_X \left(\log \frac{\gamma_0^n}{\gamma^n} - F \right) \leq b \leq \sup_X \left(\log \frac{\gamma_0^n}{\gamma^n} - F \right).$$

This proves the scalar bound.

Consider the fixed real linear elliptic operator

$$Lu = \frac{\gamma \wedge \mathcal{D}_\gamma u}{\gamma^n}.$$

Its principal part is $\text{dd}^c u \wedge \gamma^{n-1} / \gamma^n$, its remaining term is of first order, and it has no zeroth-order term. Since Γ_u is positive, $\gamma \wedge \Gamma_u \geq 0$, and therefore $Lu \geq -C_0$ for a fixed constant C_0 .

By the Fredholm and maximum-principle argument in the proof of [Theorem 4.1.1](#), the operator L has an adjoint probability measure ν with smooth strictly positive density, that is, $\int_X L\nu \, d\nu = 0$ for every smooth ν . Since $L\nu \leq 0$ at a maximum of ν , its normalized Green kernel can be written

$$\begin{aligned} \nu(x) - \int_X \nu \, d\nu &= - \int_X K(x, y) L\nu(y) \, d\nu(y), \\ K &\geq 0, \quad \sup_x \int_X K(x, y) \, d\nu(y) < +\infty. \end{aligned}$$

Here the kernel is smooth off the diagonal and locally integrable. To obtain this representation, construct the inverse of L on functions of zero ν -mean by the Fredholm alternative. With the minus sign above, the local fundamental solution has a positive leading singularity, so compactness gives a lower bound for the kernel. Adding a constant to K makes it nonnegative and does not change the formula, since $\int_X L\nu \, d\nu = 0$. The local estimates for the Green kernel give the uniform integral bound.

Apply the formula to u and use $Lu \geq -C_0$. At a maximum point, where $u = 0$, we obtain

$$- \int_X u \, d\nu \leq C_1.$$

Because $u \leq 0$ and v has a fixed smooth positive density, this is a uniform L^1 bound for u with respect to any fixed smooth volume form.

Now let $M = \min_X u$, and choose holomorphic coordinates on a ball centered at a minimum point. By compactness, the coordinate radius can be fixed, with uniform bounds for the metric coefficients and their derivatives; rescale the ball to the unit ball $B \subset \mathbb{R}^{2n}$. Write x for the real coordinates, D and D^2 for the Euclidean gradient and Hessian, dx for Euclidean volume, and I for an identity matrix of the appropriate size. Fix a small number $\varepsilon > 0$, depending only on those bounds, and set

$$v(x) = u(x) + \varepsilon|x|^2.$$

For every real vector p with $|p| < \varepsilon/2$, the function $v(x) - p \cdot x$ attains its minimum at an interior point, because its boundary values are larger than $M + \varepsilon/2$, whereas its value at the center is M . At such a point,

$$Dv = p, \quad D^2v \geq 0, \quad v \leq M + \varepsilon/2.$$

Let $A \subset B$ be the set of all points satisfying $|Dv| \leq \varepsilon/2$, $D^2v \geq 0$, and $v \leq M + \varepsilon/2$. Since $u \geq M$, this set lies in $\{|x| \leq 1/\sqrt{2}\}$. It is closed there, hence compact in B , and by the preceding paragraph its image under the gradient map Dv contains the ball $B_{\varepsilon/2}$ of radius $\varepsilon/2$. The area formula for the smooth gradient map therefore gives

$$|B_{\varepsilon/2}| \leq \int_A \det D^2v \, dx. \quad (9.14)$$

The Hessian is nonnegative on A , so no absolute value is needed in the determinant.

We now bound this determinant pointwise on A . There,

$$|Du| \leq \frac{5}{2}\varepsilon, \quad D^2u \geq -2\varepsilon I.$$

The complex Hessian of u has the corresponding lower bound. Wedging with the fixed positive form γ^{n-2} and bounding the first-order term of Γ_u by the gradient estimate, we find that $\Gamma_u \geq \gamma_0^{n-1} - C\varepsilon\gamma^{n-1}$. Let Q_u be the coefficient matrix of Γ_u in a fixed local frame of $(n-1, 0)$ -forms. Since γ_0^{n-1} is strictly positive, choosing ε small gives

$$Q_u \geq cI$$

with a uniform $c > 0$. The equation and the bounds for $F + b$ already proved bound $\det Q_u$ from above, because the determinant of this matrix is, up to a fixed positive factor depending on the frame, the $(n-1)$ st power of the density of η_u^n . All eigenvalues of Q_u are therefore bounded above as well: their product is bounded, and each of them is at least c .

In particular, $\gamma \wedge \Gamma_u / \gamma^n$ is uniformly bounded on A . Subtracting its fixed background term and its bounded first-order term, we obtain an upper bound for

$$\frac{\mathrm{dd}^c u \wedge \gamma^{n-1}}{\gamma^n}.$$

This is a fixed positive multiple of the γ -trace of the complex Hessian of u , which differs from that of v by a bounded term. The complex Hessian of v is nonnegative on A , since the real Hessian is nonnegative there, so comparison of metrics bounds its Euclidean trace from above. The real trace of D^2v is four times this complex trace. It follows that

$$0 \leq \det D^2v \leq \left(\frac{\operatorname{tr}_{\mathbb{R}} D^2v}{2n} \right)^{2n} \leq C_2 \quad \text{on } A.$$

Inequality (9.14) now gives $|A| \geq c_2 > 0$, where c_2 is independent of u . On A we also have $u \leq v \leq M + \varepsilon/2$. Consequently the uniform L^1 bound gives

$$C_3 \geq \int_A (-u) \, dx \geq c_2(-M - \varepsilon/2).$$

This bounds $-M$ and completes the proof. $\square$

9.11 The adjoint equation for Gauduchon volume

As for the Monge–Ampère equation, solving the linearized Gauduchon volume equation requires a compatibility condition, given by an adjoint probability measure. Taking the $(n-1)$ st root multiplies the trace linearization by the factor $n/(n-1)$, and the first-order term of the ansatz introduces a drift term. We compute the linearized operator at any potential with $\Gamma_u > 0$, and then express its adjoint condition as an equation for a positive $(1, 1)$ -form. Throughout this section we put $K = \gamma^{n-2}$.

Proposition 9.11.1 *On the open set of smooth potentials u with $\Gamma_u > 0$, the derivative of*

$$\mathcal{G}(u) = \log \frac{\eta_u^n}{\gamma^n}$$

is the real elliptic operator

$$\mathcal{L}_u v = \frac{n}{n-1} \frac{\eta_u \wedge \mathcal{D}_\gamma v}{\eta_u^n}. \quad (9.15)$$

It has no zeroth-order term, and its kernel consists of the constants. There is a unique smooth positive function ρ_u , normalized by $\int_X \rho_u \eta_u^n = 1$, such that the probability measure

$$d\mu_u^\gamma = \rho_u \eta_u^n$$

satisfies $\int_X \mathcal{L}_u v \, d\mu_u^\gamma = 0$ for every smooth real v .

Proof For a smooth path of potentials $u(t)$, write $\eta = \eta_{u(t)}$ and $\Gamma = \Gamma_{u(t)}$. Differentiating $\eta^{n-1} = \Gamma$ gives $(n-1)\dot{\eta} \wedge \eta^{n-2} = \dot{\Gamma}$, where $\dot{\Gamma} = \mathcal{D}_\gamma \dot{u}$. Wedging with η and dividing by η^n , we obtain

$$\frac{d}{dt} \log \eta^n = \frac{n}{n-1} \frac{\eta \wedge \dot{\Gamma}}{\eta^n},$$

which proves (9.15).

Only the second-order term $\text{dd}^c v \wedge \gamma^{n-2}$ of $\mathcal{D}_\gamma v$ contributes to the principal symbol. For a nonzero complex covector ζ of type $(1, 0)$, the form

$$\eta_u \wedge i\zeta \wedge \bar{\zeta} \wedge \gamma^{n-2}$$

is a positive volume form. Hence the principal symbol is positive definite, and by compactness the operator is uniformly elliptic for each fixed u . The remaining term is of first order, and constants are annihilated, so the strong maximum principle gives $\ker \mathcal{L}_u = \mathbb{R}$.

The Fredholm and positivity arguments in the proof of [Theorem 4.1.1](#) apply to this real elliptic operator with first-order terms and no zeroth-order term. Its index is zero by deformation to a Laplacian, so its formal adjoint with respect to η_u^n has a one-dimensional kernel spanned by a smooth strictly positive function. Normalizing its integral to one gives ρ_u and proves uniqueness. $\square$

The adjoint condition can be expressed as an equation for the positive $(1, 1)$ -form $\rho_u \eta_u$. For a smooth real $(1, 1)$ -form A , set

$$\mathcal{A}_\gamma(A) = \text{dd}^c A \wedge \gamma^{n-2} + \text{Re} \left(\frac{i}{2\pi} \partial A \wedge \bar{\partial}(\gamma^{n-2}) \right).$$

This is a real form of top degree, and $\mathcal{A}_\gamma$ is the formal adjoint of $\mathcal{D}_\gamma$ under the pairing of $(1, 1)$ -forms with $(n-1, n-1)$ -forms, as the proof below shows.

Proposition 9.11.2 *The function ρ_u of [Proposition 9.11.1](#) is characterized by*

$$\mathcal{A}_\gamma(\rho_u \eta_u) = 0, \quad \int_X \rho_u \eta_u^n = 1. \quad (9.16)$$

When $n = 2$, its first equation is $\text{dd}^c(\rho_u \eta_u) = 0$. When $\eta_u = \gamma$, the function ρ_u is constant and $d\mu_u^\gamma = \gamma^n / \int_X \gamma^n$.

Proof We first prove that, for every smooth real $(1, 1)$ -form A and every smooth real function v on X ,

$$\int_X A \wedge \mathcal{D}_\gamma v = \int_X v \mathcal{A}_\gamma(A). \quad (9.17)$$

Write $c = i/(2\pi)$. Since A, K, v are real, expanding the real part gives

$$\mathcal{D}_\gamma v = c \partial \bar{\partial} v \wedge K + \frac{c}{2} (\partial v \wedge \bar{\partial} K - \bar{\partial} v \wedge \partial K).$$

Integrating the first term by parts twice gives $\int_X v c \partial \bar{\partial} (A \wedge K)$, and integrating each first-order term by parts once gives the correction

$$\int_X v \frac{c}{2} (-\partial A \wedge \bar{\partial} K + \bar{\partial} A \wedge \partial K - 2A \wedge \partial \bar{\partial} K).$$

Finally,

$$\partial \bar{\partial} (A \wedge K) = \partial \bar{\partial} A \wedge K - \bar{\partial} A \wedge \partial K + \partial A \wedge \bar{\partial} K + A \wedge \partial \bar{\partial} K.$$

Adding these contributions cancels the terms containing $A \wedge \partial \bar{\partial} K$ and leaves $\mathcal{A}_\gamma(A)$. This proves (9.17). Applied to $A = \rho_u \eta_u$, it shows by (9.15) that $\int_X \mathcal{L}_u v d\mu_u^\gamma$ is a fixed positive multiple of $\int_X v \mathcal{A}_\gamma(\rho_u \eta_u)$, so the adjoint condition is equivalent to (9.16).

For $n = 2$, we have $K = 1$, which gives the first special case. For the second, the product rule gives

$$\mathcal{A}_\gamma(\gamma) = \frac{1}{n-1} dd^c(\gamma^{n-1}) = 0.$$

By uniqueness, ρ_u is consequently the constant $(\int_X \gamma^n)^{-1}$. $\square$

For $n > 2$ the equation for $\rho_u \eta_u$ involves the first derivatives of γ^{n-2} , so the fixed auxiliary metric γ remains part of the adjoint equation; it is not simply the Gauduchon condition for η_u .

9.12 The matrix structure of the Gauduchon equation

The Hodge star converts the positive $(n-1, n-1)$ -form Γ_u into a Hermitian matrix whose logarithmic determinant is a concave function of the complex Hessian. Two features will control the largest eigenvalue in the second-order estimate: the positive background gives coercivity, and the torsion coefficients omit exactly those gradient indices that would otherwise carry the largest inverse weight. We derive both properties before differentiating the equation.

For the matrix and derivative calculations, set $v = u/(2\pi)$, so that $dd^c u = i\partial\bar{\partial}v$. All covariant derivatives are taken with respect to the Chern connection ∇ of γ . In holomorphic coordinates $z^1, \dots, z^n$, write $v_i = \partial_i v$ and $v_{\bar{j}} = \partial_{\bar{j}} v$; indices range from 1 to n , and δ_{ij} is the Kronecker symbol. Write $\gamma = i\gamma_{a\bar{b}} dz^a \wedge d\bar{z}^b$, with repeated indices summed. We denote by $\star_\gamma$ the Hodge star of γ , and by $\det_\gamma$ the determinant of the Hermitian matrix of a real $(1, 1)$ -form relative to γ . Write the torsion of ∇ as T_{ab}^c and lower the last index with γ . Thus

$$T_{ab\bar{c}} = \partial_a \gamma_{b\bar{c}} - \partial_b \gamma_{a\bar{c}}, \quad T_{ab\bar{c}} = -T_{ba\bar{c}}.$$

Let $Q_0 = \star_\gamma \gamma_0^{n-1}/(n-1)!$ and

$$Z = \frac{1}{(n-1)!} \star_\gamma \operatorname{Re}(i\partial v \wedge \bar{\partial} \gamma^{n-2}).$$

Here the real $(1, 1)$ -forms on the right are identified with their Hermitian coefficient matrices relative to γ . Set

$$\chi = (\operatorname{tr}_\gamma Q_0)\gamma - (n-1)Q_0, \quad W = (\operatorname{tr}_\gamma Z)\gamma - (n-1)Z, \quad g = \chi + i\partial\bar{\partial}v + W.$$

The linear map $P_\gamma(A) = ((\operatorname{tr}_\gamma A)\gamma - A)/(n-1)$ on real $(1, 1)$ -forms, or Hermitian matrices, is invertible, and the equation of **Theorem 9.9.1** becomes

$$\begin{aligned} Q_u &:= P_\gamma(g) = Q_0 + P_\gamma(i\partial\bar{\partial}v) + Z > 0, \\ \log \det_\gamma Q_u &= h = (n-1)(F+b). \end{aligned} \quad (9.18)$$

Here $Q_u = \star_\gamma \Gamma_u / (n-1)!$ is the coefficient matrix of Γ_u . The tensor g need not be positive. To check the Hessian term, diagonalize $i\partial\bar{\partial}v$ in a unitary frame: the coefficient of $\star_\gamma(i\partial\bar{\partial}v \wedge \gamma^{n-2}) / (n-1)!$ in each diagonal position is the sum of the other diagonal entries divided by $n-1$. If η_u has eigenvalues a_i relative to γ , then Q_u has eigenvalues $\prod_{j \neq i} a_j$, whose product is $(\prod_i a_i)^{n-1}$. This proves the determinant identity.

Lemma 9.12.1 *At a point in a unitary frame,*

$$\begin{aligned} 2(n-1)Z_{i\bar{j}} &= \delta_{ij} \sum_{p,k} v_p \overline{T_{pk\bar{k}}} - v_i \sum_k \overline{T_{jk\bar{k}}} - \sum_k v_k \overline{T_{kj\bar{i}}} \\ &\quad + \delta_{ij} \sum_{p,k} v_{\bar{p}} T_{pk\bar{k}} - v_{\bar{j}} \sum_k T_{ik\bar{k}} - \sum_k v_{\bar{k}} T_{ki\bar{j}}. \end{aligned} \quad (9.19)$$

In particular $Z_{i\bar{j}}$ contains no v_j or $v_{\bar{i}}$. Moreover

$$2(n-1)Z_{i\bar{i}} = \sum_{p \neq i, k \neq i} (v_p \overline{T_{pk\bar{k}}} + v_{\bar{p}} T_{pk\bar{k}}). \quad (9.20)$$

Covariant differentiation preserves these coefficient identities. For example $\nabla_1 Z_{1\bar{1}}$ contains no pure Hessian v_{11} or its conjugate, and $\nabla_{\bar{1}} \nabla_1 Z_{1\bar{1}}$ contains no $v_{11\bar{1}}$ or its conjugate, nor a pure v_{11} or its conjugate.

Proof For $n = 2$, the defining expression of Z is zero, and so are the formulas below, because the generalized Kronecker symbol with three indices vanishes in two dimensions. Suppose $n \geq 3$ and use coordinates that are unitary at the point. Direct antisymmetrization gives

$$\bar{\partial}\gamma = -\frac{i}{2} \sum_{a,b,c} \overline{T_{bc\bar{a}}} dz^a \wedge d\bar{z}^b \wedge d\bar{z}^c.$$

We use $\bar{\partial}\gamma^{n-2} = (n-2)\bar{\partial}\gamma \wedge \gamma^{n-3}$. To write the contraction explicitly, put

$$\delta_{bci}^{paj} = \det \begin{pmatrix} \delta_{pb} & \delta_{pc} & \delta_{pi} \\ \delta_{ab} & \delta_{ac} & \delta_{ai} \\ \delta_{jb} & \delta_{jc} & \delta_{ji} \end{pmatrix}.$$

Let $A = \star_\gamma(i\partial v \wedge \bar{\partial}\gamma^{n-2})/(n-1)!$. Expanding the $n-3$ remaining copies of γ leaves the three complementary indices and gives

$$A_{i\bar{j}} = \frac{1}{2(n-1)} \sum_{p,a,b,c} v_p \overline{T_{bc\bar{a}}} \delta_{bc\bar{i}}^{paj}.$$

Indeed, the factor is $(n-2)(n-3)!/[2(n-1)!]$, and the determinant records the signs of the remaining holomorphic and antiholomorphic indices. Expanding its six terms and using $T_{bc\bar{a}} = -T_{cb\bar{a}}$, we obtain

$$A_{i\bar{j}} = \frac{1}{n-1} \left(\delta_{ij} \sum_{p,k} v_p \overline{T_{pk\bar{k}}} - v_i \sum_k \overline{T_{jk\bar{k}}} - \sum_k v_k \overline{T_{kj\bar{i}}} \right).$$

Since $Z = (A + A^*)/2$, where A^* denotes the Hermitian adjoint matrix, this gives (9.19).

For $i \neq j$, the coefficient of v_j in this expression vanishes because $T_{jj\bar{i}} = 0$, and the coefficient of $v_{\bar{i}}$ vanishes in the conjugate expression. For $i = j$, canceling the terms with $p = i$ and $k = i$ gives (9.20). These are tensor identities valid in every unitary frame. Since the Chern connection preserves the metric, they can be differentiated in a unitary frame that is parallel at the point. For instance, the first derivative of a summand in (9.20) is

$$(\nabla_1 v_p) \overline{T_{pk\bar{k}}} + v_p \nabla_1 \overline{T_{pk\bar{k}}}, \quad p, k \neq 1,$$

together with its conjugate counterpart. A further derivative in the direction $\bar{1}$ still has $p \neq 1$. This gives the stated exclusions, including the terms in which a derivative falls on a coefficient. $\square$

The second-order estimate uses these exclusions; an arbitrary first-order perturbation could not be substituted for Z .

Lemma 9.12.2 *Diagonalize g at a point and order its eigenvalues as $\lambda_1 \geq \dots \geq \lambda_n$. Put*

$$\mu_i = \frac{\sum_{j \neq i} \lambda_j}{n-1} > 0, \quad t_i = \mu_i^{-1}, \quad f_i = \frac{1}{n-1} \sum_{j \neq i} t_j, \quad \mathcal{F} = \sum_i f_i = \sum_i t_i.$$

Then $\mu_1 \leq \dots \leq \mu_n$, $f_1 \leq \dots \leq f_n$, and

$$\begin{aligned} \sum_i f_i \lambda_i &= n, & \frac{\mathcal{F}}{n(n-1)} &\leq f_k \leq \frac{\mathcal{F}}{n-1} \quad (k > 1), & t_i &\leq (n-1)f_1 \quad (i > 1), \\ & & & & & (9.21) \\ f_n &\geq \mathcal{F}/n. \end{aligned}$$

Fix $\tau, D > 0$ and assume $Q_0 \geq \tau\gamma$ and $\det P_\gamma(g) \leq D$. For λ_1 larger than a constant depending only on n, τ, D ,

$$\sum_i f_i (\chi_{i\bar{i}} - \lambda_i) \geq \frac{\tau}{2} \mathcal{F}. \quad (9.22)$$

There is also a uniform positive lower bound for $\mathcal{F}$ depending only on n, D .

Proof The ordering follows from the formula for μ_i , and then from that for f_i . The identity $\sum_i f_i \lambda_i = n$, which reflects the relation $\log \det P_\gamma(sg) = \log \det P_\gamma(g) + n \log s$, can be checked directly:

$$\sum_i f_i \lambda_i = \sum_j \frac{t_j}{n-1} \sum_{i \neq j} \lambda_i = \sum_j t_j \mu_j = n.$$

For $k > 1$, the sum defining f_k contains the largest weight $t_1 \geq \mathcal{F}/n$. The upper bound for f_k and the estimate for t_i are immediate, and the largest weight f_n is at least the average $\mathcal{F}/n$.

The map P_γ is self-adjoint for the matrix trace pairing. Consequently

$$\sum_i f_i \chi_{i\bar{i}} = \sum_i t_i (Q_0)_{i\bar{i}} \geq \tau \mathcal{F}.$$

Moreover $\sum_i \lambda_i = \sum_i \mu_i > \lambda_1 > 0$, where the strict inequality follows from $\mu_1 > 0$. Hence $\mu_n > \lambda_1/n$. Since the other $n-1$ numbers μ_i are at least μ_1 ,

$$\mu_1^{n-1} \mu_n \leq \prod_i \mu_i \leq D, \quad \mathcal{F} \geq \mu_1^{-1} \geq \left(\frac{\lambda_1}{nD} \right)^{1/(n-1)}.$$

For λ_1 sufficiently large this is at least $2n/\tau$, so $n \leq \tau \mathcal{F}/2$. Subtracting $\sum_i f_i \lambda_i = n$ therefore proves (9.22). Finally, the arithmetic–geometric mean inequality applied to the t_i gives $\mathcal{F} \geq nD^{-1/n}$. $\square$

The concavity of the logarithmic determinant will supply a positive term with an explicit formula. For the matrix function $\Phi(g) = \log \det P_\gamma(g)$, the negative second differential in a complex matrix direction B and its adjoint is

$$-D^2\Phi_g(B, B^*) = \operatorname{tr}(P_\gamma(g)^{-1}P_\gamma(B)P_\gamma(g)^{-1}P_\gamma(B)^*) \geq 0. \quad (9.23)$$

This follows by differentiating the inverse matrix. In a unitary frame diagonalizing g , the off-diagonal terms of this expression include

$$\frac{|B_{k\bar{1}}|^2}{(n-1)^2\mu_k\mu_1}.$$

When $\lambda_k < \lambda_1$, that coefficient is exactly

$$\frac{f_k - f_1}{\lambda_1 - \lambda_k} = \frac{1}{(n-1)^2\mu_k\mu_1}.$$

The expression on the right also makes sense when the two eigenvalues coincide. This positive square and the weights f_i enter the largest-eigenvalue estimate in the next section.

9.13 The largest-eigenvalue estimate

The matrix structure now gives a bound for the complex Hessian in terms of the squared gradient. We apply the maximum principle to the largest eigenvalue of g , corrected by functions of the gradient and of the potential. The missing torsion indices allow the concavity square to absorb the third derivatives. If the smallest eigenvalue is not too negative, the positive background closes the estimate; otherwise that eigenvalue produces a large positive Hessian square.

We keep the notation of [Section 9.12](#). Plain subscripts on scalar functions and subscripts after a comma on matrix coefficients denote coordinate derivatives, and the coefficients of the Chern connection of γ are written Γ_{ik}^q . Choose $\tau > 0$ with $Q_0 \geq \tau\gamma$.

Theorem 9.13.1 *Fix smooth Hermitian forms γ_0, γ on a compact complex manifold X of dimension $n \geq 2$. For a smooth real function h on X , suppose that v is a smooth solution of*

$$Q = Q_0 + P_\gamma(i\partial\bar{\partial}v) + Z(\partial v) > 0, \quad \log \det_\gamma Q = h,$$

with the tensors of [Section 9.12](#). If $\|v\|_{C^0}$ and $\|h\|_{C^2}$ are bounded, then

$$\sup_X |i\partial\bar{\partial}v|_\gamma \leq C(1 + \sup_X |\partial v|_\gamma^2),$$

where C depends only on these bounds and the fixed smooth data.

Proof Adding a constant, we may assume $\sup_X v = 0$, and we write $-M \leq v \leq 0$. Set

$$K = 1 + \sup_X |\partial v|_\gamma^2, \quad \phi(s) = -\frac{1}{2} \log(1 - s/(2K)), \quad \psi(t) = D_1 e^{-D_2 t}.$$

The positive constants D_1, D_2 will be chosen below using only the fixed data. On $0 \leq s \leq K$,

$$\frac{1}{4K} \leq \phi' \leq \frac{1}{2K}, \quad \phi'' = 2(\phi')^2, \quad 0 \leq \phi \leq \frac{1}{2} \log 2.$$

Let λ_1 be the largest eigenvalue of $g = \chi + i\partial\bar{\partial}v + W$ relative to γ . It is positive, because $\text{tr}_\gamma g = \text{tr}_\gamma Q > 0$. Consider a maximum point of

$$H = \log \lambda_1 + \phi(|\partial v|_\gamma^2) + \psi(v).$$

It suffices to bound λ_1/K at this point, because the other two terms of H are uniformly bounded once D_1, D_2 are fixed. We may assume that this ratio exceeds any fixed constant specified in the course of the argument.

Choose holomorphic coordinates that are unitary at the maximum point, with g diagonal there and eigenvalues ordered as $\lambda_1 \geq \dots \geq \lambda_n$. All estimates below are at this point, and repeated indices are summed only when a sum is written. Put $\lambda = \lambda_1$ and use the weights t_i, f_k and their sum $\mathcal{F}$ from [Lemma 9.12.2](#). Since $\sum_i \lambda_i > 0$ and the eigenvalues are ordered,

$$|\lambda_i| \leq (n-1)\lambda, \quad |v_{i\bar{j}}| \leq C\lambda \quad \text{if } \lambda \geq K.$$

The constant C may change from line to line; it is independent of K and, until D_1, D_2 are fixed below, also of D_1, D_2 . The pure second derivatives $v_{i\bar{j}}$ are not covered by this bound.

Differentiating the largest eigenvalue.

Since λ_1 need not be smooth where it is a multiple eigenvalue, we first perturb g . Choose a smooth local unitary frame that is parallel for the Chern connection at the point, with first vector an eigenvector for λ . Let B be the tensor that is diagonal in this frame, with eigenvalues $0, \epsilon_0, \dots, \epsilon_0$, where $\epsilon_0 > 0$ is fixed and small. Then $B \geq 0$, $\nabla B = 0$ at the point, and its second derivatives are bounded by fixed constants. The largest eigenvalue $\tilde{\lambda}$ of $g - B$ is simple near the point, is at most $\lambda_1(g)$, and equals λ at the point. Hence the smooth function $\tilde{H}$, defined like H with $\tilde{\lambda}$ in place of λ_1 , also has a local maximum there. Only the largest eigenvalue needs to be simple.

For a family of self-adjoint matrices with a simple largest eigenvalue, differentiate the equation for the normalized eigenvector. Its component in the p th eigenspace is the corresponding derivative of the matrix divided by the eigenvalue gap. Differentiating the eigenvalue once more therefore gives

$$a_k := \tilde{\lambda}_k = \nabla_k g_{1\bar{1}},$$

$$\tilde{\lambda}_{k\bar{k}} = \nabla_{\bar{k}} \nabla_k g_{1\bar{1}} + O(1) + \sum_{p>1} \frac{|\nabla_k g_{1\bar{p}}|^2 + |\nabla_k g_{p\bar{1}}|^2}{\lambda - \lambda_p + \epsilon_0}.$$

This formula remains valid if some of the lower eigenvalues coincide, with the sum taken over any orthonormal basis of their eigenspaces. The gaps are positive and at most $n\lambda + \epsilon_0$. In holomorphic coordinates, $a_k = g_{1\bar{1},k} + O(\lambda)$, while converting the second covariant derivative to partial derivatives introduces an error of at most $C \sum_p |g_{1\bar{p},k}| + C\lambda$. We also convert the off-diagonal covariant derivatives in the positive squares, with errors $O(\lambda)$, and absorb the linear off-diagonal terms by Young's inequality. Thus, after decreasing a fixed positive coefficient,

$$\tilde{\lambda}_{k\bar{k}} \geq g_{1\bar{1},k\bar{k}} + \frac{1}{8n\lambda} \sum_{p>1} (|g_{1\bar{p},k}|^2 + |g_{p\bar{1},k}|^2) - C(|g_{1\bar{1},k}| + \lambda). \quad (9.24)$$

The precise positive constant will not be used.

Write $V_k = \partial_k(|\partial v|_\gamma^2)$. The first derivative of $\tilde{H}$ gives

$$\frac{a_k}{\lambda} = -\phi' V_k - \psi' v_k, \quad |V_k| \leq C\sqrt{K} \sum_p (|v_{pk}| + |v_{p\bar{k}}|) + CK. \quad (9.25)$$

In the second derivative, the derivatives of the fixed metric in $|\partial v|_\gamma^2$ cost only a small fraction of the positive Hessian squares and a constant. Therefore

$$\begin{aligned} \tilde{H}_{k\bar{k}} &\geq \frac{\tilde{\lambda}_{k\bar{k}}}{\lambda} - \frac{|a_k|^2}{\lambda^2} + \phi' \sum_p (v_p v_{\bar{p}k\bar{k}} + v_{\bar{p}} v_{pk\bar{k}}) + \frac{1}{5K} \sum_p (|v_{pk}|^2 + |v_{p\bar{k}}|^2) \\ &\quad + \phi'' |V_k|^2 + \psi'' |v_k|^2 + \psi' v_{k\bar{k}} - C. \end{aligned} \quad (9.26)$$

The third and fourth terms are obtained by differentiating $\sum \gamma^{p\bar{q}} v_p v_{\bar{q}}$ twice and applying $ab \leq \varepsilon a^2 + C_\varepsilon b^2$ to each term containing a derivative of the metric.

The third derivatives and the torsion term.

We now estimate the third derivatives in this inequality. Define

$$E = \sum_{k,p} f_k (|v_{pk}|^2 + |v_{p\bar{k}}|^2), \quad S = \sum_{k,p} f_k (|v_{pk}| + |v_{p\bar{k}}|),$$

$$C = -D^2 \Phi_g(\nabla_1 g, (\nabla_1 g)^*) \geq 0.$$

The first differentiated equation is

$$\sum_k f_k \nabla_p g_{k\bar{k}} = h_p. \quad (9.27)$$

Since $P_\gamma(W) = Z$ and the connection preserves γ , one has the exact contractions

$$\sum_k f_k \nabla_p W_{k\bar{k}} = \sum_i t_i \nabla_p Z_{i\bar{i}}, \quad \sum_k f_k \nabla_{\bar{1}} \nabla_1 W_{k\bar{k}} = \sum_i t_i \nabla_{\bar{1}} \nabla_1 Z_{i\bar{i}}. \quad (9.28)$$

The weights in these identities are evaluated at the point; they are not differentiated.

The large weights are controlled as follows. By (9.21), the only weight t_i not bounded by $(n-1)f_1$ is t_1 . In $Z_{1\bar{1}}$, every gradient index differs from 1, by (9.20). Thus a pure second derivative in $\nabla_p Z_{1\bar{1}}$ has an index $q > 1$, and it can be weighted by f_q , which is comparable to $\mathcal{F}$; here we use that pure derivatives commute in these coordinates. A mixed second derivative can similarly be placed in column q by conjugate symmetry. All other t_i are bounded by a constant times every f_k , and derivatives of coefficients cost $C\sqrt{K}\mathcal{F}$. Applying these observations to the first identity in (9.28), and then to (9.27), we obtain, for each p ,

$$\left| \sum_k f_k v_{k\bar{k}p} \right| + \left| \sum_k f_k v_{k\bar{k}\bar{p}} \right| \leq C(S + \sqrt{K}\mathcal{F}). \quad (9.29)$$

The connection terms in the differentiated equation contribute weighted mixed second derivatives and terms bounded by $C\sqrt{K}\mathcal{F}$, which are already on the right. The bounded derivatives of h are absorbed using the positive lower bound for $\mathcal{F}$ in Lemma 9.12.2.

Next we insert the second derivative of the equation into the eigenvalue estimate. Since partial derivatives of v commute,

$$g_{1\bar{1},k\bar{k}} = g_{k\bar{k},1\bar{1}} + W_{1\bar{1},k\bar{k}} - W_{k\bar{k},1\bar{1}} + O(1).$$

Differentiating the equation twice covariantly gives

$$\sum_k f_k \nabla_{\bar{1}} \nabla_1 g_{k\bar{k}} = h_{1\bar{1}} + C.$$

The conversion to partial derivatives uses

$$\nabla_{\bar{1}} \nabla_1 g_{k\bar{k}} = g_{k\bar{k},1\bar{1}} - 2 \operatorname{Re} \sum_q \overline{\Gamma_{1k}^q} g_{k\bar{q},1} + O(\lambda).$$

We rewrite the derivative of g in this term using $g_{k\bar{q},1} = g_{1\bar{q},k} + W_{k\bar{q},1} - W_{1\bar{q},k} + O(1)$ and its conjugate. The first part is absorbed by the off-diagonal squares in (9.24), at the cost of $C\lambda\mathcal{F} + C \sum_k f_k |g_{1\bar{1},k}|$. The part involving $W_{1\bar{q},k}$ is bounded by $C\lambda\mathcal{F} + C \sum_{k,p} f_k |v_{pk}|$. For the remaining part we use

$$2 \operatorname{Re} \sum_q \overline{\Gamma_{1k}^q} W_{k\bar{q},1} = W_{k\bar{k},1\bar{1}} - \nabla_{\bar{1}} \nabla_1 W_{k\bar{k}} + O(\sqrt{K}).$$

This cancels the partial second derivative $-W_{k\bar{k},1\bar{1}}$ above, and we obtain

$$\begin{aligned} \sum_k f_k \tilde{\lambda}_{k\bar{k}} &\geq C + \sum_k f_k (W_{1\bar{1},k\bar{k}} - \nabla_{\bar{1}} \nabla_1 W_{k\bar{k}}) \\ &\quad - C \left(\sum_k f_k |g_{1\bar{1},k}| + \sum_{k,p} f_k |v_{pk}| + \lambda\mathcal{F} \right). \end{aligned} \quad (9.30)$$

The second contraction in (9.28) bounds the negative torsion term here. In the part with weight t_1 , the possible third derivatives are $v_{q1\bar{1}}$ and their conjugates with $q > 1$; all other parts have weights bounded by Cf_1 . We commute partial derivatives and use

$$v_{1\bar{1},k} = g_{1\bar{1},k} - \chi_{1\bar{1},k} - W_{1\bar{1},k}.$$

The exclusions in Lemma 9.12.1 ensure that any remaining pure derivative $v_{1\bar{1}}$ carries only the small weight Cf_1 , and derivatives of the connection contribute second derivatives with the same weighted bounds. It follows that

$$\left| \sum_k f_k \nabla_{\bar{1}} \nabla_1 W_{k\bar{k}} \right| \leq C \left(\sum_k f_k |g_{1\bar{1},k}| + \sum_{k,p} f_k |v_{pk}| + \lambda\mathcal{F} \right).$$

For the positive torsion term, write $W_{1\bar{1}} = \sum_p (c^p v_p + \overline{c^p} v_{\bar{p}})$ with fixed smooth coefficients c^p . Two derivatives give $c^p \sum_k f_k v_{pk\bar{k}}$ and its conjugate, plus terms bounded by $C(S + \sqrt{K}\mathcal{F})$. The former are bounded by (9.29), and in S the mixed second derivatives can be bounded by $C\lambda$, giving

$$\left| \sum_k f_k W_{1\bar{1},k\bar{k}} \right| \leq C \left(\sum_{k,p} f_k |v_{pk}| + \lambda\mathcal{F} \right).$$

Substitute these estimates in (9.30), multiply (9.26) by f_k and sum over k . The third derivatives in the latter are bounded by (9.29) and $\phi'|\partial v| \leq C/\sqrt{K}$, and the resulting linear terms in the second derivatives are absorbed by a small part of E/K , at the cost of $C\mathcal{F}$. Since $\tilde{H}$ has a local maximum, $\sum_k f_k \tilde{H}_{k\bar{k}} \leq 0$, and thus

$$\begin{aligned} 0 \geq & \frac{C}{\lambda} - \sum_k f_k \frac{|a_k|^2}{\lambda^2} + \frac{E}{6K} + \phi'' \sum_k f_k |V_k|^2 + \psi'' \sum_k f_k |v_k|^2 + \psi' \sum_k f_k v_{k\bar{k}} \\ & - C \left(\sum_k f_k \frac{|g_{1\bar{1},k}|}{\lambda} + \mathcal{F} \right). \end{aligned} \quad (9.31)$$

Cancellation when the smallest eigenvalue is controlled.

Fix $0 < \delta < 1/2$, to be chosen after D_1, D_2 . First suppose that $\lambda_n \geq -\delta\lambda$. Put $I = \{k : f_k > \delta^{-1}f_1\}$, so that $1 \notin I$. Equation (9.25) and $\phi'' = 2(\phi')^2$ give

$$\begin{aligned} - \sum_{k \notin I} f_k |a_k|^2 / \lambda^2 & \geq -\phi'' \sum_{k \notin I} f_k |V_k|^2 - 2(\psi')^2 \delta^{-1} f_1 K, \\ -2\delta \sum_{k \in I} f_k |a_k|^2 / \lambda^2 & \geq -2\delta \phi'' \sum_{k \in I} f_k |V_k|^2 - 4\delta(\psi')^2 \sum_{k \in I} f_k |v_k|^2. \end{aligned}$$

Choose δ small enough that $4\delta(\psi')^2 \leq \psi''/2$ throughout $[-M, 0]$. By (9.23),

$$\frac{C}{\lambda} \geq \sum_{k \in I} \frac{f_k - f_1}{\lambda(\lambda - \lambda_k)} |\nabla_1 g_{k\bar{1}}|^2 \geq (1 - 2\delta) \sum_{k \in I} \frac{f_k |\nabla_1 g_{k\bar{1}}|^2}{\lambda^2}.$$

Here we used $(1 - \delta)/(1 + \delta) \geq 1 - 2\delta$.

We need the following comparison of the two derivatives $\nabla_1 g_{k\bar{1}}$ and $a_k = \nabla_k g_{1\bar{1}}$. For every $\varepsilon > 0$, provided λ/K is sufficiently large depending on the fixed function ψ ,

$$\sum_{k \in I} f_k \frac{|\nabla_1 g_{k\bar{1}}|^2 - |a_k|^2}{\lambda^2} \geq -\frac{E}{12K} - C\mathcal{F} - \varepsilon C |\psi'| \mathcal{F} - C_\varepsilon |\psi'| \sum_k f_k |v_k|^2. \quad (9.32)$$

To prove this, let $U = \sum_{p>1,q} |v_{pq}|$. Commuting partial derivatives in g gives, for $k > 1$,

$$\nabla_1 g_{k\bar{1}} - a_k = W_{k\bar{1},1} - W_{1\bar{1},k} + O(\lambda), \quad |W_{k\bar{1},1}| + |W_{1\bar{1},k}| \leq C(\lambda + U).$$

The second inequality uses the absence of v_1 in $Z_{k\bar{1}}$, so that differentiation in the direction 1 introduces no pure derivative v_{11} . All mixed second derivatives are bounded by $C\lambda$, and every other pure second derivative occurs in U .

Use $|a + e|^2 - |a|^2 \geq -2|a||e|$, and then (9.25). For $k > 1$, the pure second derivatives in V_k all occur in U . With $H_k = \sum_p |v_{p\bar{k}}|$, the resulting negative terms, divided by λ^2 , are bounded by a constant times

$$K^{-1/2}H_k + K^{-1/2}U + \frac{U^2}{\lambda\sqrt{K}} + 1 + |\psi'| |v_k| + \frac{|\psi'|}{\lambda} |v_k| U.$$

Here we used $H_k \leq C\lambda$ and $\lambda \geq K$ to simplify the cross terms. The weight comparison (9.21), the symmetry of pure derivatives and the Cauchy–Schwarz inequality give $\mathcal{F}U^2 \leq CE$. Consequently, after multiplication by f_k and summation, the first two terms are bounded by any fixed small fraction of E/K plus $C\mathcal{F}$. The third is at most $CE/(\lambda\sqrt{K})$, which is absorbed by another such fraction when λ/K is large. For the last two terms we use

$$|v_k| \leq \varepsilon + C_\varepsilon |v_k|^2, \quad |v_k|U \leq |v_k|^2 + U^2.$$

The contribution of U^2 is at most $C|\psi'|E/\lambda$, which can again be absorbed when λ/K is large. Choosing the fractions with sum $1/12$ proves (9.32).

Insert this cancellation and the preceding inequalities into (9.31). The remaining derivative error satisfies, by (9.25),

$$C \sum_k f_k |g_{1\bar{1},k}|/\lambda \leq \frac{E}{60K} + C\mathcal{F} + \varepsilon C|\psi'|\mathcal{F} + C_\varepsilon |\psi'| \sum_k f_k |v_k|^2,$$

after Young's inequality and an adjustment of constants. The torsion contraction also satisfies

$$\left| \sum_k f_k W_{k\bar{k}} \right| = \left| \sum_i t_i Z_{i\bar{i}} \right| \leq C \sum_k f_k |v_k| \leq \varepsilon C\mathcal{F} + C_\varepsilon \sum_k f_k |v_k|^2.$$

The first inequality uses again the missing gradient index in $Z_{1\bar{1}}$. Since $\psi' < 0$ and $v_{k\bar{k}} = \lambda_k - \chi_{k\bar{k}} - W_{k\bar{k}}$, we conclude, after decreasing the remaining coefficient of E if necessary, that

$$\begin{aligned} 0 &\geq f_1 \left(\frac{\lambda^2}{40K} - 2(\psi')^2 \delta^{-1} K \right) + \left(\frac{\psi''}{2} - C_\varepsilon |\psi'| \right) \sum_k f_k |v_k|^2 \\ &\quad - C_0 \mathcal{F} - \varepsilon C_0 |\psi'|\mathcal{F} + |\psi'| \sum_k f_k (\chi_{k\bar{k}} - \lambda_k). \end{aligned} \tag{9.33}$$

For the first term we used $|v_{1\bar{1}}|^2 \geq \lambda^2/2 - CK$, which follows from $\chi + W = O(\sqrt{K})$, and $E \geq f_1 |v_{1\bar{1}}|^2$.

For large λ , Lemma 9.12.2 bounds the last sum below by $\tau\mathcal{F}/2$. Choose first ε with $\varepsilon C_0 < \tau/4$. Next choose D_2 so that $\psi''/2 > C_\varepsilon |\psi'|$, and then choose D_1 so that $|\psi'|/\tau/4 > C_0$ on $[-M, 0]$. Finally choose δ as above. All these choices depend only

on the fixed data. Inequality (9.33) then forces $\lambda^2 \leq 80 \delta^{-1} \sup_{[-M,0]} |\psi'|^2 K^2$, which proves the desired bound in the first case.

The remaining eigenvalue configuration.

Suppose now that $\lambda_n < -\delta\lambda$, keeping the same constants. Since $f_n \geq \mathcal{F}/n$ and $|\chi + W| \leq C\sqrt{K}$,

$$\frac{E}{6K} \geq \frac{f_n}{6K} |v_{n\bar{n}}|^2 \geq \frac{\delta^2 \lambda^2}{12nK} \mathcal{F} - C\mathcal{F}.$$

In (9.31), discard C and the term with ψ'' . Since ψ is now fixed, $|\psi' \sum_k f_k v_{k\bar{k}}| \leq C\lambda\mathcal{F}$. Using $g_{1\bar{1},k} = a_k + O(\lambda)$ and Young's inequality, we bound the last error term by $\frac{1}{2} \sum_k f_k |a_k|^2 / \lambda^2 + C\mathcal{F}$. This leaves

$$0 \geq -\frac{3}{2} \sum_k f_k |a_k|^2 / \lambda^2 + \frac{\delta^2 \lambda^2}{12nK} \mathcal{F} + \phi'' \sum_k f_k |V_k|^2 - C\lambda\mathcal{F}.$$

By (9.25) and the scalar inequality $\frac{3}{2}|a+b|^2 \leq 2|a|^2 + 6|b|^2$,

$$\frac{3}{2} \sum_k f_k |a_k|^2 / \lambda^2 \leq \phi'' \sum_k f_k |V_k|^2 + CK\mathcal{F}.$$

Since $\lambda \geq K$, combining the last two inequalities and dividing by $\lambda\mathcal{F} > 0$ gives $\lambda/K \leq C$. This finishes both cases. Since H attains its maximum at the chosen point, the bound for λ_1/K there gives a bound at all points, and $|\lambda_i| \leq (n-1)\lambda_1$ then bounds every entry of the complex Hessian, as asserted. $\square$

9.14 A Liouville theorem for the limiting cone

Rescaling at a point of large gradient removes the background and first-order terms of the Gauduchon equation and leaves a degenerate equation on $\mathbb{C}^n$, whose solutions are maximal for a cone of matrices. We show that its bounded Lipschitz solutions are constant. The proof argues by induction on the dimension: if the energy of a solution in some complex direction becomes small on large balls, a limit is independent of one variable; if all directional energies stay positive, they give a strictly admissible comparison function.

On $\mathbb{C}^n$ we use Euclidean coordinates $z = (z_1, \dots, z_n)$, the identity matrix I , the Euclidean balls $B(x, r)$ and Euclidean volume dy . In this section ∇ and Δ denote the Euclidean real gradient and Laplacian, and ∂_ξ denotes differentiation in a complex direction ξ .

For $n \geq 2$ and a Hermitian matrix H , set

$$P_n(H) = \frac{(\operatorname{tr} H)I - H}{n-1}.$$

This is the map P_γ of Section 9.12 for the Euclidean metric. It preserves nonnegativity and satisfies $P_n(I) = I$ and $\operatorname{tr} P_n(H) = \operatorname{tr} H$. For a real function v write $H(v) = (v_{i\bar{j}})$ in Euclidean coordinates. A continuous function v on an open set of $\mathbb{C}^n$ is *admissible* if $P_n(H(v)) \geq 0$ in the sense of matrix-valued distributions. It is *maximal for this cone* if it is admissible and every smooth function h touching v from below at a point satisfies

$$P_n(H(h)) \not\geq 0$$

at that point. Here touching means that $v - h$ has a local minimum with value zero, which need not be a strict minimum. Maximality is thus the viscosity supersolution condition for the degenerate equation $\det P_n(H(v)) = 0$ on the boundary of the cone, together with distributional admissibility.

Taking the trace shows that admissible functions are subharmonic. Since P_n is linear, convolution preserves admissibility, and so do nonnegative linear combinations and integrals of admissible smooth functions. Translations and unitary changes of coordinates preserve both conditions, as do multiplication by a positive constant and addition of a constant.

Lemma 9.14.1 *Local uniform limits of admissible maximal functions are admissible and maximal. If v is maximal on a bounded open set $D \subset \mathbb{C}^n$, h is smooth and admissible on D , both functions are continuous on $\overline{D}$, and $h \leq v$ on ∂D , then $h \leq v$ on D .*

Proof Let v_j be admissible maximal functions converging locally uniformly to v . Distributional positivity is preserved under this convergence. For maximality, suppose that a smooth function h touches v from below at z_0 and $P_n(H(h)(z_0)) > 0$. Choose a small ball on which $v - h \geq 0$. Replacing h by $h - \delta|z - z_0|^2$, with $\delta > 0$ sufficiently small, keeps its matrix strictly positive near z_0 and makes the minimum strict. Uniform convergence then produces interior minimum points of $v_j - h + \delta|z - z_0|^2$ tending to z_0 . Adding the minimum value to the test function gives a function touching v_j from below with strictly positive matrix, a contradiction.

For comparison, choose R with $\overline{D} \subset \{|z| \leq R\}$. If $h > v$ somewhere, then for small $\delta > 0$ the smooth function

$$h_\delta = h + \delta(|z|^2 - R^2)$$

still exceeds v at some interior point and is at most v on the boundary. Hence the negative minimum of $v - h_\delta$ is attained in the interior. But $P_n(H(h_\delta)) = P_n(H(h)) + \delta I > 0$ there, which contradicts maximality after the minimum value is added to h_δ . No boundary regularity of D is needed for this argument. $\square$

Theorem 9.14.1 *A bounded globally Lipschitz function on $\mathbb{C}^n$, $n \geq 2$, that is maximal for this cone is constant.*

Proof Let v be a bounded globally Lipschitz maximal function on $\mathbb{C}^n$. We argue by induction on n . For $n = 2$, $P_2(H) \geq 0$ is equivalent to $H \geq 0$, so v is plurisubharmonic, and Lemma 1.3.5 shows that it is constant.

We first explain the reduction in dimension for $n \geq 3$. If a function is independent of z_n , its complex Hessian has the block form $H \oplus 0$. The first block of $P_n(H \oplus 0)$ is

$$\frac{n-2}{n-1}P_{n-1}(H),$$

and the last entry is $\text{tr } H/(n-1)$. Nonnegativity of $P_{n-1}(H)$ implies $\text{tr } H \geq 0$, and positive definiteness implies $\text{tr } H > 0$. Thus $P_n(H \oplus 0)$ is nonnegative, respectively positive definite, exactly when $P_{n-1}(H)$ is. The distributional version follows from the same linear identities. A test function in $n-1$ variables extends to $\mathbb{C}^n$ independently of z_n , so maximality also passes to $n-1$ variables. Consequently the induction hypothesis applies to bounded Lipschitz maximal functions that are independent of one complex variable.

Suppose now that v is nonconstant. Adding a constant and multiplying by a positive constant, we may assume that $\inf v = 0$ and $\sup v = 1$. Let L be the Lipschitz constant of v . Choose a smooth radial nonnegative probability kernel η , supported in the closed unit ball and strictly positive in its interior. For a bounded measurable function f and $r > 0$, write

$$[f]_r(x) = \int_{\mathbb{C}^n} f(x+y)\eta_r(y) \, dy, \quad \eta_r(y) = r^{-2n}\eta(y/r), \quad v_\epsilon = [v]_\epsilon.$$

Both v and v^2 are subharmonic. For v^2 , use $v_\epsilon \geq 0$ and $\Delta(v_\epsilon^2) = 2v_\epsilon \Delta v_\epsilon + 2|\nabla v_\epsilon|^2 \geq 0$, and pass to the uniform limit as $\epsilon \rightarrow 0$.

For $f = v$ and for $f = v^2$, the averages $[f]_r(x)$ increase with r , by the monotonicity of spherical means of subharmonic functions. Their limit as $r \rightarrow \infty$ is independent of x , since

$$|[f]_r(x) - [f]_r(y)| \leq \|f\|_\infty \|\eta_r(\cdot - x) - \eta_r(\cdot - y)\|_{L^1} \leq C \frac{|x - y|}{r}.$$

By the submean inequality this limit is at least $f(x)$ for every x , while it is at most $\sup f = 1$. Therefore

$$[v]_r(x) \longrightarrow 1, \quad [v^2]_r(x) \longrightarrow 1. \quad (9.34)$$

We distinguish two cases. First suppose that there exist $\rho > 0$, sequences $\epsilon_k \downarrow 0$ and $r_k \rightarrow \infty$, points x_k and unit complex directions ξ_k such that

$$[v^2]_{r_k}(x_k) + [v]_{\rho}(x_k) - 2v(x_k) \geq \frac{4}{3}, \quad \int_{B(x_k, r_k)} |\partial_{\xi_k} v_{\epsilon_k}|^2 \, dy \longrightarrow 0. \quad (9.35)$$

Translate x_k to the origin and make ξ_k the last complex direction by a unitary change of coordinates. The resulting functions have the same bounds and Lipschitz constant, so by the Arzelà–Ascoli theorem and Lemma 9.14.1 a subsequence converges locally

uniformly to a maximal function a . The corresponding mollifications at scale ϵ_k have the same local uniform limit, and by the integral condition their derivatives in the last complex direction tend to zero in L^2 on every fixed ball. Hence $\partial a / \partial z_n = 0$ in the sense of distributions. Since a is real and continuous, it is independent of z_n .

The dimension reduction and the induction hypothesis show that a is a constant $c \in [0, 1]$. In the first inequality of (9.35), the first term is at most one, while the average at the fixed radius ρ and the value at the origin both tend to c . It would follow that $4/3 \leq 1 - c \leq 1$, a contradiction.

In the remaining case, for every fixed $\rho > 0$ there is $C_\rho \geq 1$ such that, whenever $0 < \epsilon < C_\rho^{-1}$, $r > C_\rho$, and

$$[v^2]_r(x) + [v]_\rho(x) - 2v(x) \geq \frac{4}{3},$$

one has

$$\int_{B(x,r)} |\partial_\xi v_\epsilon|^2 dy \geq C_\rho^{-1} \quad \text{for every unit complex direction } \xi. \quad (9.36)$$

Indeed, if this failed for $C_\rho = k$ for every integer k , a diagonal choice would give sequences as in (9.35).

After a translation we may assume that $v(0) < 1/12$. By (9.34), choose ρ with $[v]_\rho(0) > 3/4$, and then $r > C_\rho$ with $[v^2]_r(0) > 3/4$. The open set

$$D = \{x : 2v(x) < [v^2]_r(x) + [v]_\rho(x) - 4/3\}$$

contains the origin. We claim that, for some $c > 0$,

$$[v^2]_r - c|z|^2$$

is smooth and admissible on D .

To prove the claim, differentiate the square of the smooth mollification:

$$H(v_\epsilon^2) = 2v_\epsilon H(v_\epsilon) + 2(\partial_i v_\epsilon \overline{\partial_j v_\epsilon})_{ij}.$$

Denote by A_ϵ and B_ϵ the convolutions at the fixed radius r of these two terms. The first satisfies $P_n(A_\epsilon) \geq 0$, because $v_\epsilon \geq 0$, v_ϵ is admissible, and P_n is linear.

The second satisfies $B_\epsilon \geq c_0 I$ on D for small ϵ , with a constant $c_0 > 0$. Here the passage from the unweighted integral in (9.36) to the convolution needs care. The bound $|\nabla v_\epsilon| \leq L$ makes the energy of a sufficiently thin boundary annulus of $B(x, r)$ at most $C_\rho^{-1}/2$, uniformly in x, ϵ, ξ . On the remaining smaller closed ball, the fixed kernel η_r has a positive minimum. For points $x \in D$, (9.36) then gives a uniform positive lower bound for the weighted integral in every direction, which is the asserted matrix inequality for B_ϵ .

Choose $0 < c \leq c_0$. Since P_n preserves nonnegative matrices,

$$P_n(H([v_\epsilon^2]_r) - cI) \geq 0 \quad \text{on } D.$$

As $\epsilon \downarrow 0$, $v_\epsilon^2 \rightarrow v^2$ uniformly, and convolution at the fixed positive radius r gives convergence of all derivatives. This proves the claim.

The smooth function

$$h = \frac{1}{2}([v^2]_r - c|z|^2 + [v]_\rho - 4/3)$$

is therefore admissible on D . The set $D' = \{v < h\}$ contains the origin, it is bounded because v and its averages are bounded, and it lies in D . Moreover $v = h$ on $\partial D'$. **Lemma 9.14.1**, applied on D' , gives $h \leq v$ there, which contradicts the definition of D' . This excludes the second case and proves the theorem. $\square$

The Lipschitz bound is used both for the compactness of translates and for the annulus estimate. For $n > 1$, the conclusion would not follow from boundedness and subharmonicity alone, since $\mathbb{C}^n = \mathbb{R}^{2n}$ carries nonconstant bounded subharmonic functions.

9.15 The gradient bound by rescaling

If the gradients of a family of solutions were unbounded, rescaling at points of maximal gradient would produce functions on growing Euclidean balls with gradient one at the origin. The Hessian estimate makes these functions compact in C^1 on every fixed ball, so a limit is a bounded Lipschitz function on $\mathbb{C}^n$ with nonzero gradient at the origin. The rescaled determinant tends to zero, so the limit is maximal for the cone of **Section 9.14**, which contradicts **Theorem 9.14.1**.

Consider a family of smooth solutions (u, b) of the equation in **Theorem 9.9.1**, normalized by $\sup_X u = 0$, with $\|F\|_{C^0} \leq M$ for a fixed $M > 0$. By **Proposition 9.10.1**, $\|u\|_{C^0}$ and $|b|$ are uniformly bounded. The following proposition shows that a Hessian estimate in terms of the squared gradient implies bounds for both.

Proposition 9.15.1 *Suppose there is a constant K such that every solution in this family satisfies*

$$\sup_X |\mathrm{dd}^c u|_\gamma \leq K(1 + \sup_X |\partial u|_\gamma^2). \quad (9.37)$$

Then $\sup_X |\partial u|_\gamma$ and $\sup_X |\mathrm{dd}^c u|_\gamma$ are bounded by a constant depending only on X, γ_0, γ, M and K .

Proof We use the matrices Q_u of (9.18). Their background term Q_0 is fixed, and Z is linear in the first derivatives of $u/(2\pi)$.

Suppose that the gradient bound fails. Then there are solutions (u_j, b_j) with prescribed functions F_j such that

$$A_j = \sup_X |\partial u_j|_\gamma = |\partial u_j(x_j)|_\gamma \longrightarrow \infty.$$

After passing to a subsequence, the points x_j lie in one fixed coordinate neighborhood. Translate the coordinates so that x_j becomes the origin, and apply a uniformly

controlled complex linear change of coordinates so that the matrix of γ at x_j is the identity; a coordinate ball of fixed radius remains available around every x_j . On balls whose radii tend to infinity define

$$v_j(z) = u_j(x_j + z/A_j),$$

in these coordinates. The coefficient matrices $g_j(z)$ of γ at the points $x_j + z/A_j$ converge smoothly to the identity on every fixed ball. In this notation

$$|v_j| \leq C, \quad |\partial v_j|_{g_j} \leq 1, \quad |\partial v_j(0)| = 1.$$

The assumed estimate (9.37) gives a uniform bound for all complex Hessian entries of v_j on every fixed ball, since two derivatives contribute the factor A_j^{-2} . Hence the Euclidean Laplacians of the v_j are uniformly bounded, and the interior estimates for the Laplacian give local $W^{2,p}$ bounds for every finite p . Choosing $p > 2n$ and using Sobolev embedding and compactness, we extract a diagonal subsequence converging in C^1 on compact subsets to a function v on $\mathbb{C}^n$. This function is bounded and globally Lipschitz, and

$$|\partial v(0)| = 1.$$

Now divide the matrix in (9.18) by A_j^2 and evaluate it at the scaled points. The background term becomes $O(A_j^{-2})$, and the first-order term becomes $O(A_j^{-1})$, since one derivative of u_j is A_j times a derivative of v_j . Since the complex Hessians of v_j are uniformly bounded and $g_j \rightarrow I$, we obtain on any fixed ball

$$A_j^{-2}Q_{u_j} = P_n \left(\frac{H(v_j)}{2\pi} \right) + o(1), \quad \det(A_j^{-2}Q_{u_j}) = A_j^{-2n} e^{(n-1)(F_j+b_j)} \longrightarrow 0. \quad (9.38)$$

To be precise, we compute in the unitary frames obtained from the positive square roots $S_j = g_j^{-1/2}$. In these frames the principal matrix is $P_n(S_j H(v_j) S_j / (2\pi))$, which differs from $P_n(H(v_j) / (2\pi))$ by an error tending to zero uniformly; no derivatives of the frames are taken, and the determinant identity is exact in unitary frames. Since the matrices on the left of (9.38) are positive and the positive factor $1/(2\pi)$ does not change the cone, passing to the limit in the sense of distributions gives $P_n(H(v)) \geq 0$.

It remains to check maximality. Suppose that a smooth function h touches v from below at z_0 and $P_n(H(h)(z_0)) > 0$. Subtract $\delta|z - z_0|^2$ with $\delta > 0$ small; on a small ball this makes the contact strict and preserves strict positivity of the matrix. Local uniform convergence gives points $z_j \rightarrow z_0$ at which v_j minus this perturbed test function has an interior local minimum. At such a minimum,

$$H(v_j)(z_j) \geq H(h)(z_j) - \delta I.$$

Because P_n preserves nonnegative matrices, (9.38) now implies $A_j^{-2}Q_{u_j}(z_j) \geq cI$ for a fixed $c > 0$ and all sufficiently large j . The determinant of this matrix is then at least c^n , which contradicts the limit zero in (9.38). Thus v is maximal for the cone of Section 9.14.

By [Theorem 9.14.1](#), v is constant, which contradicts $|\partial v(0)| = 1$. This proves the uniform gradient bound, and substitution in [\(9.37\)](#) gives the uniform complex Hessian bound. $\square$

For prescribed functions F bounded in C^2 , [Proposition 9.10.1](#) bounds u and b , and [Theorem 9.13.1](#), applied to $v = u/(2\pi)$ and $h = (n-1)(F+b)$, proves [\(9.37\)](#). Thus both the gradient and the complex Hessian are uniformly bounded.

9.16 Existence for the Gauduchon ansatz

The potential, gradient and Hessian bounds put the matrices Q_u in a compact set of positive matrices. This yields uniform ellipticity after the real Hessian is projected to its complex part and transformed by P_n , so local elliptic regularity gives the compactness needed for closedness in the continuity method; the adjoint probability measure gives openness. The maximum principle then proves uniqueness within the scalar ansatz.

Lemma 9.16.1 *Let γ_0, γ be as in [Theorem 9.9.1](#). If the prescribed functions F range over a set of smooth functions bounded in every C^k norm, then the smooth solutions (u, b) with $\sup_X u = 0$ are bounded in every C^k norm.*

Proof Work with $v = u/(2\pi)$ and write $Q = Q_u$ for the matrix in [\(9.18\)](#). By [Propositions 9.10.1](#) and [9.15.1](#) and [Theorem 9.13.1](#), the function v , its gradient and its complex Hessian are uniformly bounded, and so are the constants b . Hence the eigenvalues of Q are uniformly bounded above, and by the equation its determinant is uniformly bounded below. Every eigenvalue is therefore also bounded below by a positive constant. Choose fixed numbers $0 < a < b_0$ such that $aI \leq Q \leq b_0I$ in unitary frames for every solution.

The function $\Delta_\gamma v = \text{tr}_\gamma(i\partial\bar{\partial}v)$ is uniformly bounded, and Δ_γ is a fixed uniformly elliptic operator. Its interior $W^{2,p}$ estimates, applied on a finite cover, bound v in $W^{2,p}$ for every finite p . Choose $p > 2n$ and $0 < \alpha < 1 - 2n/p$; Sobolev embedding gives a uniform $C^{1,\alpha}$ bound. Thus the matrix $R(x) = Q_0(x) + Z_x(\partial v(x))$ is uniformly bounded in C^α .

On a coordinate ball, let $\mathcal{H}_x(A)$ denote the Hermitian matrix of $i\partial\bar{\partial}v$ at x in a fixed smooth unitary frame, expressed as a function of the real Hessian $A = D_{\mathbb{R}}^2 v(x)$. It is a real linear function of A depending smoothly on x . If a real symmetric matrix N is nonnegative, then $\mathcal{H}_x(N) \geq 0$, and its trace is comparable to $\text{tr}_{\mathbb{R}} N$ with uniform positive constants on the ball. This follows by evaluating on a vector and its rotation by i , or from the coordinate formula for $v_{i\bar{j}}$.

Freeze the function $\partial v(x)$ already obtained in $R(x)$, and define for all real symmetric matrices A

$$\tilde{\Phi}(A, x) = \inf_{aI \leq B \leq b_0I} \left\{ \log \det B + \text{tr} \left[B^{-1} (R(x) + P_n(\mathcal{H}_x(A)) - B) \right] \right\}.$$

The infimum is over a fixed compact set of positive Hermitian matrices, and each expression in braces is an affine function of A , so $\tilde{\Phi}$ is concave in A . If $R(x) + P_n(\mathcal{H}_x(A))$ lies in that compact set, then $\tilde{\Phi}(A, x)$ equals its logarithmic determinant: each expression in braces is a tangent affine function of the concave logarithmic determinant, and the tangent at that matrix itself attains equality.

For $N \geq 0$, each of these affine functions increases by

$$\mathrm{tr}(B^{-1}P_n(\mathcal{H}_x(N)))$$

when A is replaced by $A + N$. Since P_n preserves positivity and trace, this increment lies between fixed positive multiples of $\mathrm{tr}_{\mathbb{R}} N$, uniformly in B and x . Taking infima preserves both inequalities, so $\tilde{\Phi}$ is uniformly elliptic on all real symmetric matrices.

Smoothness of $\mathcal{H}_x$ and the uniform C^α bound for R also give

$$|\tilde{\Phi}(A, x) - \tilde{\Phi}(A, y)| \leq C|x - y|^\alpha(1 + \|A\|).$$

These are the hypotheses of the local Evans–Krylov estimate for concave uniformly elliptic equations with Hölder dependence on x , in the formulation given in [Section 33.6](#). The value $\tilde{\Phi}(0, x)$ is uniformly bounded, by the compactness of the set of matrices B and the bound for R . By the choice of a and b_0 , the given smooth function solves

$$\tilde{\Phi}(D_{\mathbb{R}}^2 v, x) = (n - 1)(F + b)$$

on the ball. The Evans–Krylov estimate, applied on smaller balls of a finite cover, yields a uniform $C^{2,\beta}$ bound for some $\beta > 0$.

Differentiating the original matrix equation gives linear uniformly elliptic equations for the first derivatives of v , whose coefficients, including the first-order coefficients coming from Z , are now Hölder continuous. Local Schauder estimates give $C^{3,\beta}$ bounds, and differentiation and induction give all higher bounds. The finite coordinate cover makes the bounds global. The only regularity results used here are the standard $W^{2,p}$ estimates for the Laplacian, the Evans–Krylov estimate for concave equations, and the Schauder estimates. $\square$

Proof (of [Theorem 9.9.1](#)) Let

$$F_0 = \log \frac{\gamma_0^n}{\gamma^n}, \quad F_t = (1 - t)F_0 + tF, \quad 0 \leq t \leq 1.$$

We use the continuity method along the path F_t . At $t = 0$, the pair $u = 0, b = 0$ solves the equation, since $\eta_0 = \gamma_0$. During the continuity argument we normalize potentials by $\int_X u \gamma^n = 0$; adding a constant does not affect the equation, and at the end we impose $\sup_X u = 0$ instead.

For openness, the derivative of the equation with respect to the mean-zero potential and the scalar is $(w, a) \mapsto \mathcal{L}_u w - a$. Given a right-hand side q , integration against the adjoint probability measure of [Proposition 9.11.1](#) forces $a = -\int_X q \, d\mu_u^\gamma$. The Fredholm alternative then gives a unique mean-zero solution w , and Schauder

estimates bound this inverse between Hölder spaces. Since positivity of Γ_u is an open condition, the implicit function theorem gives solutions for all nearby parameters.

For closedness, note that the functions F_t are uniformly bounded in every C^k norm. After supremum normalization, [Proposition 9.10.1](#) bounds u and b , the second-order and rescaling estimates bound the gradient and the complex Hessian, and [Lemma 9.16.1](#) gives all higher bounds. Subtracting the mean preserves all derivative bounds and changes the potentials by uniformly bounded constants. A subsequence of mean-zero solutions along a convergent sequence of parameters therefore converges smoothly to a solution at the limiting parameter, and the bounds $aI \leq Q \leq b_0I$ preserve strict positivity in the limit. Thus the set of solvable parameters is nonempty, open and closed, hence equal to $[0, 1]$.

Finally, consider two solutions (u, b) and (w, c) for the same F . At a maximum of $u - w$ their gradients agree and their complex Hessians are ordered, so the first-order terms are equal there and, since P_n preserves the order, $Q_u \leq Q_w$. The equation then gives $b \leq c$, and at a minimum the reverse inequality gives $b \geq c$. Hence $b = c$. Along the segment between u and w , the matrices Q remain positive because the ansatz is affine in the potential. Integrating the derivative of the logarithmic determinant along that segment produces a uniformly elliptic scalar operator with first-order terms and no zeroth-order term that annihilates $u - w$. The maximum principle shows that $u - w$ is constant, and the supremum normalization makes the constant zero. $\square$

9.17 Normalization for the Gauduchon equation

By [Theorem 9.9.1](#), every smooth real function F determines a scalar $b_\gamma(F)$, the constant b of that theorem. As for the Monge–Ampère equation, its variation is governed by the adjoint probability measure μ_u^γ of [Proposition 9.11.1](#) and by the concavity of the logarithmic determinant. To differentiate solutions, we fix a smooth positive volume form dV_0 and use the normalization $\int_X u dV_0 = 0$ in place of $\sup_X u = 0$.

Lemma 9.17.1 *The solution $(u, b_\gamma(F))$, normalized by $\int_X u dV_0 = 0$, depends smoothly on the parameters of every smooth finite-dimensional family of functions F .*

Proof The map $\Gamma \mapsto \eta$ with $\eta^{n-1} = \Gamma$ is smooth on positive forms, since in a frame it is the inverse of the smooth map $\eta \mapsto \eta^{n-1}$, whose differential is invertible. The openness argument in the proof of [Theorem 9.9.1](#), with the dV_0 -mean in place of the γ^n -mean, gives a bounded inverse for the derivative with respect to the potential and the scalar between the relevant Hölder spaces. The implicit function theorem gives local smooth solution maps, and uniqueness shows that they agree on overlaps. Applying this for every order of Hölder regularity gives the assertion for smooth data. $\square$

For a smooth family of prescribed functions $F_t \in C^\infty(X, \mathbb{R})$, with t in an open interval of $\mathbb{R}$, let u_t be the corresponding solutions with $\int_X u_t dV_0 = 0$, and set $Q_t = Q_{u_t}$ as in (9.18). The expression

$$\mathrm{tr}((Q_t^{-1}\dot{Q}_t)^2)$$

is independent of the chosen frame and nonnegative, because $Q_t^{-1}\dot{Q}_t$ is similar to the Hermitian matrix $Q_t^{-1/2}\dot{Q}_tQ_t^{-1/2}$.

Theorem 9.17.1 *For a smooth family F_t and its solutions,*

$$\begin{aligned} \dot{b}_\gamma(F_t) &= - \int_X \dot{F}_t d\mu_{u_t}^\gamma, \\ \ddot{b}_\gamma(F_t) &= - \int_X \ddot{F}_t d\mu_{u_t}^\gamma - \frac{1}{n-1} \int_X \mathrm{tr}((Q_t^{-1}\dot{Q}_t)^2) d\mu_{u_t}^\gamma. \end{aligned}$$

In particular, b_γ is concave, and along $F_t = F_0 + tG$ its second derivative is strictly negative unless G is constant. Moreover, for smooth real functions F, G on X and every real constant a ,

$$b_\gamma(F + a) = b_\gamma(F) - a, \quad |b_\gamma(G) - b_\gamma(F)| \leq \|G - F\|_\infty.$$

Proof By (9.18),

$$\mathcal{G}(u) = \frac{1}{n-1} \log \det_\gamma Q_u.$$

Differentiating $\mathcal{G}(u_t) = F_t + b_\gamma(F_t)$ once gives $\mathcal{L}_{u_t}\dot{u}_t = \dot{F}_t + \dot{b}_\gamma(F_t)$, and integration against the adjoint probability measure gives the first formula.

Because Γ_u is affine in u , its second derivative along the family is $\mathcal{D}_\gamma\ddot{u}_t$. The formula for the second derivative of $\log \det$ used in the proof of **Theorem 9.7.1** therefore gives

$$\mathcal{L}_{u_t}\ddot{u}_t - \frac{1}{n-1} \mathrm{tr}((Q_t^{-1}\dot{Q}_t)^2) = \ddot{F}_t + \ddot{b}_\gamma(F_t).$$

Integrating against $\mu_{u_t}^\gamma$ at this fixed parameter gives the second formula; no derivative of the measure is needed.

For affine F_t , we have $\ddot{F}_t = 0$, and positivity of the density of $\mu_{u_t}^\gamma$ proves concavity. If the second derivative vanishes, then $\dot{Q}_t = 0$, so $\dot{\Gamma}_{u_t} = 0$ and $\mathcal{L}_{u_t}\dot{u}_t = 0$. By **Proposition 9.11.1**, $\dot{u}_t$ is constant, and the first differentiated equation forces G to be constant. Conversely, adding a constant to F changes only b , by the opposite constant. Finally, integrate the first derivative along the segment from F to G : since $\mu_{u_t}^\gamma$ is a probability measure, the derivative lies between $-\sup_X(G - F)$ and $-\inf_X(G - F)$, which proves the Lipschitz bound. $\square$

The Lipschitz bound extends b_γ uniquely to continuous functions F . Constructing corresponding weak solutions would require, in addition, a volume measure for the $(n-1)$ st roots of singular forms in the Aeppli ansatz, compactness of their potentials, and stability of the adjoint equation.

On a surface with Gauduchon background form γ_0 , conservation of the total mass makes the scalar and the adjoint probability measure explicit.

Example 9.17.1 If $n = 2$ and γ_0 is Gauduchon, then $\Gamma_u = \gamma_0 + dd^c u = \eta_u$, and η_u is also Gauduchon. The mass identity of [Theorem 2.2.2](#) gives $\int_X \eta_u^2 = \int_X \gamma_0^2$. Therefore

$$b_\gamma(F) = \log \int_X \gamma_0^2 - \log \int_X e^F \gamma^2, \quad d\mu_u^\gamma = \frac{e^F \gamma^2}{\int_X e^F \gamma^2}.$$

The adjoint equation of [Proposition 9.11.2](#) gives the same measure, because $dd^c \eta_u = 0$ and hence ρ_u is constant. Along $F + tG$, the second derivative of b_γ is minus the variance of G with respect to this probability measure.

Chapter 10

Continuous solutions and normalization

Throughout this chapter, X is a connected compact complex manifold of dimension $n \geq 1$, ω is a Hermitian form and dV is a smooth positive volume form on X . As in [Chapter 9](#), we write $\omega_u = \omega + dd^c u$; for a bounded ω -plurisubharmonic function u , the power ω_u^n is the Bedford–Taylor product of [Proposition 1.7.1](#). We fix $p > 1$ and a nonnegative $f \in L^p(X, dV)$ with $\int_X f dV > 0$. Norms and almost-everywhere statements refer to dV unless another measure is specified.

We look for continuous ω -plurisubharmonic solutions of the equations $(\omega + dd^c u)^n = c f dV$, with an unknown constant $c > 0$, and $(\omega + dd^c u)^n = e^{\lambda u} f dV$, with $\lambda > 0$. Approximating f by smooth positive densities, the preceding chapter gives smooth solutions, but normalized L^1 compactness of the potentials does not by itself identify the limit of their Monge–Ampère measures. Two estimates close this gap. Integration against a Gauduchon metric bounds the normalization constants, and hence gives uniform L^p control of the densities of the approximating equations. A modified comparison principle, which compensates for the variation of the total mass, then upgrades normalized L^1 convergence of the potentials to uniform convergence. For the exponential equation, the same Gauduchon trace controls the additive constants. Letting the exponent λ tend to zero shows that the constant c is determined by f , even though the normalized potential need not be unique.

On the Hopf threefold, the normalization constant satisfies a sharp lower bound, with equality exactly for densities pulled back from the projective plane. Finally, for concave fully nonlinear equations with a fixed admissible reference satisfying a strict asymptotic gap, an auxiliary Monge–Ampère equation gives a uniform stability estimate. The resulting compactness provides the smooth comparison functions for a gradient bound.

10.1 Continuous solvability

There are two natural ways to normalize the prescribed density: by an unknown positive constant, or by an exponential of the potential.

Theorem 10.1.1 (Kołodziej–Nguyen) *There are $c > 0$ and $u \in \text{PSH}(X, \omega) \cap C(X)$ such that*

$$(\omega + \text{dd}^c u)^n = c f \, dV.$$

The potential can be normalized by $\sup_X u = 0$.

The constant c is uniquely determined by f , by [Proposition 10.5.1](#). The normalized potential, however, need not be unique, even for a smooth density; see [Theorem 11.6.1](#).

Theorem 10.1.2 (Nguyen) *For every $\lambda > 0$, there is a unique continuous ω -plurisubharmonic function u_λ satisfying*

$$(\omega + \text{dd}^c u_\lambda)^n = e^{\lambda u_\lambda} f \, dV. \quad (10.1)$$

10.2 The modified comparison principle

For a Hermitian background, the total Monge–Ampère mass varies with the potential, and the ordinary comparison principle fails in general (see [Theorem 11.5.2](#)). A weaker form survives. Replacing the comparison potential v by $(1 - \varepsilon)v$ leaves the strictly positive form $\varepsilon\omega$ in reserve, and this reserve absorbs the torsion terms. On a sublevel set of height s , integration by parts makes the error proportional to s , and a finite induction controls the intermediate mixed products. The resulting multiplicative correction tends to one as s tends to zero with ε fixed.

Since X is compact and ω is positive, we can choose $B_0 \geq 1$ such that

$$-B_0\omega^2 \leq \text{dd}^c \omega \leq B_0\omega^2, \quad -B_0\omega^3 \leq d\omega \wedge \text{dd}^c \omega \leq B_0\omega^3.$$

These inequalities are understood after wedging with positive forms of complementary degree; forms of degree larger than $2n$ vanish, and the corresponding terms below are omitted.

Theorem 10.2.1 *Let $u, v \in \text{PSH}(X, \omega) \cap L^\infty(X)$ and $0 < \varepsilon < 1$. For $s > 0$, put*

$$m_\varepsilon = \inf_X (u - (1 - \varepsilon)v), \quad U_{\varepsilon, s} = \{u < (1 - \varepsilon)v + m_\varepsilon + s\}.$$

If $0 < s < \varepsilon^3 / (32B_0n^2)$, then, with $a = B_0n^2s\varepsilon^{-3}$,

$$(1 - 4a)^n \int_{U_{\varepsilon, s}} \omega_{(1-\varepsilon)v}^n \leq \int_{U_{\varepsilon, s}} \omega_u^n. \quad (10.2)$$

In particular, the reverse factor $(1 - 4a)^{-n}$ tends to one as $s \downarrow 0$ for fixed ε .

Proof Write $v_\varepsilon = (1 - \varepsilon)v$, $U = U_{\varepsilon, s}$ and

$$\phi = \max(u, v_\varepsilon + m_\varepsilon + s), \quad T_k = \omega_u^k \wedge \omega_\phi^{n-k}, \quad I_k = \int_U T_k \quad (0 \leq k \leq n).$$

Set $I_{-1} = I_{-2} = 0$. Then $0 \leq \phi - u \leq s$, this difference vanishes outside U , and on U plurifine locality gives $\omega_\phi = \omega_{v_\varepsilon} \geq \varepsilon\omega$ in all bounded products.

By [Lemma 1.7.1](#), for every fixed positive mixed product W of $n - 1$ bounded-potential factors,

$$\mathbf{1}_{\{u=\phi\}}\omega_u \wedge W \leq \mathbf{1}_{\{u=\phi\}}\omega_\phi \wedge W.$$

For $0 \leq k \leq n - 1$, apply this with $W = \omega_u^k \wedge \omega_\phi^{n-k-1}$. Since $u = \phi$ on $X \setminus U$, the difference $T_k - T_{k+1} = (\omega_\phi - \omega_u) \wedge W$ is nonnegative there. Consequently

$$I_k - I_{k+1} \leq \int_X \mathrm{dd}^c(\phi - u) \wedge W = \int_X (\phi - u) \mathrm{dd}^c W. \quad (10.3)$$

This integration by parts is valid for bounded potentials. To see this, approximate u and ϕ by decreasing sequences of smooth, uniformly bounded ω -plurisubharmonic functions, using [Theorem 1.11.1](#). For smooth functions the identity is ordinary integration by parts. The form $\mathrm{dd}^c W$ expands as below into bounded Hessian products and smooth forms, and bounded Bedford–Taylor convergence, also against bounded quasi-continuous coefficients converging in capacity, passes each term to the limit.

Set $r = n - k - 1$. Since $d\omega_u = d\omega_\phi = d\omega$, expansion gives

$$\begin{aligned} \mathrm{dd}^c W &= k \mathrm{dd}^c \omega \wedge \omega_u^{k-1} \wedge \omega_\phi^r + r \mathrm{dd}^c \omega \wedge \omega_u^k \wedge \omega_\phi^{r-1} \\ &\quad + k(k-1) d\omega \wedge d^c \omega \wedge \omega_u^{k-2} \wedge \omega_\phi^r \\ &\quad + 2kr d\omega \wedge d^c \omega \wedge \omega_u^{k-1} \wedge \omega_\phi^{r-1} \\ &\quad + r(r-1) d\omega \wedge d^c \omega \wedge \omega_u^k \wedge \omega_\phi^{r-2}. \end{aligned}$$

Terms containing a negative power have coefficient zero and are omitted. On U we may replace each ω^j in an upper bound by $\varepsilon^{-j}\omega_\phi^j$, since $\omega_\phi \geq \varepsilon\omega$ there. Using $\phi - u \leq s$ and $\varepsilon^{-2} \leq \varepsilon^{-3}$ in (10.3), we obtain

$$I_k - I_{k+1} \leq B_0 s \varepsilon^{-3} (k(k-1)I_{k-2} + k(1+2r)I_{k-1} + r^2 I_k).$$

Each coefficient is at most n^2 , and $a = B_0 n^2 s \varepsilon^{-3}$. Hence

$$I_k - I_{k+1} \leq a(I_{k-2} + I_{k-1} + I_k). \quad (10.4)$$

Put $q = 1 - 4a$; the assumption on s gives $a < 1/32$, so $q > 7/8$. Suppose inductively that $qI_j \leq I_{j+1}$ for $j < k$. Then $I_{k-1} \leq q^{-1}I_k$ and $I_{k-2} \leq q^{-2}I_k$ whenever the indices exist. Since

$$1 + q^{-1} + q^{-2} \leq 1 + 8/7 + 64/49 < 4,$$

(10.4) gives $qI_k \leq I_{k+1}$. The case $k = 0$ follows from the same formula with the two absent terms set to zero. By induction, $q^n I_0 \leq I_n$. Since $T_0 = \omega_{v_\varepsilon}^n$ on U and $T_n = \omega_u^n$, this is the theorem. In dimension one all torsion terms vanish and the same argument applies. $\square$

A strict multiplicative inequality between the Monge–Ampère measures on $\{u < v\}$ absorbs the error in modified comparison. One first chooses the positivity reserve ε , and then a sublevel set thin enough to preserve the strict inequality.

Theorem 10.2.2 *Let $u, v \in \text{PSH}(X, \omega) \cap L^\infty(X)$, and let $0 \leq c < 1$. If*

$$\mathbf{1}_{\{u < v\}} \omega_u^n \leq c \mathbf{1}_{\{u < v\}} \omega_v^n,$$

then $u \geq v$. In particular, $\omega_u^n(\{u < v\}) = 0$ implies $u \geq v$.

Proof Suppose $m = \inf_X(u - v) < 0$. Choose $\varepsilon > 0$ so small that

$$(1 - \varepsilon)^n > c, \quad 2\varepsilon\|v\|_\infty < -m/4,$$

omitting the second restriction if $v = 0$. Let m_ε and $U_{\varepsilon,s}$ be defined as in [Theorem 10.2.1](#) for this pair u, v . Since $|m_\varepsilon - m| \leq \varepsilon\|v\|_\infty$, for all sufficiently small $s > 0$ the set $U = U_{\varepsilon,s}$ is contained in $\{u < v\}$; there

$$u - v < m_\varepsilon + s - \varepsilon v \leq m + 2\varepsilon\|v\|_\infty + s < 0.$$

The set U is nonempty by the definition of the infimum and has positive volume by [Lemma 1.3.4](#).

Decrease s further so that [Theorem 10.2.1](#) applies and $(1 - 4B_0n^2s\varepsilon^{-3})^n(1 - \varepsilon)^n > c$. Write the first factor as q^n . Positivity of every mixed term gives

$$\omega_{(1-\varepsilon)v}^n \geq (1 - \varepsilon)^n \omega_v^n + \varepsilon^n \omega_u^n.$$

Modified comparison and the assumption would therefore imply

$$q^n(1 - \varepsilon)^n \int_U \omega_v^n + q^n \varepsilon^n \int_U \omega_u^n \leq \int_U \omega_u^n \leq c \int_U \omega_v^n.$$

All integrals are finite, so the choice $q^n(1 - \varepsilon)^n > c$ and the positive volume of U make this impossible. Hence $m \geq 0$. $\square$

Corollary 10.2.1 *Every bounded ω -plurisubharmonic function has strictly positive Monge–Ampère mass.*

Proof Let u be a bounded ω -plurisubharmonic function. If $\omega_u^n = 0$, then [Theorem 10.2.2](#), applied with $c = 0$ and the constant potential $v = \sup_X u + 1$, would give $u \geq v$, a contradiction. $\square$

The positive lower bound in [Corollary 10.2.1](#) depends on the potential. A bound that is uniform over all bounded potentials is the condition $v_-(\omega) > 0$ of [Definition 6.5.1](#).

Corollary 10.2.2 *If $u, v \in \text{PSH}(X, \omega) \cap L^\infty(X)$ and $\lambda > 0$, then*

$$e^{-\lambda v} \omega_v^n \geq e^{-\lambda u} \omega_u^n \implies v \leq u.$$

Proof For every $t > 0$, the assumption gives $\omega_u^n \leq e^{-\lambda t} \omega_v^n$ on $\{u < v - t\}$. Since $\omega_{v-t} = \omega_v$, **Theorem 10.2.2**, applied to u and $v - t$, gives $u \geq v - t$. Letting $t \downarrow 0$ proves $v \leq u$. $\square$

10.3 Capacity estimates and uniform compactness

Let $\text{Cap} = \text{Cap}_\omega$ denote the capacity of **Section 1.8**. Modified comparison bounds the capacity of a thin sublevel set by the Monge–Ampère mass of a slightly larger one. For an L^p density, **Corollary 1.8.1** bounds this mass by the square of the capacity. Iterating the two inequalities gives a lower bound for the capacity of every sublevel set of fixed height above the minimum. Since the capacity of deep sublevel sets of normalized potentials is small by the tail estimate (1.15), this bounds the depth of a normalized solution.

Lemma 10.3.1 *Let $u, v \in \text{PSH}(X, \omega) \cap L^\infty(X)$, with $-H \leq v \leq 0$ and $H \geq 1$. Fix $0 < \varepsilon < 1$, and put*

$$m = \inf_X (u - (1 - \varepsilon)v), \quad U_s = \{u < (1 - \varepsilon)v + m + s\}.$$

There are $\delta_\varepsilon > 0$, depending only on (X, ω, ε) , and $C_H > 0$, depending only on (n, H) , such that

$$t^n \text{Cap}(U_s) \leq C_H \int_{U_{s+t}} \omega_u^n \quad (0 < s, t, s + t < \delta_\varepsilon). \quad (10.5)$$

Every U_s , $s > 0$, has positive capacity.

Proof Let B_0 be the constant of **Theorem 10.2.1**, and set

$$\delta_\varepsilon = \min\{1 - \varepsilon, \varepsilon^3 / (128 B_0 n^2)\}.$$

For a capacity test $0 \leq \rho \leq 1$, put

$$\tau = \frac{t}{2(1 - \varepsilon)(H + 1)}, \quad w = (1 - \tau)v + \tau\rho, \quad m' = \inf_X (u - (1 - \varepsilon)w).$$

Then $0 < \tau < 1$ and $0 \leq (1 - \varepsilon)(w - v) \leq t/2$, so $m - t/2 \leq m' \leq m$. Consequently

$$U_s \subset V := \{u < (1 - \varepsilon)w + m' + s + t/2\} \subset U_{s+t}.$$

We apply modified comparison to u, w at height $s + t/2 < \delta_\varepsilon$; by the choice of δ_ε , its inverse factor is at most $(8/7)^n$. Moreover,

$$\omega_{(1-\varepsilon)w} \geq (1-\varepsilon)\tau\omega_\rho = \frac{t}{2(H+1)}\omega_\rho.$$

Integrating over $U_s \subset V$, applying modified comparison on V , and taking the supremum over ρ , we obtain (10.5) with $C_H = [2(H+1)]^n(8/7)^n$. Finally, each U_s is nonempty by the definition of the infimum, so it has positive smooth volume by Lemma 1.3.4, and hence positive capacity, as the constant test function shows. $\square$

Lemma 10.3.2 *In the preceding setting, suppose*

$$\int_E \omega_u^n \leq A \operatorname{Cap}(E)^2 \quad (E \subset X \text{ Borel}), \quad A > 0.$$

For every $0 < D < \delta_\varepsilon$,

$$\operatorname{Cap}(U_D) \geq \frac{D^n}{4^n C_H A}. \quad (10.6)$$

Proof Write $a(s) = \operatorname{Cap}(U_s)^{1/n} > 0$ and $K = (C_H A)^{1/n}$. The preceding lemma and the hypothesis, applied to $E = U_{s+t}$, give

$$t a(s) \leq K a(s+t)^2 \quad (s+t < \delta_\varepsilon).$$

Suppose, to the contrary, that $4Ka(D) < D$. Starting with $s_0 = D$, define

$$t_j = 2Ka(s_j), \quad s_{j+1} = s_j - t_j.$$

We check that $s_{j+1} > 0$ before applying the sublevel inequality. If $a(s_i) \leq 2^{-i}a(D)$ for $0 \leq i \leq j$, then

$$\sum_{i=0}^j t_i \leq 2Ka(D) \sum_{i=0}^j 2^{-i} < 4Ka(D) < D.$$

Hence $s_{j+1} > 0$, and the sublevel inequality with $s = s_{j+1}$ and $t = t_j$ gives $a(s_{j+1}) \leq a(s_j)/2$. By induction, every step is justified, and $s_j \downarrow s_\infty \geq D - 4Ka(D) > 0$. Monotonicity gives $0 < a(s_\infty) \leq a(s_j) \leq 2^{-j}a(D)$, a contradiction. Therefore $D \leq 4Ka(D)$, which is (10.6). $\square$

Theorem 10.3.1 *There are constants $C_p, c_p > 0$, depending only on (X, ω, dV, p) , such that, whenever $u \in \operatorname{PSH}(X, \omega) \cap L^\infty(X)$, $\sup_X u = 0$, and*

$$\omega_u^n = F dV, \quad F \in L^p(X, dV), \quad F \geq 0,$$

we have

$$\|u\|_\infty \leq C_p(1 + \|F\|_p), \quad \|F\|_p \geq c_p. \quad (10.7)$$

Proof By Corollary 10.2.1, F is not almost everywhere zero. Apply Lemma 10.3.2 with $v = 0$, $H = 1$, $\varepsilon = 1/2$, and $A = C\|F\|_p > 0$, where C is the constant of

Corollary 1.8.1. Fix $D = \delta_{1/2}/2$, and put $M = -\inf_X u$. Since $U_D = \{u < -M + D\}$, the resulting inequality reads

$$\text{Cap}(\{u < -M + D\}) \geq c/\|F\|_p.$$

If $M > D + 1$, (1.15) bounds this capacity above by $C/(M - D)$, and the first assertion follows; the case $M \leq D + 1$ is immediate. Bounding the same capacity above by $\text{Cap}(X)$ gives the second assertion. $\square$

Suppose that two uniformly bounded solutions are far apart at some point. The preceding estimates give a fixed positive lower bound for the capacity of a sublevel set of their difference. If their L^1 distance is small, this set has small volume, and the uniform L^p bound for the densities then makes its Monge–Ampère mass small. This contradicts the sublevel estimate (10.5), and so upgrades L^1 compactness to uniform compactness. Put $p' = p/(p - 1)$.

Theorem 10.3.2 Suppose $u_j \in \text{PSH}(X, \omega) \cap C(X)$, $\sup_X u_j = 0$, and

$$\omega_{u_j}^n = F_j \, dV, \quad F_j \geq 0, \quad \sup_j \|F_j\|_p < \infty$$

for the fixed $p > 1$. If (u_j) is Cauchy in $L^1(X, dV)$, then it is Cauchy uniformly. In particular, every such family has a subsequence converging uniformly to a continuous ω -plurisubharmonic function.

Proof By Theorem 10.3.1, there is a common $H \geq 1$ with $-H \leq u_j \leq 0$. Suppose that the sequence is not uniformly Cauchy. After exchanging indices if necessary, we find $a > 0$ and arbitrarily large j, k with

$$S := \inf_X (u_k - u_j) \leq -a.$$

Choose $0 < \varepsilon < 1$ such that $\varepsilon H < a/4$, and choose a fixed $D > 0$ with $2D < \delta_\varepsilon$ and $2D < a/4$. Apply the preceding sublevel lemmas with $u = u_k$ and $v = u_j$. Since $v \leq 0$, $m = \inf(u - (1 - \varepsilon)v) \leq S$. Thus

$$U_{2D} \subset \{u - v < S + 2D + \varepsilon H\} \subset \{|u - v| > a/2\}.$$

The capacity lower bound (10.6), with a constant A independent of j, k given by Corollary 1.8.1, yields $\text{Cap}(U_D) \geq c > 0$. On the other hand, (10.5) and the inequalities of Hölder and Chebyshev give

$$\begin{aligned} D^n \text{Cap}(U_D) &\leq C_H \int_{U_{2D}} F_k \, dV \\ &\leq C_H \|F_k\|_p \left(\frac{2\|u_k - u_j\|_1}{a} \right)^{1/p'} \longrightarrow 0. \end{aligned}$$

This contradiction proves that the sequence is uniformly Cauchy. For the last assertion, the normalized compactness theorem, Theorem 1.4.1, gives an L^1 -Cauchy

subsequence of any such family. Its uniform limit is continuous, and distributional convergence preserves ω -plurisubharmonicity. $\square$

10.4 Construction of continuous solutions

Smooth approximation gives solutions with unknown normalization constants. A Gauduchon trace bounds these constants above, and the lower bound for the density norm in [Theorem 10.3.1](#) bounds them away from zero. The resulting uniform L^p bound puts the potentials in the compact family of [Theorem 10.3.2](#), so their limit solves the prescribed equation.

Proof (of [Theorem 10.1.1](#)) Choose smooth strictly positive functions $f_j \rightarrow f$ in $L^p(X, dV)$. By [Theorem 9.1.1](#), there are smooth u_j with $\omega_{u_j} > 0$ and constants c_j such that

$$\omega_{u_j}^n = c_j f_j dV, \quad \sup_X u_j = 0, \quad c_j > 0.$$

We first bound the constants. For $n \geq 2$, fix a Gauduchon metric γ . By [Proposition 4.2.2](#),

$$c_j^{1/n} A_j \leq \int_X \omega \wedge \gamma^{n-1}, \quad A_j = \int_X (f_j dV / \gamma^n)^{1/n} \gamma^n.$$

Since $|x^{1/n} - y^{1/n}| \leq |x - y|^{1/n}$ for $x, y \geq 0$, Hölder's inequality gives $A_j \rightarrow A > 0$, where $A = \int_X (f dV / \gamma^n)^{1/n} \gamma^n$. Thus c_j is bounded above. In dimension one, Stokes' theorem gives the same estimate, with $A_j = \int_X f_j dV$.

The lower bound for the density norm in [Theorem 10.3.1](#) gives $c_j \|f_j\|_p \geq c_p$, so the constants are bounded away from zero. The densities $c_j f_j$ are therefore uniformly bounded in L^p , and the same theorem gives a common bound for the u_j . By [Theorem 1.4.1](#), we may pass to a subsequence with $c_j \rightarrow c > 0$ and u_j Cauchy in L^1 . By [Theorem 10.3.2](#), $u_j \rightarrow u$ uniformly, with u continuous and $\sup_X u = 0$.

Bounded Bedford–Taylor continuity gives $\omega_{u_j}^n \rightarrow \omega_u^n$, while $c_j f_j \rightarrow c f$ in L^p . Hence $\omega_u^n = c f dV$, as required. $\square$

For the exponential equation, the role of the normalization constant is played by $e^{\lambda \sup_X u}$. Its upper bound comes from Jensen's inequality: weighting the Gauduchon volume by the n th root of the density relates $\sup_X u$ to the Gauduchon trace of ω_u , which does not depend on u . The lower bound for the density norm again gives the reverse bound.

Lemma 10.4.1 *Fix $\lambda > 0$. Suppose that smooth functions u_j with $\omega_{u_j} > 0$ solve*

$$\omega_{u_j}^n = e^{\lambda u_j} f_j dV,$$

where the smooth strictly positive functions f_j converge in L^p to a nonnegative nonzero f . Then $M_j = \sup_X u_j$ is bounded above and below, uniformly in j .

Proof Absorbing the fixed smooth positive ratio dV/ω^n into f_j and f preserves their L^p convergence, so we may assume $dV = \omega^n$. Choose $\rho > 0$ smooth with $\text{dd}^c(\rho\omega^{n-1}) = 0$, using [Theorem 4.1.1](#); for $n = 1$, take $\rho = 1$. Put

$$\alpha = \int_X \rho \omega^n, \quad A_j = \int_X f_j^{1/n} \rho \omega^n, \quad \psi_j = u_j - M_j \leq 0.$$

Set $A = \int_X f^{1/n} \rho \omega^n$. The inequality for n th roots used in the preceding existence proof gives $A_j \rightarrow A > 0$. Since $\text{dd}^c(\rho\omega^{n-1}) = 0$, the trace $\int_X \omega_{u_j} \wedge \rho\omega^{n-1}$ equals α ; the arithmetic–geometric mean inequality therefore implies

$$\alpha = \int_X \omega_{u_j} \wedge \rho\omega^{n-1} \geq e^{\lambda M_j/n} \int_X e^{\lambda \psi_j/n} f_j^{1/n} \rho \omega^n.$$

Applying Jensen’s inequality to the probability measure $A_j^{-1} f_j^{1/n} \rho \omega^n$ and taking logarithms, we obtain

$$\lambda M_j \leq n \log(\alpha/A_j) + \frac{\lambda}{A_j} \int_X (-\psi_j) f_j^{1/n} \rho \omega^n. \quad (10.8)$$

By [Lemma 1.5.1](#), the normalized potentials ψ_j have uniform L^q bounds for every finite q . With $q = np/(np - 1)$, Hölder’s inequality gives a uniform bound for the last integral, since $\|f_j^{1/n}\|_{np} = \|f_j\|_p^{1/n}$. This proves the upper bound for M_j .

Finally, the density $F_j = e^{\lambda u_j} f_j$ satisfies $\|F_j\|_p \leq e^{\lambda M_j} \|f_j\|_p$. The lower-density bound of [Theorem 10.3.1](#), applied to ψ_j , gives $c_p \leq e^{\lambda M_j} \|f_j\|_p$, which bounds M_j below. $\square$

Proof (of [Theorem 10.1.2](#)) Choose smooth strictly positive functions $f_j \rightarrow f$ in L^p . By [Theorem 9.6.1](#), there are smooth u_j with $\omega_{u_j} > 0$ and $\omega_{u_j}^n = e^{\lambda u_j} f_j dV$. The preceding lemma bounds $M_j = \sup_X u_j$, and consequently bounds $F_j = e^{\lambda u_j} f_j$ in L^p . The normalized potentials $\psi_j = u_j - M_j$ are uniformly bounded by [Theorem 10.3.1](#). We may pass to a subsequence with $M_j \rightarrow M$ and ψ_j Cauchy in L^1 . [Theorem 10.3.2](#) gives uniform convergence $u_j \rightarrow u \in \text{PSH}(X, \omega) \cap C(X)$.

Uniform convergence and $f_j \rightarrow f$ in L^p give $e^{\lambda u_j} f_j \rightarrow e^{\lambda u} f$ in L^p , and continuity of bounded products therefore gives $\omega_u^n = e^{\lambda u} f dV$. Uniqueness, even among all bounded solutions, follows from bounded exponential comparison, [Corollary 10.2.2](#). $\square$

For the exponential equation, a larger density gives a smaller solution, since the factor $e^{\lambda u}$ has to compensate for the increase. Bounded exponential comparison gives this monotonicity even where the densities vanish.

Lemma 10.4.2 *Let $\lambda > 0$, and let f_a, f_b be nonnegative nonzero L^p densities. Suppose that $a, b \in \text{PSH}(X, \omega) \cap L^\infty(X)$ solve*

$$\omega_a^n = e^{\lambda a} f_a dV, \quad \omega_b^n = e^{\lambda b} f_b dV.$$

If $f_a \leq f_b$ almost everywhere, then $b \leq a$ on X .

Proof Since $f_a \leq f_b$, the two equations give $e^{-\lambda b} \omega_b^n \geq e^{-\lambda a} \omega_a^n$. Hence $b \leq a$ by [Corollary 10.2.2](#), applied with $u = a$ and $v = b$. $\square$

Corollary 10.4.1 *Every bounded ω -plurisubharmonic solution of $\omega_u^n = f \, dV$ is continuous.*

Proof Since u is bounded, the density $e^{-u} f$ is nonnegative, nonzero and belongs to L^p . By [Theorem 10.1.2](#), applied with $\lambda = 1$ to this density, there is a continuous solution r of

$$\omega_r^n = e^{r-u} f \, dV.$$

The bounded potential u solves the same exponential equation. Applying [Lemma 10.4.2](#) with $f_a = f_b = e^{-u} f$ in both orders gives $u = r$, so u is continuous. $\square$

10.5 The vanishing exponent and scalar uniqueness

To show that the constant in [Theorem 10.1.1](#) is unique, we compare the solution u_λ of (10.1) with constant translates of a solution u of the normalized equation. Translating u by its maximum and by its minimum gives two barriers for the exponential equation, whose separation is the oscillation of u . After multiplication by λ , both barriers converge to the logarithm of the constant as $\lambda \downarrow 0$. Since u_λ depends only on f and λ , the constant is determined by f .

Proposition 10.5.1 *Suppose $u \in \text{PSH}(X, \omega) \cap C(X)$ and $c > 0$ satisfy $\omega_u^n = c f \, dV$. Set $m = \inf_X u$ and $M = \sup_X u$. Then, for every $\lambda > 0$, the solution of (10.1) satisfies*

$$u + \frac{\log c}{\lambda} - M \leq u_\lambda \leq u + \frac{\log c}{\lambda} - m. \quad (10.9)$$

In particular,

$$\|\lambda u_\lambda - \log c\|_\infty \leq \lambda(M - m), \quad e^{\lambda u_\lambda} \longrightarrow c \quad \text{uniformly on } X \text{ as } \lambda \downarrow 0.$$

Consequently, c is the only constant for which the equation $\omega_v^n = c f \, dV$ has a solution $v \in \text{PSH}(X, \omega) \cap C(X)$.

Proof Set $a = u + \lambda^{-1} \log c - M$ and $b = u + \lambda^{-1} \log c - m$. These translates of u have the same Monge–Ampère measure as u , and since $m \leq u \leq M$,

$$e^{\lambda a} f \, dV \leq c f \, dV = \omega_a^n = \omega_b^n \leq e^{\lambda b} f \, dV.$$

Thus $e^{-\lambda a} \omega_a^n \geq f \, dV = e^{-\lambda u_\lambda} \omega_{u_\lambda}^n \geq e^{-\lambda b} \omega_b^n$. Applying [Corollary 10.2.2](#) first to the pair (u_λ, a) and then to the pair (b, u_λ) gives $a \leq u_\lambda \leq b$, which is (10.9). Multiplying these inequalities by λ and using $m \leq u \leq M$ gives the norm bound, and the uniform convergence follows.

If (v, c') is another such pair, the same argument applied to v gives $\lambda u_\lambda \rightarrow \log c'$, because u_λ depends only on f and λ . Hence $c' = c$. $\square$

The barriers also give $\text{osc}_X u_\lambda \leq 2(M - m)$, and the densities $e^{\lambda u_\lambda} f$ converge to $c f$ in L^p . By [Theorem 10.3.2](#), the normalized potentials $u_\lambda - \sup_X u_\lambda$ are therefore precompact in $C^0(X)$ as $\lambda \downarrow 0$, and every cluster point solves the equation with constant c . Uniqueness of the constant does not, however, single out one cluster point; [Proposition 13.19.1](#) describes the symmetries that these limits inherit.

For C^2 potentials, uniqueness of the constant also follows directly from the maximum principle: replacing one potential v by $(1 + \varepsilon)v$ leaves a strictly positive multiple of ω in reserve at an extremum.

Proposition 10.5.2 *Let $u, v \in C^2(X, \mathbb{R})$, and set $A = \omega + \text{dd}^c u$ and $B = \omega + \text{dd}^c v$. If $A, B \geq 0$ and $A^n = cB^n$ for a constant $c > 0$, then $c = 1$.*

Proof Fix $\varepsilon > 0$. At a maximum point of $u - (1 + \varepsilon)v$, the complex Hessian of this function is nonpositive, so that

$$A + \varepsilon\omega \leq (1 + \varepsilon)B.$$

At this point $B > 0$, because $A + \varepsilon\omega > 0$. Monotonicity of the determinant and $A^n = cB^n$ give $c \leq (1 + \varepsilon)^n$. Letting $\varepsilon \downarrow 0$ gives $c \leq 1$, and interchanging the two potentials gives $c^{-1} \leq 1$. $\square$

10.6 Normalization on the Hopf threefold

In this section, X is the Hopf threefold of [Chapter 8](#), with its Hermitian form ω and projection $\pi : X \rightarrow \mathbb{P}^2$. Recall that $\alpha = \pi^* \omega_{\text{FS}}$ and $\beta = \omega - \alpha$, and that $\nu = \omega^3/6$ is a probability measure. We write E for the elliptic fiber, τ_a for the translation by $a \in E$, dA_E for the probability Haar measure of E , and A for the fiber-averaging operator of [Proposition 8.6.1](#).

The minimum-mass characterization in that proposition gives a lower bound for the normalization constant, and equality forces every solution to descend to the projective base. The uniform L^p control of this chapter makes the equality case stable under limits of the data, although the densities themselves need only converge weakly.

Here we take $dV = \omega^3$; the density f is still a nonnegative nonzero function in L^p . By [Theorem 10.1.1](#) and [Proposition 10.5.1](#), there is a unique positive constant c_f for which the equation

$$(\omega + \text{dd}^c u)^3 = c_f f \omega^3$$

has a continuous ω -plurisubharmonic solution. Put $I_f = \int_X f d\nu$.

Proposition 10.6.1 *One has $c_f I_f \geq 1$, and every continuous solution u satisfies*

$$\|u - Au\|_{L^2(X, \nu)}^2 \leq 4(c_f I_f - 1). \quad (10.10)$$

Moreover, $c_f I_f = 1$ if and only if $f = \pi^ g$ almost everywhere with respect to ν , for some nonnegative $g \in L^p(\mathbb{P}^2, \omega_{\text{FS}}^2)$. In this case every continuous solution is the pullback of a continuous ω_{FS} -plurisubharmonic function.*

Proof Integrating the equation gives $\int_X \omega_u^3 = 6c_f I_f$. Both the inequality $c_f I_f \geq 1$ and (10.10) therefore follow from (8.20), whose left-hand side is nonnegative.

Suppose $c_f I_f = 1$. By Proposition 8.6.1, $u = \pi^* q$ for a bounded ω_{FS} -plurisubharmonic function q ; local holomorphic sections of π show that q is continuous. Thus $u \circ \tau_a = u$ for every $a \in E$. Since bounded products are natural under biholomorphisms and ω is invariant under the translations, it follows that

$$\tau_a^*(f\nu) = f\nu \quad (a \in E).$$

As f is defined only almost everywhere, we use this invariance as an identity of measures.

By Fubini's theorem, the fiber average Af is defined almost everywhere. It equals $\pi^* g$ for a measurable function g on the base, because local trivializations differ by translations of the Haar variable. Jensen's inequality gives

$$\int_{\mathbb{P}^2} |g|^p \omega_{\text{FS}}^2 \leq \int_X |f|^p d\nu.$$

For every continuous real test function χ on X , the invariance of the measure gives $\int_X \chi f d\nu = \int_X (\chi \circ \tau_a) f d\nu$. Integrating in a , and using Fubini's theorem together with the invariance of Haar measure under $a \mapsto -a$, we obtain $\int_X \chi f d\nu = \int_X \chi Af d\nu$. Hence $f = Af = \pi^* g$ almost everywhere, with $g \geq 0$.

Conversely, suppose $f = \pi^* g$ almost everywhere. Disintegration gives $I_f = \int_{\mathbb{P}^2} g \omega_{\text{FS}}^2$. Applying Theorem 10.1.1 on the base, we find a continuous ω_{FS} -plurisubharmonic function q and a constant $k > 0$ with $(\omega_{\text{FS}} + \text{dd}^c q)^2 = k g \omega_{\text{FS}}^2$. Bounded decreasing regularization and Stokes' theorem give $\int_{\mathbb{P}^2} (\omega_{\text{FS}} + \text{dd}^c q)^2 = 1$, so $k = I_f^{-1}$.

Put $u = \pi^* q$. To compute its bounded product, take smooth strictly ω_{FS} -plurisubharmonic functions $q_j \downarrow q$ by Theorem 1.11.1. Their pullbacks decrease to u and are strictly ω -plurisubharmonic. Since $\alpha^3 = \beta^2 = 0$, the smooth cube identity gives, for each j ,

$$(\omega + \text{dd}^c \pi^* q_j)^3 = 3\pi^*(\omega_{\text{FS}} + \text{dd}^c q_j)^2 \wedge \beta.$$

In a local trivialization, the right-hand side is $6dA_E$ times the base measure $(\omega_{\text{FS}} + \text{dd}^c q_j)^2$: the horizontal components of β vanish against the base top-degree form, and its vertical restriction is $2dA_E$. Continuity of bounded products on the base and on X , tested in these trivializations and patched by a partition of unity, therefore gives

$$(\omega + \text{dd}^c u)^3 = \frac{f}{I_f} \omega^3.$$

Uniqueness of the constant implies $c_f = I_f^{-1}$. Every continuous solution then has mass 6, so the mass characterization in Proposition 8.6.1 makes it a pullback from the base, and the descended potential is continuous by local sections, as above. $\square$

When $c_f I_f$ is close to one, compactness gives uniform convergence of subsequences of potentials and weak convergence of their densities, and the equality case identifies the limits.

Proposition 10.6.2 *Fix $1 < p < \infty$ and $M \geq 1$. Suppose $f_j \geq 0$ satisfy*

$$\int_X f_j \, d\nu = 1, \quad \|f_j\|_{L^p(X, \nu)} \leq M, \quad c_{f_j} \longrightarrow 1.$$

For each j , let u_j be any continuous solution of $\omega_{u_j}^3 = c_{f_j} f_j \omega^3$ normalized by $\sup_X u_j = 0$. Then

$$\|u_j - Au_j\|_{C^0(X)} \longrightarrow 0, \quad f_j - Af_j \rightharpoonup 0 \text{ weakly in } L^p(X, \nu).$$

Every subsequence has a further subsequence with $u_j \rightarrow \pi^ q$ uniformly and $f_j \rightharpoonup \pi^* g$ weakly in L^p , where q is a continuous ω_{FS} -plurisubharmonic function, $g \geq 0$, $\int_{\mathbb{P}^2} g \omega_{\text{FS}}^2 = 1$, and*

$$(\omega_{\text{FS}} + \text{dd}^c q)^2 = g \omega_{\text{FS}}^2.$$

Proof Since the constants c_{f_j} converge, the densities $c_{f_j} f_j$ have a common L^p bound. By [Theorem 10.3.2](#), every subsequence has a further subsequence on which $u_j \rightarrow u$ uniformly. Since L^p is reflexive, a further extraction gives $f_j \rightharpoonup f$ weakly in L^p . Positivity, the unit integral and the bound $\|f\|_p \leq M$ pass to the limit, and continuity of bounded products under uniform convergence gives

$$(\omega + \text{dd}^c u)^3 = f \omega^3.$$

Thus $c_f = 1$. Since also $I_f = 1$, [Proposition 10.6.1](#) gives $u = \pi^* q$ and $f = \pi^* g$. The bounded cube identity proved there, tested against pullbacks of continuous functions on the base, gives the asserted base equation. In particular, both limits are fixed by A .

Haar averaging is a contraction on $C^0(X)$ and on $L^p(X, \nu)$. It is also self-adjoint with respect to ν : Fubini's theorem and the invariance of ν under the fiber translations give $\int \chi A f \, d\nu = \int A \chi f \, d\nu$ for $\chi \in L^{p'}$. Along the extracted subsequence, therefore, $u_j - Au_j \rightarrow 0$ uniformly and $f_j - Af_j \rightharpoonup 0$ in L^p . If either convergence failed for the original sequence, some subsequence would stay away from the limit (for the weak convergence, when tested against one fixed function in $L^{p'}$), and a further subsequence of the kind just constructed would give a contradiction. This proves both conclusions for the whole sequence. $\square$

Example 10.6.1 Choose $0 < a < 1/2$, and use the function $s = \log |z|^2$ on the covering space $\mathbb{C}^3 \setminus \{0\}$ from [Chapter 8](#). Since s changes by -2 under the defining contraction, every 2-periodic function of s descends to X . For an integer $m \geq 1$, define the smooth normalized potential

$$u_m = \frac{a}{\pi^2 m^2} (\cos(\pi m s) - 1), \quad \|u_m - Au_m\|_{C^0} = \frac{a}{\pi^2 m^2} \longrightarrow 0.$$

Primes below denote derivatives with respect to s . Since $dd^c s = \alpha$ and $ds \wedge d^c s = \beta$, the chain rule gives

$$\omega + dd^c u_m = (1 + u'_m)\alpha + (1 + u''_m)\beta, \quad u'_m = -\frac{a}{\pi m} \sin(\pi m s), \quad u''_m = -a \cos(\pi m s).$$

Both coefficients are bounded below by positive constants independent of m . The rank identities $\alpha^3 = \beta^2 = 0$ imply

$$(\omega + dd^c u_m)^3 = H_m \omega^3, \quad H_m = \left(1 - \frac{a}{\pi m} \sin(\pi m s)\right)^2 (1 - a \cos(\pi m s)).$$

On each fiber, s is twice the real Haar coordinate plus a constant depending on the base point, so its distribution modulo 2 is uniform. When the periodic expression $H_m = (1 + u'_m)^2 (1 + u''_m)$ is averaged, the terms $u'_m, u''_m, u'_m u''_m$ and $(u'_m)^2 u''_m$ contribute zero, since they are derivatives of periodic functions. Hence

$$I_m := \int_X H_m \, dv = AH_m = 1 + \frac{a^2}{2\pi^2 m^2}.$$

Set $f_m = H_m/I_m$. These smooth densities have unit integral and common strictly positive lower and finite upper bounds. Uniqueness of the constant gives $c_{f_m} = I_m \rightarrow 1$, and $Af_m = 1$. Nevertheless,

$$\|f_m - 1 + a \cos(\pi m s)\|_{C^0(X)} = O(m^{-1}), \quad \lim_{m \rightarrow \infty} \|f_m - Af_m\|_{L^1(X, \nu)} = \frac{2a}{\pi} > 0.$$

Here the constant in $O(m^{-1})$ depends only on a , and the last identity uses the fact that the average of $|\cos|$ over a period is $2/\pi$. Thus near equality does not imply strong L^1 convergence to the fiber average, even for uniformly positive bounded smooth densities. For any pullback g of a function on the base, the contraction property gives $\|f_m - Af_m\|_1 \leq 2\|f_m - g\|_1$, so approximation by such pullbacks also fails in L^1 .

10.7 Stability for concave equations

We now consider fully nonlinear equations defined by a concave symmetric function of the eigenvalues of $\omega^{-1}(\chi + dd^c u)$. For such equations, a fixed admissible reference with a strict asymptotic gap replaces the determinant bounds used above: it bounds the positive matrix perturbations of the reference along which the operator stays below a given level. An auxiliary Monge–Ampère equation, whose density is concentrated

where the difference of two solutions is nearly maximal, then shows that this set cannot be small. The resulting stability estimate remains uniform when the positive right-hand sides tend to zero.

Throughout this section and the next, $n \geq 2$, and χ is a fixed smooth real $(1, 1)$ -form on X . In these two sections the letter f denotes the function of eigenvalues introduced below, not the density fixed at the beginning of the chapter. For a smooth real function w and an endomorphism A of $T^{1,0}X$ that is Hermitian with respect to ω , put

$$A_w = \omega^{-1}(\chi + \text{dd}^c w), \quad F(A) = f(\lambda(A)),$$

where $\lambda(A) \in \mathbb{R}^n$ is the vector of eigenvalues of A . Let Γ be an open convex symmetric cone with $\Gamma_n \subseteq \Gamma \subseteq \Gamma_1$, where Γ_n is the positive orthant and $\Gamma_1 = \{\sum_i \lambda_i > 0\}$. Assume that $f \in C^\infty(\Gamma) \cap C^0(\bar{\Gamma})$ is symmetric, concave, positive on Γ , zero on $\partial\Gamma$, and satisfies

$$f_i > 0, \quad \lim_{t \rightarrow \infty} f(t\lambda) = +\infty \quad (\lambda \in \Gamma),$$

where $f_i = \partial f / \partial \lambda_i$. We call w *admissible* if $\lambda(A_w) \in \Gamma$ everywhere. Write $e_1, \dots, e_n$ for the standard basis of $\mathbb{R}^n$ and $\mathbf{1} = (1, \dots, 1)$. For $\mu \in \Gamma$, define

$$f_{\infty,i}(\mu) = \lim_{t \rightarrow \infty} f(\mu + te_i), \quad f_\infty(\mu) = \min_i f_{\infty,i}(\mu),$$

allowing the value $+\infty$. Fix a smooth admissible function $\underline{u}$ and positive constants H_0, δ_0 . We consider smooth admissible solutions u of

$$F(A_u) = h, \quad 0 < h \leq H_0, \quad f_\infty(\lambda(A_{\underline{u}}(x))) \geq h(x) + \delta_0,$$

where the right-hand side h is a positive function on X ; the last condition is the strict asymptotic gap at the reference $\underline{u}$. The right-hand sides satisfying these two conditions form the *family* of right-hand sides, and the solutions are normalized by $\inf_X u = 0$. We call $X, \omega, \chi, f, \Gamma, \underline{u}, H_0, \delta_0$ the *fixed data*; all constants in this section depend only on them. Norms are taken with respect to ω^n , and $\langle a \rangle_\omega = (\int_X \omega^n)^{-1} \int_X a \omega^n$ denotes the average of a function a .

Lemma 10.7.1 *There are a positive continuous function H on X and constants $r, R, \delta > 0$ with the following properties. Every right-hand side in the family satisfies $h \leq H$; on X ,*

$$\mu - 2r\mathbf{1} \in \Gamma, \quad f_\infty(\mu - 2r\mathbf{1}) \geq H + 3\delta, \quad \mu = \lambda(A_{\underline{u}});$$

and at every point of X , every positive semidefinite Hermitian endomorphism P satisfies

$$F(A_{\underline{u}} - r \text{Id} + P) \leq H + 2\delta \implies P \leq R \text{Id}.$$

Proof Each $f_{\infty,i}$ is an increasing limit of positive concave functions, hence concave with values in $(0, +\infty]$. Suppose it is infinite at one point and finite at another point of Γ . Extend the segment joining them slightly beyond the second point, inside the open cone. The second point is then an interior point of the longer segment, so

concavity forces the value there to be infinite, a contradiction. Thus $f_{\infty,i}$ is either finite everywhere, and then continuous, or infinite everywhere. By symmetry, the same alternative holds for every i .

Take $\delta = \frac{1}{8} \min\{\delta_0, \min_X f(\mu)\} > 0$. In the finite case set $H = \min\{H_0, f_{\infty}(\mu) - 4\delta\}$; otherwise set $H = H_0$. Since $f_{\infty}(\mu) \geq f(\mu) \geq 8\delta$, this function is positive. The conditions on the family give $h \leq H$ and $f_{\infty}(\mu) \geq H + 4\delta$. Since $\mu(X)$ is a compact subset of Γ and the functions $f_{\infty,i}$ are continuous (or identically infinite), a sufficiently small $r > 0$ gives $\mu - 2r\mathbf{1} \in \Gamma$ and $f_{\infty}(\mu - 2r\mathbf{1}) \geq H + 3\delta$ on X .

If the matrix bound failed, there would be points $x_j \rightarrow x_*$ and $P_j \geq 0$ with unbounded norms and $F(A_{\underline{u}}(x_j) - r \text{Id} + P_j) \leq H(x_j) + 2\delta$. By monotonicity of eigenvalues, the ordered eigenvalues $\lambda^{(j)}$ of $A_{\underline{u}}(x_j) - r \text{Id} + P_j$ satisfy $\lambda_i^{(j)} \geq \mu_i(x_j) - r$. Their sum tends to infinity, so some component k tends to infinity along a subsequence. For every fixed $t > 0$, eventually

$$\lambda^{(j)} \geq \mu(x_*) - 2r\mathbf{1} + te_k.$$

Since f is increasing in each variable, letting $t \rightarrow \infty$ shows that the lower limit of $F(A_{\underline{u}}(x_j) - r \text{Id} + P_j)$ is at least $f_{\infty}(\mu(x_*) - 2r\mathbf{1}) \geq H(x_*) + 3\delta$, which contradicts the upper bound $H(x_j) + 2\delta$. Adding positive semidefinite matrices preserves the cone, so all these comparisons take place in Γ . $\square$

Proposition 10.7.1 *Every solution satisfies $0 \leq u \leq C$.*

Proof Put $\theta = \chi + \text{dd}^c \underline{u}$ and $w = u - \underline{u} - \sup_X(u - \underline{u}) \leq 0$. Since $\Gamma \subseteq \Gamma_1$, we have $\text{tr}_{\omega} \text{dd}^c w \geq -\text{tr}_{\omega} \theta \geq -C$. The Green-kernel argument in the proof of [Proposition 9.10.1](#), applied to the operator $\text{tr}_{\omega} \text{dd}^c$, therefore bounds $\|w\|_{L^1}$ uniformly.

Center a holomorphic coordinate ball of fixed size at a minimum point of w , and rescale it to the real unit ball. For a fixed sufficiently small $\varepsilon > 0$, set $q = w + \varepsilon|x|^2$ and $m = \min_X w$. The real contact-set construction of [\(9.14\)](#) gives a compact set E on which

$$D^2 q \geq 0, \quad q \leq m + \varepsilon/2, \quad |B_{\varepsilon/2}| \leq \int_E \det D^2 q \, dx.$$

On E , $\text{dd}^c w \geq -C\varepsilon\omega$. Choose ε so that $C\varepsilon < r$. Then $P = \omega^{-1}(\text{dd}^c w + r\omega) \geq 0$ and

$$F(A_{\underline{u}} - r \text{Id} + P) = F(A_{\underline{u}}) = h \leq H.$$

Lemma 10.7.1 bounds P , and hence the complex trace of the Hessian of q . The nonnegative real Hessian of q on E therefore has bounded trace, and hence bounded determinant, so the contact inequality implies $|E| \geq c > 0$. Since $w \leq m + \varepsilon/2$ on E , the L^1 bound gives $c(-m - \varepsilon/2) \leq C$. This bounds the oscillation of w , hence that of u ; with the normalization $\inf_X u = 0$, this is the assertion. $\square$

Theorem 10.7.1 *There is a constant C , depending only on the fixed data, such that any two normalized solutions u_1, u_2 with right-hand sides h_1, h_2 in the family satisfy*

$$\|u_1 - u_2\|_\infty \leq C(\|h_1 - h_2\|_\infty + \|u_1 - u_2\|_{L^1}).$$

In particular, C does not depend on a positive lower bound for the h_i or on bounds for their derivatives.

Proof Set $a = u_1 - \underline{u}$, $b = u_2 - \underline{u}$ and $\theta = \chi + \text{dd}^c \underline{u}$. By [Proposition 10.7.1](#), $|a|, |b| \leq C_0$ for a fixed $C_0 \geq 1$. It suffices to bound $s = \max_X(b - a)$ when it is positive; the opposite difference is handled by interchanging the solutions.

Fix r, R, δ from [Lemma 10.7.1](#) and put $\alpha = r\omega$. For every smooth positive ρ with

$$\rho \geq \frac{1}{2}, \quad \langle \rho \rangle_\alpha = 1, \quad \langle \rho^2 \rangle_\alpha \leq 4,$$

[Theorem 9.1.1](#) gives a smooth solution

$$(\alpha + \text{dd}^c \psi)^n = c\rho\alpha^n, \quad \alpha + \text{dd}^c \psi > 0, \quad \sup_X \psi = 0.$$

At a maximum of ψ , $c\rho \leq 1$, so $c \leq 2$. Apply [Theorem 10.3.1](#) with $p = 2$ and background α . Its potential and lower-density bounds give fixed $c_0, C_\psi > 0$ with

$$c \geq c_0, \quad -C_\psi \leq \psi \leq 0.$$

These constants depend only on the three bounds for ρ , and not on the cutoff function chosen below.

Choose $\kappa > 0$ so that $2C_0\kappa \leq 1/4$, $\kappa C_0 \leq 1/16$ and $\kappa C_\psi/2 \leq 1/16$. Next choose $M \geq 1$ with $2^{-n}c_0Mr^n > R^n$, and then $\varepsilon_0 > 0$ with

$$\frac{16}{7}\varepsilon_0 \leq \min\{(2M)^{-1}, M^{-2}\}.$$

If one of the inequalities

$$\|h_1 - h_2\|_\infty \leq \kappa\delta s, \quad \langle (b - a)_+ \rangle_\omega \leq \varepsilon_0 s.$$

fails, then $s \leq C(\|h_1 - h_2\|_\infty + \|u_1 - u_2\|_{L^1})$, with C depending only on $\kappa, \delta, \varepsilon_0$ and the volume of X . We assume both and derive a contradiction. Put $t = \kappa s$; since $s \leq 2C_0$, we have $t \leq 1/4$. On $\Omega = \{(1 - t)b - a > s/2\}$, we have $b - a > 7s/16$, so by Chebyshev's inequality the relative volume of Ω is at most $16\varepsilon_0/7$.

Take a smooth $\zeta : \mathbb{R} \rightarrow [0, 1]$, zero on $(-\infty, 1/2]$ and one on $[3/4, \infty)$, and set

$$\rho = b_0 + M\zeta(((1 - t)b - a)/s), \quad b_0 = 1 - M\langle \zeta(((1 - t)b - a)/s) \rangle_\omega.$$

The second term is supported in Ω , so $1/2 \leq b_0 \leq 1$ and $\langle \rho^2 \rangle_\alpha \leq 2 + 2M^2(16\varepsilon_0/7) \leq 4$; here we use that averages with respect to $\alpha = r\omega$ and ω agree. Thus the auxiliary solution for this ρ satisfies the bounds with the same constants c_0, C_ψ .

At a point where $b - a = s$, the function $\Phi = (1 - t)b - a + t\psi/2$ is at least $7s/8$, by the choice of κ . At a maximum point x_0 of Φ , therefore, $(1 - t)b - a \geq 7s/8$ because $\psi \leq 0$, and so $\rho(x_0) \geq M$. The second derivative test gives, at x_0 ,

$$P = \alpha + \text{dd}^c((a - (1 - t)b)/t) \geq \frac{1}{2}(\alpha + \text{dd}^c\psi) + \frac{1}{2}\alpha > 0.$$

The identity

$$\theta + \text{dd}^c a = t((\theta - \alpha) + P) + (1 - t)(\theta + \text{dd}^c b)$$

and concavity imply

$$F(\omega^{-1}((\theta - \alpha) + P)) \leq h_2 + (h_1 - h_2)/t \leq H + \delta.$$

Both forms in the convex combination are admissible, since $\mu - r\mathbf{1} \in \Gamma$ and $P > 0$. By [Lemma 10.7.1](#), $P \leq R\omega$. On the other hand, $P \geq \frac{1}{2}(\alpha + \text{dd}^c\psi)$, so the auxiliary equation gives

$$R^n \geq P^n/\omega^n \geq 2^{-n}c\rho r^n \geq 2^{-n}c_0Mr^n > R^n,$$

a contradiction. Hence one of the two smallness inequalities fails, which gives the required bound for s . Interchanging the solutions proves the theorem. $\square$

Corollary 10.7.1 *Let $\mathcal{H}$ be a set of right-hand sides in the family that is equicontinuous. Then the normalized solutions with right-hand sides in $\mathcal{H}$ form a precompact subset of $C^0(X)$ and have a common modulus of continuity.*

Proof Admissibility and $\Gamma \subseteq \Gamma_1$ give $\text{tr}_\omega \text{dd}^c u \geq -C$. By [Theorem 4.1.1](#), there is a smooth function $\rho_0 > 0$ with $\text{dd}^c(\rho_0\omega^{n-1}) = 0$, so that $\int_X \text{dd}^c\varphi \wedge \rho_0\omega^{n-1} = 0$ for every smooth φ . Integrating the product rule $\text{dd}^c(u^2) = 2u\text{dd}^c u + 2\text{d}u \wedge \text{d}^c u$ against $\rho_0\omega^{n-1}$, and using $0 \leq u \leq C$ from [Proposition 10.7.1](#), we obtain a uniform bound for $\int_X |\text{d}u|_\omega^2 \omega^n$, because ρ_0 is bounded above and below. Rellich's theorem therefore gives precompactness in L^1 .

Given a sequence of such solutions, the Arzelà–Ascoli theorem gives a subsequence whose right-hand sides converge uniformly, since they are equicontinuous and bounded by H_0 . A further subsequence of the solutions is Cauchy in L^1 , and [Theorem 10.7.1](#) makes it uniformly Cauchy. This proves precompactness in $C^0(X)$. A common modulus of continuity follows from a finite uniform $\varepsilon/3$ -net, since each of its finitely many members is uniformly continuous. $\square$

10.8 Gradient bounds for concave equations

We keep the fixed data, the family of right-hand sides and the normalization of [Section 10.7](#), and assume in addition that $\|\partial h\|_{L^\infty(\omega)} \leq H_1$; throughout the section, u denotes a solution with such a right-hand side h . The gradient bound is obtained by

comparison with a nearby smooth admissible function V . A maximum principle for a weighted gradient quantity bounds the gradient of u in terms of that of V , provided $\|u - V\|_\infty$ is below a threshold that does not depend on the derivatives of V . The C^0 compactness of [Corollary 10.7.1](#) then shows that finitely many such comparison functions suffice for all solutions.

For the derivative calculation, write $U = u/(2\pi)$ and $\underline{U} = \underline{u}/(2\pi)$. Thus $\text{dd}^c u = i\partial\bar{\partial}U$. For any smooth real V , put $\mathcal{A}_V = \omega^{-1}(\chi + i\partial\bar{\partial}V)$ and call V admissible if $\lambda(\mathcal{A}_V) \in \Gamma$. We use the Chern connection of ω , and define the endomorphism $B = DF(\mathcal{A}_U)$ by $\frac{d}{dt}F(\mathcal{A}_U + tM)|_{t=0} = \text{tr}(BM)$. Write $\lambda = (\lambda_1, \dots, \lambda_n) = \lambda(\mathcal{A}_U)$. At a point where $\mathcal{A}_U$ is diagonal in a unitary frame, set

$$B_i = f_i(\lambda), \quad \mathcal{L}q = \sum_i B_i q_{i\bar{i}}, \quad T = \sum_i B_i, \quad |\partial q|_B^2 = \sum_i B_i |q_i|^2.$$

Here subscripts denote frame derivatives, $U_{ki} = \nabla_i U_k$ and $U_{i\bar{j}} = \partial_i \partial_{\bar{j}} U$; the second derivatives U_{ki} need not be symmetric. The trace expressions below do not depend on the unitary frame.

Lemma 10.8.1 *There are fixed $\tau, \kappa > 0$ such that*

$$\begin{aligned} T &\geq \tau, & 0 &\leq \text{tr}(B\mathcal{A}_U) \leq h, \\ \mathcal{L}(U - V) &\leq h \quad (V \text{ admissible}), & \mathcal{L}(\underline{U} - U) &\geq -h. \end{aligned}$$

Moreover, at every point at least one of the alternatives

$$\mathcal{L}(\underline{U} - U) \geq \kappa T, \quad B \geq \kappa T \text{ Id}$$

holds. The constants depend only on the fixed data; in particular they are uniform for all right-hand sides in the family.

Proof If $\lambda(P) \in \Gamma$, then $\mathcal{A}_U + tP$ is admissible for $t \geq 0$. The function $t \mapsto F(\mathcal{A}_U + tP)$ is positive and concave on $[0, \infty)$, so its derivative at $t = 0$ cannot be negative; thus $\text{tr}(BP) \geq 0$. Since F is concave and $F(0) = 0$, the tangent inequality at $\mathcal{A}_U$, evaluated at the origin, gives $\text{tr}(B\mathcal{A}_U) \leq h$. Choose $a_* > 0$ with $F(a_* \text{ Id}) > H_0 + 1$. Concavity gives

$$H_0 + 1 < F(a_* \text{ Id}) \leq h + a_* T - \text{tr}(B\mathcal{A}_U) \leq H_0 + a_* T.$$

Thus $T \geq a_*^{-1}$. Since $\mathcal{L}(U - V) = \text{tr}(B\mathcal{A}_U) - \text{tr}(B\mathcal{A}_V)$ and $\mathcal{L}(\underline{U} - U) = \text{tr}(B\mathcal{A}_\underline{U}) - \text{tr}(B\mathcal{A}_U)$, the remaining two bounds follow from the nonnegativity of $\text{tr}(B\mathcal{A}_V)$ and $\text{tr}(B\mathcal{A}_\underline{U})$.

We derive the alternative from the strict gap. Fix r, H, δ from [Lemma 10.7.1](#), and put $\mu = \lambda(\mathcal{A}_\underline{U})$. Compactness and the gap give one $S > r$ such that

$$f(\mu - 2r\mathbf{1} + Se_i) > H + 2\delta \quad (1 \leq i \leq n)$$

everywhere. We first prove a scalar alternative. At a point of X , let $\lambda \in \Gamma$ satisfy $f(\lambda) = \sigma$, where $\sigma = h$ at that point, and consider the set

$$K = \{v \geq \mu - r\mathbf{1} : f(v) \leq \sigma\}.$$

It is contained in Γ because $\mu - r\mathbf{1} \in \Gamma$, it is closed, and the matrix bound of [Lemma 10.7.1](#), applied to diagonal matrices, makes it bounded; thus K is compact. When nonempty, it contains $\mu - r\mathbf{1}$ and is star-shaped about that point: moving along a segment toward it decreases each coordinate, hence decreases f . Thus K is connected. Let $N = \nabla f(\lambda)$, whose entries are positive, and let Π be the tangent hyperplane $N \cdot (v - \lambda) = 0$.

If $f(\mu - r\mathbf{1}) > \sigma$, concavity gives $N \cdot (\mu - \lambda) > r \sum_i N_i$. Otherwise $\mu - r\mathbf{1} \in K$. The diagonal ray $\mu - r\mathbf{1} + t\mathbf{1}$, $t \geq 0$, meets $\{f = \sigma\}$, since f diverges along it; at the meeting point v , the tangent inequality gives $N \cdot (v - \lambda) \geq 0$. If Π misses K , connectedness makes $N \cdot (v - \lambda)$ strictly positive throughout K , and in particular at $\mu - r\mathbf{1}$; this again gives $N \cdot (\mu - \lambda) > r \sum_i N_i$.

If $v \in \Pi \cap K$, put $z_i = v - r\mathbf{1} + Se_i$. Then $z_i \geq \mu - 2r\mathbf{1} + Se_i$, so $f(z_i) > \sigma$. The tangent inequality at λ gives

$$0 < N \cdot (z_i - v) = SN_i - r \sum_j N_j.$$

Thus $N_i > (r/S) \sum_j N_j$ for every i . We have proved that $N \cdot (\mu - \lambda) > r \sum_i N_i$ or $N_i > (r/S) \sum_j N_j$ for all i , at every positive level σ , with constants independent of σ .

To pass to matrices, take $\lambda = \lambda(\mathcal{A}_U)$, and order λ and μ decreasingly. By concavity and symmetry, the numbers $f_i(\lambda)$ are then ordered increasingly. In the eigenframe of $\mathcal{A}_U$, the diagonal of $\mathcal{A}_U$ is a doubly stochastic average of permutations of μ , so the rearrangement inequality gives

$$\mathrm{tr}(B(\mathcal{A}_U - \mathcal{A}_U)) \geq \sum_i f_i(\lambda)(\mu_i - \lambda_i).$$

Since $N = (f_i(\lambda))_i = (B_i)_i$, taking κ smaller than $\min\{r, r/S\}$ proves the matrix alternative. $\square$

Lemma 10.8.2 Put $Q = 1 + |\partial U|_\omega^2$. For any smooth real ξ , one has

$$\begin{aligned} e^{-\xi} \mathcal{L}(e^\xi Q) &\geq \sum_{i,k} B_i |U_{ki} + U_k \xi_i|^2 + \frac{1}{4} \sum_i B_i \lambda_i^2 + Q \mathcal{L}\xi + |\partial \xi|_B^2 \\ &\quad + 2 \operatorname{Re} \sum_i B_i \lambda_i U_i \xi_{\bar{i}} - 2 \operatorname{Re} \sum_{i,k} B_i \chi_{i\bar{k}} U_k \xi_{\bar{i}} - C_g T Q - 2H_1 |\partial U|_\omega, \end{aligned}$$

where C_g depends only on ω and χ .

Proof Write $\mathcal{T}_{ik}^p$ and $R_{i\bar{j}k}^p$ for the torsion and curvature of the Chern connection. The commutation formula and the differentiated equation read

$$\begin{aligned}\nabla_{\bar{j}}\nabla_i U_k &= \nabla_k U_{i\bar{j}} + \sum_p (R_{i\bar{j}k}^p U_p - \mathcal{T}_{ik}^p U_{p\bar{j}}), \\ \sum_i B_i \nabla_k U_{i\bar{i}} &= h_k - \sum_i B_i \nabla_k \chi_{i\bar{i}}.\end{aligned}$$

The product rule for $|\partial U|^2$ gives both squares $\sum B_i |U_{ki}|^2$ and $\sum B_i |U_{k\bar{i}}|^2$, the term $2 \operatorname{Re} \sum_k h_k U_{\bar{k}}$, a curvature error bounded by $CT|\partial U|^2$, and the errors from $\nabla \chi$ and torsion. The latter are bounded by

$$CT|\partial U| + CT|\partial U|^2 + C|\partial U|T^{1/2} \left(\sum_{i,k} B_i |U_{k\bar{i}}|^2 \right)^{1/2}.$$

Absorb the last term into half of the mixed square. Since $U_{i\bar{j}} = \lambda_i \delta_{ij} - \chi_{i\bar{j}}$, the remaining half is at least $\frac{1}{4} \sum_i B_i \lambda_i^2 - CT$. Hence

$$\mathcal{L}|\partial U|^2 \geq \sum_{i,k} B_i |U_{ki}|^2 + \frac{1}{4} \sum_i B_i \lambda_i^2 - C_g TQ - 2H_1 |\partial U|.$$

Finally,

$$\partial_i |\partial U|^2 = \sum_k U_{ki} U_{\bar{k}} + \lambda_i U_i - \sum_k \chi_{i\bar{k}} U_k.$$

In the product rule for $e^{\xi} Q$, combine the cross term coming from the first sum with $|\partial U|^2 |\partial \xi|_B^2$ and with the square $\sum B_i |U_{ki}|^2$. This gives $\sum B_i |U_{ki} + U_k \xi_i|^2$, while the remaining weight term is $|\partial \xi|_B^2$. $\square$

Proposition 10.8.1 *There are constants $\eta, C > 0$, depending only on the fixed data and H_1 , such that every smooth admissible V with $\|U - V\|_{\infty} \leq \eta$ satisfies*

$$\|\partial U\|_{\infty} \leq C(1 + \|\partial V\|_{\infty}^2).$$

The comparison radius η is independent of the derivatives of V .

Proof Let $a \geq 1$ and $\beta > 1$ be constants, to be chosen below. Assuming $\|U - V\|_{\infty} \leq \beta^{-1}$, put

$$w = U - V - \beta^{-1}, \quad \xi = a(\underline{U} - U) + \beta w^2, \quad K_V = 1 + \|\partial \underline{U}\|_{\infty} + \|\partial V\|_{\infty}.$$

Then $-2\beta^{-1} \leq w \leq 0$ and

$$\xi_i = a(\underline{U}_i - V_i) + (-a + 2\beta w)(U_i - V_i), \quad |-a + 2\beta w| \leq a + 4.$$

Writing $D = |\partial(U - V)|_B^2$, the Cauchy–Schwarz inequality gives

$$\begin{aligned} \left| 2 \operatorname{Re} \sum_i B_i \lambda_i U_i \xi_{\bar{i}} \right| &\leq \frac{1}{8} \sum_i B_i \lambda_i^2 + C_a K_V^4 T + C_a (Q + K_V^2) D, \\ \left| 2 \operatorname{Re} \sum_{i,k} B_i \chi_{i\bar{k}} U_k \xi_{\bar{i}} \right| &\leq \frac{1}{2} Q D + C_a T + C_a K_V Q^{1/2} T. \end{aligned}$$

For the first line, split ξ_i as above and use $\sum B_i |U_i|^2 \leq 2D + 2K_V^2 T$; then apply Young's inequality to the resulting three products, each absorbing at most $\frac{1}{24} \sum B_i \lambda_i^2$. For the second line, use $|\partial \xi|_B \leq a K_V T^{1/2} + (a+4)D^{1/2}$ and the bound for χ . In both lines, C_a depends on a but not on β or on the derivatives of V .

By [Lemma 10.8.1](#) and $w \leq 0$,

$$\mathcal{L}\xi \geq a\mathcal{L}(\underline{U} - U) - 4H_0 + 2\beta D.$$

Choose a so large that $(a\kappa - C_g - 2)\tau > 4H_0 + 2H_1 + 1$, and then $\beta \geq 2C_a + 2$. Combining the preceding bounds with [Lemma 10.8.2](#), we obtain, at every point where $Q \geq C'(1 + K_V^4)$ for a suitable constant C' ,

$$\begin{aligned} e^{-\xi} \mathcal{L}(e^{\xi} Q) &\geq \frac{1}{8} \sum_i B_i \lambda_i^2 \\ &\quad + Q[a\mathcal{L}(\underline{U} - U) - (C_g + 2)T + \beta D - (4H_0 + 2H_1)]. \end{aligned}$$

Indeed, the coefficient of D before absorption is $(2\beta - C_a - 1/2)Q - C_a K_V^2$, which is at least βQ once C' is large enough. The other errors satisfy $C_a K_V^4 \leq Q$ and $C_a + C_a K_V Q^{1/2} \leq Q$, and they account for the additional term $-2T$ in the bracket.

Consider a maximum point of $e^{\xi} Q$ at which $Q \geq C'(1 + K_V^4)$. In the first alternative of [Lemma 10.8.1](#), the bracket is positive by the choice of a , since $T \geq \tau$. In the second, $D \geq \kappa T |\partial(U - V)|^2$. For $Q \geq 4(1 + K_V^2)$, the triangle inequality gives $|\partial(U - V)|^2 \geq c_* Q$, where $c_* = (\sqrt{3} - 1)^2/4$. Since $\mathcal{L}(\underline{U} - U) \geq -H_0$, the bracket is then at least

$$(\beta \kappa c_* Q - C_g - 2)T - (a + 4)H_0 - 2H_1.$$

This is positive once C' is large enough, because $T \geq \tau$. In both cases $\mathcal{L}(e^{\xi} Q) > 0$ at a maximum point, which contradicts the second derivative test. Thus $Q \leq C(1 + K_V^4)$ at the maximum point. The weight has uniformly bounded oscillation:

$$\operatorname{osc}_X \xi \leq a(\operatorname{osc}_X \underline{U} + \operatorname{osc}_X U) + 4/\beta.$$

By the potential bound in [Proposition 10.7.1](#), this oscillation is bounded independently of V , so the estimate at the maximum point gives $Q \leq C(1 + K_V^4)$ everywhere. Taking square roots and setting $\eta = \beta^{-1}$ proves the assertion. $\square$

Theorem 10.8.1 *There is a constant C , depending only on the fixed data and H_1 , such that $\|du\|_{L^\infty(\omega)} \leq C$ for every normalized solution u whose right-hand side h lies in the family and satisfies $\|\partial h\|_\infty \leq H_1$. In particular, the bound is uniform as the positive right-hand sides tend to zero.*

Proof The right-hand sides in the family with $\|\partial h\|_\infty \leq H_1$ form an equicontinuous set. By [Corollary 10.7.1](#), the corresponding functions U form a precompact subset of $C^0(X)$. Choose a finite η -net in this set, consisting of smooth admissible functions $V_1, \dots, V_N$. Each solution is within η of some V_j , so [Proposition 10.8.1](#) bounds its gradient by $C(1 + \max_j \|\partial V_j\|_\infty^2)$. The set of solutions, and hence the chosen finite net, depends only on the fixed data and H_1 . Finally, $u = 2\pi U$, so the same conclusion holds for du . $\square$

Chapter 11

Uniqueness for degenerate equations

Throughout this chapter, X is a connected compact complex manifold of dimension $n \geq 1$, ω is a Hermitian form and dV is a smooth positive volume form on X . As before, $\omega_u = \omega + dd^c u$, and for bounded ω -plurisubharmonic u we write $MA_\omega(u) = \omega_u^n$ for the Bedford–Taylor product of [Proposition 1.7.1](#). The preceding chapter shows that, for a nonnegative nonzero density $f \in L^p(X, dV)$ with $p > 1$, the constant c in the equation $\omega_u^n = cf dV$ is determined by f . We now ask when the potential is unique up to an additive constant.

For real potentials u, v , with the regularity stated in each result, set

$$A = \omega + dd^c u, \quad B = \omega + dd^c v, \quad w = u - v, \quad T = \sum_{j=0}^{n-1} A^j \wedge B^{n-1-j}.$$

Then

$$dd^c w \wedge T = A^n - B^n. \quad (11.1)$$

Thus, if $A^n = B^n$, the difference w solves the linear equation $dd^c w \wedge T = 0$. When $A, B \geq 0$, the polarized cofactor T is semipositive, but it may be degenerate and need not be closed. For Sobolev or $C^{1,1}$ potentials, products of coefficients in these identities are understood almost everywhere.

For $C^{1,1}$ solutions with the same continuous density, strict positivity of the density gives local uniform ellipticity of this linear equation. The main issue is to locate the extrema of w in these elliptic regions and to decide whether their values propagate across the zero set of the density. A positive weight making T dd^c -closed gives another route: a global energy identity forces the derivative of w to vanish in the directions of the cofactor. For bounded potentials, an energy measure replaces this pointwise calculation.

If the background has invariant mass, ordinary comparison proves uniqueness of bounded solutions for L^p densities, $p > 1$, without any connectedness condition on the set where the density is positive. For a general Hermitian background, however, two hypersurfaces on which the density vanishes can separate regions in which w attains different extremal values. The examples on $\mathbb{P}^3$ at the end of the chapter first

place this freedom in an open band where the density vanishes, and then keep it with a density having only quadratic zeros, which can even be chosen real analytic. They show that smallness of the zero set alone does not restore uniqueness.

11.1 Extrema and density sublevels

To apply the strong maximum principle to $w = u - v$, we first locate a maximum point and a minimum point of w in the region where the linear equation $\text{dd}^c w \wedge T = 0$ is uniformly elliptic. Maximizing a small perturbation of w by a function χ with $\omega + \text{dd}^c \chi > 0$ does this, even when the Hessians are only measurable. The strong maximum principle then makes w constant on the components of this region that contain these points, and w is constant if the closures of the two components meet.

In this section, $u, v \in C^{1,1}(X)$ satisfy $A, B \geq 0$ almost everywhere and

$$A^n = B^n = f \, dV, \quad f \in C^0(X), \quad f \geq 0. \quad (11.2)$$

Fix a smooth positive $(1, 1)$ -form β , put $H = A + B$, and let E_{unif} be the set of points near which H is uniformly positive:

$$E_{\text{unif}} = \left\{ x : \begin{array}{l} \text{there are a neighborhood } V \ni x \text{ and } c > 0 \\ \text{with } H \geq c\beta \text{ almost everywhere on } V \end{array} \right\}. \quad (11.3)$$

This open set does not depend on β or on the choice of representatives of the measurable coefficients.

Theorem 11.1.1 *Assume (11.2). If $\chi \in C^2(X, \mathbb{R})$ satisfies $C := \omega + \text{dd}^c \chi > 0$, put*

$$P_\chi = \{x \in X : f(x) dV_x \geq C_\chi^n\}, \quad U = \{f > 0\}.$$

Then P_χ is a nonempty compact subset of U , and $U \subset E_{\text{unif}}$. There are components G_+, G_- of E_{unif} , each meeting P_χ , such that $w = u - v$ satisfies

$$w \equiv \max_X w \quad \text{on } \overline{G_+}, \quad w \equiv \min_X w \quad \text{on } \overline{G_-}. \quad (11.4)$$

If w is nonconstant, these closures are disjoint. Consequently w is constant if any one of the following holds:

- (1) *every two components of E_{unif} meeting P_χ have intersecting closures;*
- (2) *E_{unif} is connected;*
- (3) *E_{unif} is dense and has at most two components.*

The assertions about components, including the three criteria, also hold with U in place of E_{unif} . In particular, w is constant when $\{f = 0\}$ is a nonempty connected embedded C^1 real hypersurface; this hypersurface need not be orientable or coorientable.

Since the Hessians of $C^{1,1}$ functions exist only almost everywhere, the contact argument must use points where they exist. The following lemma finds such points

near a maximum; it also provides the strict comparison step in the measurable strong maximum principle.

Lemma 11.1.1 *In Euclidean space $\mathbb{R}^m$, let $B(p, r)$ be the ball of center p and radius $r > 0$, and let I be the identity matrix. Let $g \in C^{1,1}$ near $\overline{B(p, r)} \subset \mathbb{R}^m$, suppose $g \leq g(p)$ on the ball, and let E be any subset of full measure in the ball at whose points g has a second-order Taylor expansion. For every $\delta > 0$ and $0 < \rho < r$, there is $x \in E \cap B(p, \rho)$ such that*

$$D^2g(x) \leq 2\delta I.$$

Proof Put $g_\delta(x) = g(x) - \delta|x - p|^2$. The gradient map $F = \nabla g_\delta$ is Lipschitz on the ball, so it maps the null set $N = \overline{B(p, r)} \setminus E$ to a null set. Choose $s \in B(0, \delta\rho) \setminus F(N)$ and maximize $g_\delta(x) - s \cdot (x - p)$ on the closed ball. At any point with $|x - p| \geq \rho$, its value is strictly smaller than its value at p , because

$$g(x) - g(p) - \delta|x - p|^2 - s \cdot (x - p) \leq -\delta|x - p|^2 + |s||x - p| < 0.$$

Thus a maximizer x lies in $B(p, \rho)$. The first-order condition at x gives $F(x) = s$, so $x \notin N$. The second-order Taylor expansion at this upper contact point gives $D^2g(x) \leq 2\delta I$. Finally, sets E as in the statement exist: by Rademacher's theorem, applied to the Lipschitz gradient of g , the function g has a second-order Taylor expansion almost everywhere. $\square$

Lemma 11.1.2 *Let $a = (a^{ij})$ be a measurable symmetric matrix field on a connected domain $\Omega \subset \mathbb{R}^m$. For each compact $K \Subset \Omega$, suppose there are constants $0 < \lambda_K \leq \Lambda_K < \infty$ such that*

$$\lambda_K I \leq a(x) \leq \Lambda_K I$$

almost everywhere on K , where I is the identity matrix. Repeated indices $i, j = 1, \dots, m$ are summed, and $z_{ij} = \partial_i \partial_j z$. If $z \in W_{\text{loc}}^{2,\infty}(\Omega)$, $a^{ij}z_{ij} \geq 0$ almost everywhere, and z attains its supremum at a point of Ω , then z is constant.

Proof We first prove strict weak comparison on a relatively compact domain: if $b \in C^{1,1}$, $Lb := a^{ij}b_{ij} \geq \kappa > 0$ almost everywhere, and $b \leq M$ on the boundary, then $b \leq M$ inside. Otherwise an interior maximum point lies in a closed ball on which $a \leq \Lambda I$. Apply **Lemma 11.1.1** to the set of full measure where both the differential inequality and the Taylor expansion hold. Choosing $2\delta m\Lambda < \kappa$ gives the contradiction $\kappa \leq Lb \leq 2\delta \text{tr } a \leq 2\delta m\Lambda$.

Take the $C^{1,1}$ representative of z , write $M = \sup_\Omega z$, and suppose that $K = \{z = M\}$ is a nonempty proper subset of Ω . Near a relative boundary point of K , choose $y \notin K$ so that the ball of radius $r = \text{dist}(y, K) > 0$ is compactly contained in Ω and touches K at x_0 . On the closed annulus $r/2 \leq |x - y| \leq r$, use fixed bounds $\lambda I \leq a \leq \Lambda I$ and set

$$b(x) = e^{-\alpha|x-y|^2} - e^{-\alpha r^2}.$$

For sufficiently large α ,

$$Lb = e^{-\alpha|x-y|^2} (4\alpha^2 a^{ij}(x_i - y_i)(x_j - y_j) - 2\alpha \text{tr } a) \geq \kappa > 0$$

almost everywhere on the annulus. On its inner sphere $z < M$ uniformly; on its outer sphere $b = 0$. Choose $\eta > 0$ small enough that $z + \eta b \leq M$ on both spheres. Strict weak comparison, applied to $z + \eta b$, gives this inequality throughout the annulus. At x_0 , however, $z = M$, $b = 0$, $\nabla z = 0$, and b increases to first order in the inward radial direction, which contradicts that inequality. Thus K has no relative boundary point in Ω , and connectedness proves the assertion. The argument uses no derivatives of the measurable coefficients. $\square$

At a point where A, B are semipositive, define the cofactor quadratic form on real cotangent vectors

$$Q_x(\xi)dV_x = i\xi^{1,0} \wedge \overline{\xi^{1,0}} \wedge T_x. \quad (11.5)$$

Here $\xi^{1,0}$ is the $(1, 0)$ -part of ξ , and forms of bidegree $(n-1, n-1)$ are ordered by testing against $i\xi^{1,0} \wedge \overline{\xi^{1,0}}$ in this way. Mixed products of semipositive $(1, 1)$ -forms are semipositive in this order. Expanding H^{n-1} , where $H = A + B$, gives

$$2^{-(n-1)}H^{n-1} \leq T \leq H^{n-1}. \quad (11.6)$$

At a point, choose a β -unitary coframe $dz_1, \dots, dz_n$ that diagonalizes H , and write $\lambda_1, \dots, \lambda_n$ for the eigenvalues of H . For a $(1, 0)$ -covector $\alpha = \sum_{k=1}^n b_k dz_k$ with complex coefficients b_k , the coefficient of $i\alpha \wedge \bar{\alpha} \wedge H^{n-1}$ in this coframe is a positive constant depending only on n , times

$$\sum_{k=1}^n |b_k|^2 \prod_{\ell \neq k} \lambda_\ell. \quad (11.7)$$

For $n \geq 2$, (11.6) and (11.7) show that Q is locally uniformly elliptic exactly on E_{unif} , that is, where H has a local essential positive lower bound. The implication from ellipticity of Q to a lower bound for H uses the local upper bound for H : testing each eigendirection bounds every product $\prod_{\ell \neq k} \lambda_\ell$ below, and choosing k different from an index of a smallest eigenvalue then bounds that eigenvalue below. For $n = 1$ one has $T = 1$, so the linearized equation is elliptic everywhere.

Proof (of Theorem 11.1.1) We first locate the extrema. Fix $s > 0$ and consider a maximum point of

$$w - s(v - \chi). \quad (11.8)$$

For smooth data, the complex Hessian of this function is nonpositive at a maximum point, that is,

$$(1 + s)B \geq A + sC. \quad (11.9)$$

Since $sC > 0$, this gives $B > 0$, and since $A^n = B^n$, also $A > 0$. In a B -unitary frame put $J = B^{-1/2}AB^{-1/2}$, $K = B^{-1/2}CB^{-1/2}$. Since $\det J = 1$, arithmetic–geometric mean and (11.9) give

$$n + s \operatorname{tr} K \leq \operatorname{tr} J + s \operatorname{tr} K \leq n(1 + s).$$

Consequently $\operatorname{tr} K \leq n$, $B \geq C/n$, and $\det K \leq (\operatorname{tr} K/n)^n \leq 1$. In particular $B^n \geq C^n$.

For $C^{1,1}$ potentials, fix a maximum point p of (11.8) and apply [Lemma 11.1.1](#) on a coordinate ball, with radii tending to zero and errors $\delta_j \downarrow 0$. For the set of full measure in that lemma, take the points where both Hessians are defined and semipositive and have the common determinant given by (11.2). With $\beta_0 = \text{dd}^c|z|^2$, the resulting points $x_j \rightarrow p$ satisfy

$$A(x_j) + sC_j(x_j) \leq (1+s)B(x_j), \quad C_j = C - (\delta_j/s)\beta_0 > 0$$

for large j . The matrix argument just given yields $f(x_j)dV_{x_j} \geq C_j(x_j)^n$. Since f , dV and C are continuous, letting $j \rightarrow \infty$ gives $p \in P_\chi$; no continuity of the Hessians is needed. Thus every maximum point of the perturbed function lies in P_χ . The set P_χ is closed, by continuity of f , dV and C , hence compact, and it is contained in U because $C^n > 0$. Letting $s \downarrow 0$, a limit point of these maximum points is a maximum point of w lying in P_χ . Applying the same argument to $-w$ gives a minimum point of w in P_χ as well. In particular, P_χ is nonempty.

On a relatively compact ball in U , the determinants of A and B have a positive lower bound, while their coefficients have an essential upper bound. Every eigenvalue is therefore bounded below by the determinant lower bound divided by a fixed power of the upper bound. Thus $U \subset E_{\text{unif}}$.

By (11.1), w solves a linear equation in nondivergence form with measurable coefficients, whose principal quadratic form is a fixed positive multiple of Q . On each relatively compact coordinate ball in E_{unif} , these coefficients are uniformly elliptic. [Lemma 11.1.2](#), applied to w and to $-w$, makes w constant on the component of E_{unif} containing the maximum point found above, and constant on the component containing the minimum point found above. Continuity extends the two constant values to the closures, proving (11.4). Distinct extrema force disjoint closures.

The same argument applies on U itself, since U contains the extremal points found in P_χ and the cofactor is locally uniformly elliptic on $U \subset E_{\text{unif}}$. This proves the assertions with U in place of E_{unif} .

The component criteria are immediate except for the dense two-component case. If an open dense subset of connected X has at most two components with disjoint closures, those closures are disjoint nonempty closed sets whose union is X , contradicting connectedness. Finally, when $Z = \{f = 0\}$ is a connected embedded real hypersurface, flattening charts assign to each point of Z the unordered pair of components containing its two local sides. This pair is locally constant along Z , so connectedness makes it independent of the point; the two labels may coincide or be exchanged along a loop. Every component of $X \setminus Z$ has a nonempty boundary in Z , since otherwise it would be both open and closed in connected X . Near such a boundary point it contains a local side. Thus the pair accounts for every component, and U has at most two components. It is dense because a hypersurface has empty interior. This proves the last assertion without choosing a global side. $\square$

In this argument, the $C^{1,1}$ bound controls the measurable coefficients, and continuity of the density places the limiting contact points in $\{f > 0\}$. The next criterion gives a quantitative condition for $\{f > 0\}$ to be connected.

11.1.1 A square-root threshold

A nonnegative $C^{1,1}$ density grows at most quadratically away from each of its zeros. If its zero set separates a small ball, a family of parallel segments crossing the zero set therefore contributes at least a constant times $\sqrt{t}$ to the volume of $\{f \leq t\}$ for small $t > 0$. Excluding this lower bound makes $\{f > 0\}$ connected, and [Theorem 11.1.1](#) then gives uniqueness.

Write $\text{Vol}(E) = \int_E dV$ for Borel sets E .

Theorem 11.1.2 *Let $u, v \in C^2(X)$ satisfy $A, B \geq 0$ and $A^n = B^n = f dV$, where $f \geq 0$ is $C^{1,1}$. If*

$$\liminf_{t \downarrow 0} \frac{\text{Vol}\{f \leq t\}}{\sqrt{t}} = 0, \quad (11.10)$$

then $\{f > 0\}$ is connected and $u - v$ is constant. In particular this holds when $f^{-1/2} \in L^1(dV)$, with $f^{-1/2} = +\infty$ on $\{f = 0\}$. The exponent $1/2$ is sharp in every dimension $n \geq 3$.

Proof Write $Z = \{f = 0\}$. Condition (11.10) first implies $\text{Vol}(Z) = 0$. We show that the complement of Z in every sufficiently small coordinate ball is connected. Fix such a ball with convex Euclidean image. If the complement of Z in it were disconnected, choose points a, b in different components and small closed disks centered at a and b , perpendicular to the segment $[a, b]$ and contained in those respective components. By making the disks small, all parallel segments between corresponding points stay in the ball. Each segment meets Z , since otherwise it would connect the two components.

On a fixed coordinate region containing the closed ball, the gradient of f is Lipschitz with some constant $K > 0$. Since $f \geq 0$, we have $\nabla f(z) = 0$ at every zero z , hence

$$f(x) \leq \frac{K}{2} |x - z|^2 \quad (11.11)$$

whenever the segment from z to x stays in that region. The endpoint disks are compact and disjoint from Z , so the parts of the segments near them contain no zeros. Thus every parallel segment contains a zero at a fixed positive distance from its endpoints. For small $t > 0$, (11.11) gives on that segment an interval of length $2\sqrt{2t/K}$ contained in $\{f \leq t\}$. Integrating over the transverse disk, which has positive measure, and using that dV is comparable to coordinate volume, we obtain

$$\text{Vol}\{f \leq t\} \geq c\sqrt{t}$$

for all sufficiently small t , contradicting (11.10). This proves the local connectedness assertion.

For each such ball, the complement of Z in it is nonempty, since Z has zero volume, and it lies in one component of $U = X \setminus Z$. Two overlapping balls give the same component, because their open overlap contains a point outside Z . Since X is connected, all these balls give the same component. Hence U is connected, and [Theorem 11.1.1](#) shows that $u - v$ is constant.

If $f^{-1/2} \in L^1$, then, outside the null zero set,

$$\frac{\text{Vol}\{f \leq t\}}{\sqrt{t}} \leq \int_{\{f \leq t\}} f^{-1/2} dV \longrightarrow 0$$

by dominated convergence. This proves the sufficient integrability condition. The sharpness assertion follows from the examples in [Section 11.9](#), as quantified at the end of that section. $\square$

11.2 Polarized cofactors and propagation

Uniform ellipticity is sufficient for the propagation of an extremum, but it is not necessary: the directions in which the cofactor is positive may already connect enough points to force constancy. For C^2 potentials, the quadratic form Q in (11.5) is continuous, and its polarization defines $Q^\# : T^*X \rightarrow TX$ by $\eta(Q^\#\xi) = Q(\xi, \eta)$. The *reachable set* of a point consists of the endpoints of absolutely continuous curves starting there whose velocity lies in $\text{im } Q^\#$ almost everywhere. The *control orbit* of a point consists of the endpoints of finite concatenations of flow lines, starting there, of locally Lipschitz vector fields with values in $\text{im } Q^\#$.

A positive weight h satisfying $\text{dd}^c(hT) = 0$ gives an energy identity that controls dw everywhere. Without such a weight, a degenerate maximum principle gives propagation only from the extremal sets. This distinction accounts for the different density assumptions on reachable sets and on orbits in the following theorem.

Theorem 11.2.1 *Let $u, v \in C^2(X)$ satisfy $A, B \geq 0$ and $A^n = B^n$, and put $w = u - v$.*

(1) *If there is a continuous $h > 0$ such that $\text{dd}^c(hT) = 0$ in distributions, then*

$$i \partial w \wedge \bar{\partial} w \wedge T \equiv 0. \quad (11.12)$$

It follows that w is constant if the set where T is strictly positive is dense, or if the reachable set of one point is dense.

(2) *Without the weight hypothesis, the sets where w attains its maximum and its minimum are invariant under the flow of every locally Lipschitz vector field with values in $\text{im } Q^\#$. If every control orbit is dense, then w is constant. For smooth data it is enough that smooth vector fields with values in $\text{im } Q^\#$, for example the columns of the symbol a in (11.18) below, together with their iterated Lie brackets, span TX at every point.*

11.2.1 Weighted energy

Testing the weighted cofactor against w^2 produces a nonnegative gradient integral. Only distributional dd^c -closedness of hT is needed: for a continuous $h > 0$, the

condition is

$$\int_X \mathrm{dd}^c \varphi \wedge hT = 0 \quad (\varphi \in C^\infty(X, \mathbb{R})). \quad (11.13)$$

Proof (of Theorem 11.2.1(I)) The product rule gives

$$\mathrm{dd}^c(w^2) = 2w\mathrm{dd}^c w + 2\mathrm{d}w \wedge \mathrm{d}^c w = 2w\mathrm{dd}^c w + \frac{i}{\pi} \partial w \wedge \bar{\partial} w. \quad (11.14)$$

Approximate w^2 in C^2 by smooth functions φ in (11.13). Since hT is continuous and $\mathrm{dd}^c w \wedge T = 0$ by (11.1), this gives

$$0 = \frac{1}{\pi} \int_X h i \partial w \wedge \bar{\partial} w \wedge T. \quad (11.15)$$

The continuous integrand is nonnegative, so it vanishes identically, which is (11.12).

By (11.5), (11.12) says that $Q(dw) = 0$. For the nonnegative quadratic form Q , this implies $Q(dw, \eta) = 0$ for every η . Therefore

$$\mathrm{d}w_x(Q_x^\# \eta) = 0 \quad (x \in X, \eta \in T_x^* X). \quad (11.16)$$

By the chain rule and (11.16), w is constant along every absolutely continuous curve whose velocity lies in $\mathrm{im} Q^\#$ almost everywhere. Thus w is constant on each reachable set, and by continuity one dense reachable set suffices. If instead Q is positive definite on a dense set, (11.15) gives $\mathrm{d}w = 0$ there, and hence everywhere. $\square$

The argument uses only the test function w^2 . For general test functions, integration by parts introduces derivatives of hT ; the condition $\mathrm{dd}^c(hT) = 0$ alone does not make $L\varphi = (\mathrm{dd}^c \varphi \wedge T)/\mathrm{d}V$ a symmetric operator in divergence form.

11.2.2 The real symbol and exterior-ball propagation

To propagate an extremum without a weight, we write the linearized operator in real coordinates. Its symbol is continuous and semipositive. At a point where a ball outside the maximum set touches it, the normal direction must lie in the kernel of the symbol; this forces the maximum set to be invariant under the flows of vector fields with values in the range of the symbol.

In a holomorphic chart $z_j = x_j + iy_j$, let C_{cf} be the Hermitian matrix characterized by

$$\frac{(i \sum H_{j\bar{k}} \mathrm{d}z_j \wedge \mathrm{d}\bar{z}_k) \wedge T}{\mathrm{d}V} = \mathrm{Tr}(C_{\mathrm{cf}} H) \quad (11.17)$$

for every Hermitian matrix $H = (H_{j\bar{k}})$. Positivity of mixed products makes C_{cf} positive semidefinite. Write $C_{\mathrm{cf}} = P_{\mathrm{cf}} + iQ_{\mathrm{cf}}$, where P_{cf} is real symmetric and Q_{cf} is real skew-symmetric. In the real coordinate order $(x_1, \dots, x_n, y_1, \dots, y_n)$,

$$L\varphi := \frac{dd^c\varphi \wedge T}{dV} = \text{Tr}(aD^2\varphi), \quad a = \frac{1}{8\pi} \begin{pmatrix} P_{\text{cf}} & Q_{\text{cf}} \\ -Q_{\text{cf}} & P_{\text{cf}} \end{pmatrix}. \quad (11.18)$$

Indeed $\varphi_{j\bar{k}} = (\varphi_{x_j x_k} + \varphi_{y_j y_k} + i\varphi_{x_j y_k} - i\varphi_{y_j x_k})/4$; inserting this expression in (11.17) proves (11.18). For real coordinate vectors $\xi, \eta \in \mathbb{R}^n$, moreover,

$$(\xi, \eta)^T a(\xi, \eta) = \frac{1}{8\pi} (\xi - i\eta)^* C_{\text{cf}} (\xi - i\eta) \geq 0.$$

Thus a is a continuous positive semidefinite principal symbol, the operator L has no first-order term in holomorphic coordinates, and the range of a is that of $Q^\#$.

An exterior-ball argument propagates the maximum for this operator. Let $W \in C^2$ satisfy $LW \geq 0$ in a chart, suppose $W \leq M$, and put $K = \{W = M\}$. If $z \in K$ is a point of K nearest to a point $y \notin K$ of the chart, then

$$(y - z)^T a(z)(y - z) = 0. \quad (11.19)$$

To prove this, suppose the left side is positive, set $r_0 = |y - z|$, and shrink the tangent ball toward z : $y' = z + \theta(y - z)$, $R = \theta r_0$, with $0 < \theta < 1$ small. The closed ball $\overline{B(y', R)}$ lies in the chart and meets K only at z . This follows from the triangle inequality; equality in $|k - y| \leq |k - y'| + |y' - y| \leq r_0$, for $k \in K$, forces $k = z$. For large $\alpha > 0$, the function

$$\psi(x) = e^{-\alpha R^2} - e^{-\alpha|x-y'|^2}$$

satisfies

$$L\psi = 2\alpha e^{-\alpha|x-y'|^2} (\text{tr } a - 2\alpha(x - y')^T a(x)(x - y')) < 0$$

in a neighborhood of z , because $z - y'$ is a nonzero multiple of $y - z$, so that $(z - y')^T a(z)(z - y') > 0$ by assumption. Choose a sufficiently small $r < R$, and consider the lens $D = B(z, r) \cap B(y', R)$. On the part of its boundary lying on the sphere $\partial B(y', R)$, we have $\psi = 0$ and $W - M \leq 0$. On the remaining compact boundary portion, $W - M < 0$, since the tangent ball meets K only at z . Hence, for sufficiently small $\varepsilon > 0$, $W - M \leq \varepsilon\psi$ on ∂D . At a positive interior maximum of $W - M - \varepsilon\psi$, the Hessian would be nonpositive, whereas $L(W - M - \varepsilon\psi) > 0$; this is impossible since $a \geq 0$. Hence the inequality $W - M \leq \varepsilon\psi$ holds in D . Outside the ball $B(y', R)$ we have $\psi \geq 0$, so this inequality holds in a full neighborhood of z . Since equality holds at z , the function $W - M - \varepsilon\psi$ has a local maximum at z , and therefore

$$0 \leq LW(z) \leq \varepsilon L\psi(z) < 0,$$

proving (11.19).

Since $a \geq 0$, its range is the orthogonal complement of its kernel, and (11.19) implies that $y - z$ lies in this kernel. Consequently $(y - z) \cdot Z(z) = 0$ for every vector field Z with values in the range of a . If Z is locally Lipschitz and γ is one of its flow curves starting in K , let $d(t)$ denote the squared distance from $\gamma(t)$ to K in a sufficiently small compact chart neighborhood. Shortening the time interval ensures that nearest points z_t lie in the chart interior. Write $D^+d(t) = \limsup_{h \downarrow 0} (d(t+h) - d(t))/h$ for

the upper right derivative. Holding such a nearest point fixed when differentiating the distance from above gives

$$\begin{aligned} D^+ d(t) &\leq 2(\gamma(t) - z_t) \cdot Z(\gamma(t)) \\ &= 2(\gamma(t) - z_t) \cdot (Z(\gamma(t)) - Z(z_t)) \leq 2 \operatorname{Lip}(Z) d(t). \end{aligned}$$

As $d(0) = 0$, Gronwall's inequality gives $d(t) = 0$. The same argument for $-Z$, followed by continuation, proves invariance under both signs of time and under finite concatenations of such flows.

Proof (of Theorem 11.2.1(2)) Apply the preceding argument to $W = w$ and to $W = -w$ in each chart; both satisfy $LW = 0$ by (11.1). The maximum set of w is nonempty, closed, and contains every control orbit starting in it. If every orbit is dense, this maximum set is all of X , proving constancy. The argument for the minimum set is identical.

It remains to prove the bracket criterion. Suppose that a family of smooth vector fields with values in $\operatorname{im} Q^\sharp$ is bracket generating. At p , let $\mathcal{D}_p$ be the span of the values of all original fields pushed forward by finite compositions of their local flows and inverse flows. This distribution contains the original fields and is invariant under their flows. Differentiation of pushed-forward fields along a flow shows that it contains their nested Lie brackets; finite-dimensional subspaces are closed, so the derivative remains in $\mathcal{D}_p$. Induction and the Jacobi identity give every iterated bracket. The assumed rank condition therefore gives $\mathcal{D}_p = T_p X$.

Choose $2n$ such pushed-forward fields independent at p . The flow of each is a conjugate of an original flow and hence preserves its orbit. The map obtained by successively flowing for $2n$ small times has invertible derivative at zero. The inverse function theorem puts a neighborhood of p in its orbit. All orbits are open, and their partition of connected X has only one member. This proves the Hörmander-type sufficient condition; it requires neither a constant-rank hypothesis nor a smooth matrix square root of a . In particular, the columns of a smooth symbol a may be used as the original vector fields. $\square$

For $C^{2,1}$ potentials, the columns of a are locally Lipschitz, so the orbit criterion still applies to them. The bracket criterion requires smooth vector fields.

11.2.3 The unweighted energy defect

Integration against w^2 also measures the obstruction to using the unweighted cofactor, that is, the case $h = 1$. For smooth potentials, the error is exactly the pairing of w^2 with $\operatorname{dd}^c T$. On a surface, the Gauduchon condition makes this error vanish for every pair of potentials; in dimension three, $\operatorname{dd}^c T$ contains an additional term depending on the potentials.

Proposition 11.2.1 *Let $n \geq 2$, and let u, v be smooth ω -plurisubharmonic functions with $A^n = B^n = f \, dV$ for a smooth function $f \geq 0$. Then*

$$\int_X dw \wedge d^c w \wedge T = \frac{1}{2} \int_X w^2 dd^c T. \quad (11.20)$$

If $dd^c T = 0$ and $\{f > 0\}$ is dense in X , then $u - v$ is constant.

Proof By (11.1), $dd^c w \wedge T = 0$. Integrating (11.14) against T , and applying Stokes' theorem twice to the left-hand side, yields

$$\int_X dd^c(w^2) \wedge T = \int_X w^2 dd^c T.$$

Substitution proves (11.20).

For the uniqueness assertion, apply **Theorem 11.2.1**(1) with $h = 1$. At every point where $f > 0$, the form B is positive definite, so the term B^{n-1} makes the cofactor T strictly positive. The set where T is strictly positive is therefore dense, as required. $\square$

Corollary 11.2.1 Assume $n = 2$ and $dd^c \omega = 0$. Let $f \geq 0$ be smooth, with a zero set of empty interior, and let $c > 0$. Then any two smooth ω -plurisubharmonic solutions of

$$(\omega + dd^c u)^2 = cf \, dV$$

normalized by $\sup_X u = 0$ coincide.

Proof Here $T = A + B$ and $dd^c T = 2dd^c \omega = 0$. The set $\{f > 0\}$ is dense, so the proposition, applied to the density cf , makes the difference of the two solutions constant, and the normalization makes this constant zero. $\square$

In dimension three, direct expansion gives

$$dd^c T = 3dd^c(\omega^2) + 3dd^c \omega \wedge dd^c(u + v).$$

The Gauduchon condition cancels the first term but need not cancel the second. For instance, take both potentials equal to the perturbation sv in **Example 4.7.1**. The common form $A = B$ is positive and satisfies $dd^c(A^2) \neq 0$, so $dd^c T = 3dd^c(A^2) \neq 0$. Thus even for two equal positive solution forms, the cofactor need not be dd^c -closed.

11.3 Integral rigidity in dimensions two and three

In dimensions two and three, if two positive forms A, B have equal determinants, an algebraic expression quadratic in $A - B$ has a strict sign unless the two forms agree. On a surface its integral vanishes because it is exact. On a threefold the integral is a term involving $dd^c \omega$, so a sign condition on $dd^c \omega$ leads to the same conclusion. Approximation in the Sobolev norm justifies the integral identities for $W^{2,n}$ potentials.

In this section $n \in \{2, 3\}$. Norms of coefficients of forms are taken with respect to a fixed smooth metric and dV .

Theorem 11.3.1 *Let $u, v \in W^{2,n}(X, \mathbb{R})$, and assume that $A, B \geq 0$ almost everywhere and*

$$A^n = B^n = f \, dV, \quad f > 0 \quad \text{almost everywhere.}$$

If $n = 3$, assume in addition that

$$\text{dd}^c \omega \wedge i\eta \wedge \bar{\eta} \leq 0 \quad (11.21)$$

for every $(1, 0)$ -covector η ; for $n = 2$ no condition on ω is needed. Then $\text{dd}^c(u - v) = 0$ in the sense of distributions, and $u - v$ is almost everywhere constant. For the ω -plurisubharmonic representatives of u and v , the difference is constant everywhere.

Proof Put

$$\begin{aligned} s &= (u + v)/2, & D &= \text{dd}^c w = A - B, \\ C &= (A + B)/2 = \omega + \text{dd}^c s. \end{aligned}$$

The coefficients of C and D lie in L^n , so their products of top degree are integrable by Hölder's inequality. At almost every point the common determinant is positive, so A and B are positive definite there, and we may diagonalize them simultaneously by congruence: for a suitable coframe of $(1, 0)$ -covectors $\theta_1, \dots, \theta_n$, write $A = \sum e_j$, $B = \sum \lambda_j e_j$, where $e_j = i\theta_j \wedge \bar{\theta}_j$, $\lambda_j > 0$, and $\prod \lambda_j = 1$.

In dimension two,

$$D^2 = A^2 + B^2 - 2A \wedge B = 2(2 - \lambda_1 - \lambda_2)e_1 \wedge e_2 \leq 0, \quad (11.22)$$

with equality if and only if $A = B$. In dimension three,

$$2C \wedge D^2 = A^3 + B^3 - A^2 \wedge B - A \wedge B^2 \leq 0. \quad (11.23)$$

Indeed, with $E = e_1 \wedge e_2 \wedge e_3$, the four terms on the right are

$$6E, \quad 6E, \quad 2\left(\sum_j \lambda_j\right)E, \quad 2\left(\sum_{i < j} \lambda_i \lambda_j\right)E.$$

By the arithmetic–geometric mean inequality and $\prod_j \lambda_j = 1$, each sum is at least three, and equality forces all $\lambda_j = 1$, that is, $A = B$.

Choose smooth real functions $w_k \rightarrow w$ in $W^{2,n}$ and set $D_k = \text{dd}^c w_k$; such approximations are obtained by a partition of unity and convolution, and they need not preserve semipositivity. For $n = 2$, Stokes' theorem gives $\int_X D_k^2 = 0$, since $D_k^2 = d(\text{d}^c w_k \wedge D_k)$. For a fixed norm-comparison constant $C_0 > 0$,

$$\|D_k^2 - D^2\|_{L^1} \leq C_0 \|D_k - D\|_{L^2} (\|D_k\|_{L^2} + \|D\|_{L^2}) \rightarrow 0.$$

Thus $\int_X D^2 = 0$, and the nonpositive integrand in (11.22) vanishes almost everywhere. By the equality case, $D = 0$ almost everywhere.

For $n = 3$, also choose smooth functions $s_k \rightarrow s$ in $W^{2,3}$, and put $C_k = \omega + dd^c s_k$. We need the identity

$$\int_X C_k \wedge D_k^2 = \int_X \omega \wedge D_k^2 = - \int_X dw_k \wedge d^c w_k \wedge dd^c \omega. \quad (11.24)$$

The first equality holds because $dd^c s_k \wedge D_k^2 = d(d^c s_k \wedge D_k^2)$. For the second equality, including its sign, put $J_k = dw_k \wedge d^c w_k$. Using $d^c d = -dd^c$ and $(d^c)^2 = 0$,

$$d^c J_k = -D_k \wedge d^c w_k, \quad dd^c J_k = -D_k^2.$$

Stokes, first for $d(\omega \wedge d^c J_k)$ and then for $d^c(d\omega \wedge J_k)$, gives

$$\begin{aligned} \int_X \omega \wedge dd^c J_k &= - \int_X d\omega \wedge d^c J_k, \\ 0 &= - \int_X dd^c \omega \wedge J_k - \int_X d\omega \wedge d^c J_k. \end{aligned}$$

Combining them yields (11.24).

With a fixed norm-comparison constant $C_0 > 0$, strong L^3 convergence implies convergence in L^1 of all products of three factors. For example,

$$\|(C_k - C) \wedge D_k^2\|_1 \leq C_0 \|C_k - C\|_3 \|D_k\|_3^2 \rightarrow 0,$$

and

$$\|C \wedge (D_k^2 - D^2)\|_1 \leq C_0 \|C\|_3 \|D_k - D\|_3 (\|D_k\|_3 + \|D\|_3) \rightarrow 0.$$

Also $dw_k \wedge d^c w_k \rightarrow dw \wedge d^c w$ in $L^{3/2}$, so the right side of (11.24) converges. Consequently

$$\int_X C \wedge D^2 = - \int_X dw \wedge d^c w \wedge dd^c \omega \geq 0. \quad (11.25)$$

The sign follows from $dw \wedge d^c w = (i/(2\pi))\partial w \wedge \bar{\partial} w$ and (11.21). The integrand on the left is nonpositive by (11.23), so it vanishes almost everywhere, and the equality case, which applies where the common determinant is positive, gives $D = 0$ almost everywhere.

In both dimensions, therefore, $dd^c w = 0$ in the sense of distributions. By [Proposition 1.1.1](#) with background zero, w has a plurisubharmonic representative on X . It attains its maximum on the compact manifold X , so the maximum principle and connectedness make it constant.

For the ω -plurisubharmonic representatives, [Lemma 1.3.3](#) upgrades the almost-everywhere equality $u = v + \text{constant}$ to equality everywhere. In particular, normalizing the means gives equality in the Sobolev class, and normalizing the suprema gives equality of the plurisubharmonic representatives. $\square$

Corollary 11.3.1 *Let $n \in \{2, 3\}$, and let $u, v \in C^2(X)$ satisfy $A, B \geq 0$ and $A^n = B^n = f dV$, where $f \geq 0$ is continuous and positive on a dense set. If $n = 3$, assume (11.21); for instance, $dd^c \omega = 0$ suffices. Then $u - v$ is constant.*

Proof Put $D = A - B$ and $C = (A + B)/2$. At a point where the common top power vanishes, the algebraic expressions in the proof of [Theorem 11.3.1](#) are still nonpositive: in dimension two $D^2 = -2A \wedge B$, and in dimension three $2C \wedge D^2 = -A^2 \wedge B - A \wedge B^2$. The same integral identities force these continuous expressions to vanish everywhere. The equality cases give $D = 0$ on $\{f > 0\}$, and density and continuity then give $D = 0$ on X . As in the proof of the theorem, $u - v$ is then constant. $\square$

For example, on the Hopf threefold X of [Chapter 8](#), with projection $\pi : X \rightarrow \mathbb{P}^2$ and the semipositive form $\alpha = \pi^* \omega_{\text{FS}}$, where ω_{FS} is the Fubini–Study form, the Hermitian metric ω satisfies $\text{dd}^c \omega = -\alpha^2$, and hence (11.21). [Theorem 11.3.1](#) therefore applies to this metric, even though its upper mass $v_+(\omega)$ of [Definition 6.5.1](#) is infinite by [Theorem 8.0.1](#). The following sections return to a general Hermitian background.

11.4 Bounded uniqueness and connectedness

Connectedness of the set where the density is positive also gives uniqueness for bounded potentials. The missing differentiability is replaced by an energy measure of the difference $w = u - v$, whose pushforward to the real line under w has a Lipschitz density vanishing at the extreme values of w . This forces the sets where w attains its extreme values to have zero mass for the common Monge–Ampère measure. Smooth test potentials whose Monge–Ampère measures concentrate near such a set then contradict modified comparison.

Theorem 11.4.1 *Let $F \in C^\infty(X)$ satisfy $F \geq 0$, $F \not\equiv 0$, with $U = \{F > 0\}$ connected and dense. If bounded ω -plurisubharmonic functions u, v satisfy*

$$\omega_u^n = \omega_v^n = F \omega^n,$$

then $u - v$ is constant. In particular, $\sup_X u = \sup_X v$ implies $u = v$.

Bounded solutions are continuous by [Corollary 10.4.1](#), so we may use pointwise extrema throughout the proof. We shall also use modified comparison in the following form. If b is continuous and $\omega_b \geq \varepsilon \omega$ for some $0 < \varepsilon < 1$, then $b/(1 - \varepsilon)$ is ω -plurisubharmonic, so [Theorem 10.2.1](#) applies with $(1 - \varepsilon)v = b$. Thus its thin-sublevel estimate applies directly to such a strictly positive comparison potential b , and the correction factor tends to one as the height of the sublevel set tends to zero, with ε fixed.

Proposition 11.4.1 *Let u, v be continuous ω -plurisubharmonic functions with $\omega_u^n = \omega_v^n = F \omega^n$, where $F \geq 0$ is bounded and measurable. Let q be a smooth strictly ω -plurisubharmonic function, and write $\omega_q^n = G \omega^n$. Then for every $0 < \kappa < 1$ and $\eta > 0$,*

$$F \omega^n(\{u - v < \min_X(u - v) + \eta\} \cap \{F > \kappa G\}) > 0. \quad (11.26)$$

The analogous assertion holds for the set $\{u - v > \max_X(u - v) - \eta\}$.

Proof Choose $\delta \in (0, 1]$ with $\omega_q \geq \delta\omega$. For $0 < t < 1$, put $b_t = (1 - t)v + tq$, $m_t = \min_X(u - b_t)$, and $E_s = \{u < b_t + m_t + s\}$. Then $\omega_{b_t} \geq t\delta\omega$. Write $\mu = F\omega^n$, $d = \kappa^{-1/n} - 1$, and $\gamma = nd$. By (1.12),

$$\omega_{b_t}^n \geq ((1 - t)F^{1/n} + tG^{1/n})^n \omega^n.$$

On $L = \{F \leq \kappa G\}$ this is at least $(1 + \gamma t)\mu$, since $G^{1/n} \geq (1 + d)F^{1/n}$ there, and on $R = \{F > \kappa G\}$ it is at least $(1 - nt)\mu$. Choose $s > 0$ so small that the reverse comparison factor in (10.2), with $\varepsilon = t\delta$, is at most $1 + \gamma t/2$. Modified comparison on E_s , with $x = \mu(E_s \cap L)$ and $y = \mu(E_s \cap R)$, gives

$$(1 + \gamma t)x + (1 - nt)y \leq (1 + \gamma t/2)(x + y), \quad \text{and hence} \quad y \geq \frac{1 - \kappa^{1/n}}{2} \mu(E_s).$$

The open set E_s is nonempty by the definition of m_t . As $\omega_{b_t}^n \geq (t\delta)^n \omega^n$, (10.2) forces $\mu(E_s) > 0$, hence $y > 0$.

Let $a = \min_X(u - v)$ and $\Lambda = \|v - q\|_\infty$. Since $u - b_t = u - v + t(v - q)$, we have $|m_t - a| \leq t\Lambda$ and $E_s \subset \{u - v < a + 2t\Lambda + s\}$. Given η , choose t and then s with $2t\Lambda + s < \eta$. Since $y = \mu(E_s \cap R) > 0$, this proves (11.26). Interchanging u and v gives the assertion for the near-maximum set. $\square$

11.4.1 The energy of the difference

In this subsection, u, v are continuous ω -plurisubharmonic functions with $A^n = B^n = F\omega^n$ for a bounded measurable function $F \geq 0$, and $w = u - v$. Although the cofactor T is now only a current, its product with $dw \wedge d^c w$ still defines a positive measure. The identity $dd^c w \wedge T = 0$ determines how this energy is distributed over the level sets of w .

Proposition 11.4.2 *There is a finite positive measure $E = dw \wedge d^c w \wedge T$, defined below as a limit of regularizations, with the following properties.*

For every smooth real function χ on $\mathbb{R}$,

$$\int_X \chi''(w) dE = \int_X \chi(w) dd^c T. \quad (11.27)$$

The signed current $dd^c T$ is a finite measure. If $a = \min_X w$, $b = \max_X w$, and

$$k(t) = \int_X (w - t)_+ dd^c T,$$

then k is nonnegative, globally Lipschitz, supported on $[a, b]$, and

$$w_* E = k(t) dt. \quad (11.28)$$

In particular, E charges no level set of w .

Let V be a relatively compact coordinate domain such that F has a positive essential lower bound on a neighborhood of $\bar{V}$. Then there is $C_V < \infty$ such that every piecewise C^1 Lipschitz function p on $[a, b]$ satisfies

$$\int_V |d(p(w))| d\lambda \leq C_V \left(\int_V |p'(w)|^2 dE \right)^{1/2}, \quad (11.29)$$

where $d\lambda$ is Euclidean coordinate volume.

Proof Locally, expand T into powers of the smooth form ω multiplied by closed Bedford–Taylor products of $dd^c u$ and $dd^c v$. The operator dd^c then acts only on the powers of ω , and the local mass bounds in [Section 1.6](#) show that $dd^c T$ is a finite signed measure.

We first construct E and prove (11.27). On a coordinate ball, convolve u, v and the coefficients of ω with a common nonnegative radial mollifier. Write the resulting smooth positive forms as $A_\rho = \omega_\rho + dd^c u_\rho$ and $B_\rho = \omega_\rho + dd^c v_\rho$, and let T_ρ be their mixed sum. On a slightly larger ball, add the same fixed multiple of $|z|^2$ to each potential to obtain plurisubharmonic functions. Their radial regularizations decrease to the originals, so Bedford–Taylor continuity applies to all closed Hessian products. Since u, v are continuous, u_ρ, v_ρ, w_ρ converge uniformly on compact subsets.

For a closed smooth product S_ρ appearing in T_ρ , the identity

$$dw_\rho \wedge d^c w_\rho \wedge S_\rho = \frac{1}{2} dd^c (w_\rho^2 S_\rho) - w_\rho dd^c w_\rho \wedge S_\rho \quad (11.30)$$

has a distributional limit: both Hessian products on the right converge weakly with uniformly bounded local variation, and their weights converge uniformly. The same holds after multiplication by the convergent smooth factors coming from ω_ρ . Thus the positive measures $E_\rho = dw_\rho \wedge d^c w_\rho \wedge T_\rho$ converge to a finite positive measure E . By (11.30), this limit does not depend on the regularization, so the local limits agree on overlapping charts.

For smooth regularizations, the chain rule gives

$$dd^c \chi(w_\rho) \wedge T_\rho = \chi''(w_\rho) E_\rho + \chi'(w_\rho) dd^c w_\rho \wedge T_\rho.$$

The last current tends to zero, because $dd^c w_\rho \wedge T_\rho = A_\rho'' - B_\rho''$ tends weakly to $A'' - B'' = 0$ with uniformly bounded variation, and $\chi'(w_\rho)$ converges uniformly. Passing to the limit and integrating by parts on the compact manifold X gives (11.27). A partition of unity justifies this passage without a global regularization; the terms containing derivatives of the cutoff functions cancel after summation.

Let $\sigma = w_*(dd^c T)$ and $\nu = w_* E$. Equation (11.27) says that $\nu'' = \sigma$ as distributions on $\mathbb{R}$. Stokes' theorem and $dd^c w \wedge T = 0$ give

$$\sigma(\mathbb{R}) = \int_X dd^c T = 0, \quad \int_{\mathbb{R}} s d\sigma(s) = \int_X w dd^c T = \int_X dd^c w \wedge T = 0.$$

Consequently $k(t) = \int (s - t)_+ d\sigma(s)$ is globally Lipschitz and vanishes outside $[a, b]$. It satisfies $k'' = \sigma$, so the compactly supported distribution $\nu - k(t) dt$ has

second derivative zero and therefore vanishes. Positivity of ν and continuity of k imply $k \geq 0$. This proves (11.28), and the assertion about level sets follows because ν is absolutely continuous.

We now prove (11.29). On a coordinate neighborhood of $\bar{V}$, set $\beta = dd^c|z|^2$ and choose $c_V > 0$ with $F\omega^n \geq c_V\beta^n$. Let A_{ac} denote the absolutely continuous part of the current A , whose coefficients are locally integrable functions. Applying Lemma 1.7.4 with the constant function $g = c_V^{1/n}$ and differentiating the coefficient measures, we obtain $\det_\beta A_{ac} \geq c_V$ almost everywhere. The local Sobolev regularity in Section 1.6 gives $w_\rho \rightarrow w$ strongly in $W_{loc}^{1,2}$, so a subsequence of the gradients converges almost everywhere. Moreover, $A_\rho \rightarrow A_{ac}$ almost everywhere, by differentiation of the coefficient measures.

Since T_ρ contains the term A_ρ^{n-1} and all its terms are positive, Fatou's lemma, applied to E_ρ , yields the measure inequality

$$E \geq dw \wedge d^c w \wedge A_{ac}^{n-1}. \quad (11.31)$$

The cofactor matrix of A_{ac} has smallest eigenvalue at least $\det A_{ac} / \operatorname{tr} A_{ac} \geq c_V / \operatorname{tr} A_{ac}$, where traces and determinants are taken with respect to β . The trace is locally integrable because A has locally finite mass. The chain rule for Sobolev functions, (11.31) and the Cauchy–Schwarz inequality give

$$\int_V |d(p(w))| d\lambda \leq C \left(\int_V |p'(w)|^2 dE \right)^{1/2} \left(\int_V \frac{\operatorname{tr} A_{ac}}{c_V} d\lambda \right)^{1/2}.$$

The last factor is finite and is absorbed into C_V . The values of p' at the finitely many corners of p are immaterial, because E charges no level set of w . $\square$

Lemma 11.4.1 *In the setting of Proposition 11.4.2, assume in addition that F is continuous and that $U = \{F > 0\}$ is connected and dense. If $w = u - v$ is nonconstant, then*

$$F\omega^n(\{w = \min_X w\}) = F\omega^n(\{w = \max_X w\}) = 0.$$

Proof Put $a = \min_X w < b = \max_X w$, and let k be the function of Proposition 11.4.2. It is Lipschitz and nonnegative, and $k(a) = 0$. Choose $\epsilon_j \downarrow 0$ with $a + \epsilon_j < b$. For $\delta > 0$, set

$$J_j(\delta) = \int_a^{a+\epsilon_j} \frac{dt}{k(t) + \delta}.$$

If L is a Lipschitz constant for k , then $k(t) \leq L(t - a)$ on this interval, so $J_j(\delta) \rightarrow \infty$ as $\delta \downarrow 0$. Choose $\delta_j > 0$ with $J_j = J_j(\delta_j) \geq j$. Let $p_j = 0$ on $(-\infty, a]$, $p_j = 1$ on $[a + \epsilon_j, \infty)$, and

$$p'_j(t) = \frac{1}{J_j(k(t) + \delta_j)} \quad (a < t < a + \epsilon_j).$$

The pushforward identity (11.28) gives

$$\int_X |p'_j(w)|^2 dE = \frac{1}{J_j^2} \int_a^{a+\epsilon_j} \frac{k(t)}{(k(t) + \delta_j)^2} dt \leq \frac{1}{J_j} \rightarrow 0.$$

Every point of U has a coordinate neighborhood V as in [Proposition 11.4.2](#), since F is continuous. By (11.29), therefore, $d(p_j(w)) \rightarrow 0$ in $L^1_{\text{loc}}(U)$. The bounded functions $p_j(w)$ converge pointwise and in L^1_{loc} to $\mathbf{1}_{\{w>a\}}$, whose distributional gradient therefore vanishes on U . Since U is connected, this indicator function is almost everywhere constant on U . As w is nonconstant, $\{w > a\}$ is a nonempty open set, and its intersection with the dense open set U is nonempty and open; hence the constant is one. Thus $\{w = a\} \cap U$ has zero volume, and since $F = 0$ off U , the first assertion follows. Applying the argument to $-w$ gives the assertion for the maximum set. $\square$

11.4.2 Concentrating smooth test potentials

The next proposition produces smooth test potentials whose Monge–Ampère density dominates a fixed multiple of a prescribed function g , with a constant independent of $\sup_X g$ and of the derivatives of g . This uniformity allows the test densities to concentrate near a set of measure zero.

Proposition 11.4.3 *For every $B_0 > \|1\|_{L^2(\omega^n)}$ there is $\varepsilon = \varepsilon(X, \omega, B_0) > 0$ such that every smooth function $g \geq 1$ with $\|g\|_{L^2(\omega^n)} \leq B_0$ admits a smooth strictly ω -plurisubharmonic function q satisfying*

$$\omega_q^n \geq \varepsilon g \omega^n. \quad (11.32)$$

Proof Choose finitely many coordinate balls $B_j = \{|z_j| < R_j\}$, with closures in their charts, such that the concentric smaller balls $\{|z_j| < r_j\}$ cover X . On B_j , let ψ_j solve the Dirichlet problem

$$(\text{dd}^c \psi_j)^n = g \omega^n, \quad \psi_j|_{\partial B_j} = 0. \quad (11.33)$$

The density of $g \omega^n$ with respect to coordinate volume is smooth and strictly positive. The classical smooth Dirichlet theorem therefore applies, since $C_j(|z_j|^2 - R_j^2)$ is a smooth strict subsolution with zero boundary values for sufficiently large $C_j > 0$. Thus ψ_j is smooth and strictly plurisubharmonic on $\overline{B_j}$, and the maximum principle gives $\psi_j \leq 0$.

We need a lower bound for ψ_j independent of $\sup_X g$. Write the coordinate equation as $\det(\partial_a \bar{\partial}_b \psi_j) = D_j$, and put $M_j = -\min_{B_j} \psi_j$. Let x_j be a minimum point. For each real slope p with $|p| < M_j/(2R_j)$, the function $\psi_j - p \cdot (x - x_j)$ attains its minimum at an interior point, because its value at x_j is $-M_j$, while its boundary values are larger than $-M_j$. At such a contact point the real Hessian S of ψ_j is nonnegative, and the gradient of ψ_j maps the contact set onto the ball of these slopes. The area formula and the matrix inequality

$$\det_{\mathbb{R}} S \leq 4^n (\det_{\mathbb{C}} (\partial_a \bar{\partial}_b \psi_j))^2 = 4^n D_j^2$$

therefore give $M_j \leq C(n, R_j) \|D_j\|_{L^2(B_j)}^{1/n}$. To prove the matrix inequality, let J be the standard complex structure on the real coordinate space and average S with $J^T S J$. Concavity of $\log \det$, and the fact that the eigenvalues of this J -invariant average occur in pairs, give the displayed factor; singular matrices are handled by approximation. Since the ratio of ω^n to coordinate volume is fixed and bounded, $\|D_j\|_2$ is controlled by B_0 . Consequently

$$-M_0 \leq \psi_j \leq 0 \quad \text{on every } B_j, \quad (11.34)$$

where M_0 depends only on X, ω, B_0 and the chosen finite cover.

Next we glue the local solutions. Put $\beta_j = \text{dd}^c |z_j|^2$. Choose $a_j > 0$ such that $a_j \beta_j \leq \omega/2$ on B_j , and let $t_j = (R_j^2 + r_j^2)/2$. Fix $\tau > 0$ so small that $\tau M_0 < a_j(R_j^2 - r_j^2)/4$ for every j . The smooth function

$$s_j = \tau \psi_j + a_j(t_j - |z_j|^2)$$

is bounded below by a fixed positive constant on the smaller ball, negative on a collar of ∂B_j , and satisfies $\omega_{s_j} \geq \omega/2 + \tau \text{dd}^c \psi_j$. Choose a smooth convex function $\phi_j : \mathbb{R} \rightarrow \mathbb{R}$ approximating $s \mapsto \max(s, 0)$, equal to zero below a small negative threshold and to s above the corresponding positive threshold, with $0 \leq \phi'_j \leq 1$ and $\phi''_j \geq 0$; the thresholds are chosen smaller in absolute value than both margins of s_j . Set $Q_j = \phi_j(s_j)$ on B_j and extend it by zero. This extension is smooth, and

$$\omega_{Q_j} = \phi'_j(s_j) \omega_{s_j} + (1 - \phi'_j(s_j)) \omega + \phi''_j(s_j) ds_j \wedge d^c s_j \geq \omega/2.$$

On the smaller ball, $Q_j = s_j$ and $\omega_{Q_j} \geq \tau \text{dd}^c \psi_j$. If N is the number of balls, put $q = N^{-1} \sum_j Q_j$. Then $\omega_q = N^{-1} \sum_j \omega_{Q_j} \geq \omega/2$ everywhere. Each point belongs to at least one smaller ball $\{|z_j| < r_j\}$, so positivity of the other summands and (11.33) give

$$\omega_q^n \geq (\tau/N)^n (\text{dd}^c \psi_j)^n = (\tau/N)^n g \omega^n.$$

Thus (11.32) holds with $\varepsilon = (\tau/N)^n$, independent of $\sup g$ and of all derivatives of g . $\square$

Proof (of Theorem 11.4.1) By Corollary 10.4.1, u, v are continuous. In dimension one, $\text{dd}^c w = 0$, so the maximum principle makes w constant. Assume $n \geq 2$.

Suppose that $w = u - v$ is nonconstant. Let $a = \min_X w$, $K = \{w = a\}$, and $\mu = F \omega^n$. By Lemma 11.4.1, $\mu(K) = 0$. Choose $B_0 > \|1\|_{L^2(\omega^n)}$ and let $\varepsilon > 0$ be the constant from Proposition 11.4.3. Since $\mu(K) = 0$, the compact set $K_0 = K \cap \{F \geq \varepsilon/2\}$ has zero ω^n -volume. Fix $A > 1$ with $\varepsilon A > \max_X F$. By outer regularity of the smooth volume measure, choose an open neighborhood O of K_0 so small that

$$\int_X \omega^n + (A^2 - 1) \int_O \omega^n < B_0^2.$$

Take a smooth $0 \leq \chi \leq 1$ equal to one near K_0 and supported in O , and set $g = 1 + (A - 1)\chi$. If $K_0 = \emptyset$, take $\chi = 0$. Then $g \geq 1$, $g = A$ on K_0 , and $\|g\|_{L^2(\omega^n)} < B_0$.

By [Proposition 11.4.3](#), there is a smooth strictly ω -plurisubharmonic q with $\omega_q^n = G\omega^n \geq \varepsilon g\omega^n$. On K_0 we have $G \geq \varepsilon A > F$; on $K \setminus K_0$ we have $F < \varepsilon/2 < \varepsilon \leq G$. Thus $G > F$ throughout the compact set K . By compactness and continuity, we can choose $0 < \kappa < 1$ such that $F < \kappa G$ on K ; put $W = \{F < \kappa G\}$. The complement of this open neighborhood of K is compact, and $w - a$ has a strictly positive minimum there if it is nonempty. Hence some $\eta > 0$ satisfies $\{w < a + \eta\} \subset W$.

[Proposition 11.4.1](#) asserts that $\mu(\{w < a + \eta\} \cap \{F > \kappa G\}) > 0$. By the preceding inclusion, however, this set is empty. This contradiction shows that w is constant. If $\sup_X u = \sup_X v$, the constant is zero. $\square$

For a bounded measurable density, a positive lower bound gives the same conclusion. In this case coercivity holds on all of X , and the concentrating test potential can dominate the essential upper bound of the density on a whole neighborhood of the extremal set.

Corollary 11.4.1 *If $0 < c_0 \leq F \leq C_0 < \infty$ almost everywhere and bounded ω -plurisubharmonic functions satisfy $\omega_u^n = \omega_v^n = F\omega^n$, then $u - v$ is constant.*

Proof The functions u, v are continuous by [Corollary 10.4.1](#), and in dimension one the assertion follows from $\text{dd}^c(u - v) = 0$ and the maximum principle. Let $n \geq 2$, suppose that $w = u - v$ is nonconstant, and put $K = \{w = \min_X w\}$. The proof of [Lemma 11.4.1](#) applies with $U = X$, since [Proposition 11.4.2](#) gives the pushforward identity and local coercivity on every chart. Thus K has zero volume.

Fix $B_0 > \|1\|_{L^2(\omega^n)}$ and the corresponding ε in [Proposition 11.4.3](#). Choose $A > 1$ with $\varepsilon A > C_0$, and a smooth cutoff function χ , equal to one on a neighborhood W of K and supported in an open set of volume so small that $g = 1 + (A - 1)\chi$ satisfies $\|g\|_2 < B_0$. The resulting test potential q has density $G \geq \varepsilon g$. Choose $\kappa < 1$ with $C_0 < \kappa \varepsilon A$. Then $F < \kappa G$ almost everywhere on W . By continuity of w , a sufficiently thin set $\{w < \min_X w + \eta\}$ lies inside W , which contradicts [Proposition 11.4.1](#). Hence w is constant. $\square$

11.5 Comparison and invariant mass

The preceding argument controls the extremal level sets of $u - v$ through connectedness of the set where the density is positive. When the background satisfies the Guan–Li condition below, invariance of the total mass gives the ordinary comparison principle instead. An auxiliary solution whose density is larger on a strict sublevel set of $u - v$ then forces this set to have zero mass for the common Monge–Ampère measure, and the domination principle proves uniqueness.

Set $V = \int_X \omega^n$. The *Guan–Li condition*

$$\mathrm{dd}^c \omega = 0, \quad \mathrm{dd}^c (\omega^2) = 0 \quad (11.35)$$

is equivalent to invariance of the total mass $\int_X \mathrm{MA}_\omega(u)$ by [Lemma 2.1.2](#) and [Theorem 2.2.2](#). In dimension one it holds automatically, for degree reasons.

Theorem 11.5.1 *Assume (11.35), let $p > 1$, and let $f \geq 0$ belong to $L^p(X, \omega^n)$ with positive integral. Then there is exactly one pair (c, u) , with $c > 0$, $u \in \mathrm{PSH}(X, \omega) \cap L^\infty(X)$ and $\sup_X u = 0$, satisfying*

$$(\omega + \mathrm{dd}^c u)^n = c f \omega^n.$$

Moreover

$$c = \frac{\int_X \omega^n}{\int f \omega^n},$$

and u is continuous. Thus two bounded solutions with the same L^p density differ by a constant, without any positive lower bound on f .

We first show that the ordinary comparison principle is equivalent to invariance of the mass.

Theorem 11.5.2 *Condition (11.35) holds if and only if every pair of bounded ω -plurisubharmonic functions a, b satisfies*

$$\int_{\{a < b\}} \mathrm{MA}_\omega(b) \leq \int_{\{a < b\}} \mathrm{MA}_\omega(a). \quad (11.36)$$

For the converse implication, it suffices to require this inequality for smooth potentials.

Proof Under (11.35), [Theorem 2.2.2](#) gives $\int_X \mathrm{MA}_\omega(a) = V$ for every bounded potential a ; for $n = 1$ this is Stokes' theorem.

Set $q = \max(a, b)$. On $\{a < b\}$, plurifine locality gives $\mathrm{MA}_\omega(q) = \mathrm{MA}_\omega(b)$. On $\{a \geq b\}$, one has $a = q$, and $a \leq q$ everywhere, so bounded ordered contact ([Lemma 1.7.1](#)) gives

$$\mathbf{1}_{\{a \geq b\}} \mathrm{MA}_\omega(a) \leq \mathbf{1}_{\{a \geq b\}} \mathrm{MA}_\omega(q).$$

The total masses of a, b and q all equal V . Hence

$$\int_{\{a < b\}} \mathrm{MA}_\omega(b) = V - \int_{\{a \geq b\}} \mathrm{MA}_\omega(q) \leq V - \int_{\{a \geq b\}} \mathrm{MA}_\omega(a) = \int_{\{a < b\}} \mathrm{MA}_\omega(a),$$

which is (11.36).

Conversely, comparison for smooth potentials implies that all smooth potentials have the same mass: given a smooth pair a, b , add to b a constant so large that $\{a < b\} = X$, apply (11.36), and then interchange the roles of a and b . Comparison

with the zero potential shows that the common mass is V . By [Theorem 2.2.2](#) and [Lemma 2.1.2](#), this implies (11.35) when $n \geq 2$; for $n = 1$ that condition holds for degree reasons. $\square$

For the uniqueness argument we need, in addition to comparison, auxiliary solutions and the mixed inequality (1.12). The auxiliary solutions come from continuous existence: if $G \geq 0$ lies in $L^p(X, \omega^n)$ and $\int_X G \omega^n = V$, [Theorem 10.1.1](#) gives a continuous solution of $\text{MA}_\omega(\rho) = cG\omega^n$ with a constant $c > 0$, and since all bounded potentials have mass V , this constant equals one. Thus

$$\text{MA}_\omega(\rho) = G\omega^n \quad (11.37)$$

has a continuous solution ρ for every such G , in particular for the density with an indicator factor used below.

Proof (of [Theorem 11.5.1](#)) We use the domination principle in the form of the case $c = 0$ of [Theorem 10.2.2](#): if $\text{MA}_\omega(a)(\{a < b\}) = 0$ for bounded ω -plurisubharmonic functions a, b , then $a \geq b$.

We first prove that two bounded solutions u, v of $\text{MA}_\omega(u) = \text{MA}_\omega(v) = \mu = F\omega^n$, with $F \in L^p$, $p > 1$, differ by a constant. The mass identity gives $\mu(X) = V$. If $u - v$ is nonconstant, add a constant to u so that $u - v$ has supremum $s > 0$ and infimum $-s$. Since $\{v < u\}$ and $\{u < v\}$ are disjoint, after interchanging u and v if necessary, the set $S = \{v < u\}$ satisfies $\mu(S) \leq V/2$. Define

$$b_0 = \frac{V - 2\mu(S)}{V} \geq 0, \quad G = 2F\mathbf{1}_S + b_0.$$

This nonnegative L^p function has total integral V , so we can choose a continuous solution ρ of (11.37). Take C_0 with $\rho - C_0 \leq u$, and set

$$q_\delta = (1 - \delta)u + \delta(\rho - C_0), \quad E_\delta = \{v < q_\delta\} \subset S, \quad 0 < \delta < 1.$$

Since $G \geq 2F$ on S , the mixed inequality (1.12) gives, on S ,

$$\text{MA}_\omega(q_\delta) \geq ((1 - \delta) + \delta 2^{1/n})^n \mu =: A_\delta \mu, \quad A_\delta > 1. \quad (11.38)$$

Ordinary comparison (11.36), applied to the pair v, q_δ , yields

$$A_\delta \mu(E_\delta) \leq \int_{E_\delta} \text{MA}_\omega(q_\delta) \leq \int_{E_\delta} \text{MA}_\omega(v) = \mu(E_\delta).$$

Thus $\mu(E_\delta) = 0$, that is, $\text{MA}_\omega(v)(\{v < q_\delta\}) = 0$. Bounded domination gives $v \geq q_\delta$ everywhere, and letting $\delta \downarrow 0$ gives $v \geq u$, which contradicts $\sup_X(u - v) = s > 0$. Therefore $u - v$ is constant. The argument never divides by F , so F may vanish on an open set.

Finally, for the density f in the theorem, put $I = \int_X f \omega^n > 0$ and $c = V/I$. By (11.37) with $G = cf$, there is a continuous solution, which we normalize by subtracting its supremum. Any other bounded solution, with constant c' , satisfies

$V = c'I$ by mass invariance, hence $c' = c$; the uniqueness just proved and the common normalization then identify the potentials. In particular, every bounded solution with this L^p density is continuous, although continuity was not assumed. $\square$

Remark 11.5.1 **Theorem 11.5.2** is an equivalence between a differential condition, the comparison principle and mass invariance. It is not an equivalence between the Guan–Li condition and uniqueness: the other criteria in this chapter apply without that condition on the background. On the other hand, imposing the Guan–Li condition on an auxiliary metric rather than on ω does not give (11.36) for MA_ω .

11.6 Smooth nonuniqueness for a degenerate density

The first example places the freedom in the potential inside an open region where the density vanishes. Three independent semipositive forms of rank one reduce equality of the Monge–Ampère measures to equality of products of three scalar coefficients. We construct two semipositive forms with the same cube, and then add the same exact correction to both to obtain a strictly positive background.

In this section and the following ones, $X = \mathbb{P}(\mathbb{C}^2 \oplus \mathbb{C}^2) = \mathbb{P}^3$, with block homogeneous coordinates $[A : B]$, where $A, B \in \mathbb{C}^2$, and ω_X is its Fubini–Study form. Here A and B denote coordinates, not the forms of (11.1); the two solution forms will be written A_0 and B_0 .

Theorem 11.6.1 *On $X = \mathbb{P}^3$ there exist a smooth Hermitian form ω with $d\omega \neq 0$, a smooth nonnegative nonzero function f , and distinct smooth functions $u, v \in \text{PSH}(X, \omega)$ such that*

$$\sup_X u = \sup_X v = 0, \quad (\omega + \text{dd}^c u)^3 = f \omega_X^3 = (\omega + \text{dd}^c v)^3.$$

The density vanishes on a nonempty open set, and both potentials have minimal singularities.

11.6.1 Three rank-one directions

On $U = \{A \neq 0, B \neq 0\}$ put

$$r = \log \frac{|A|^2}{|B|^2}, \quad P = \text{dd}^c \log |A|^2, \quad Q = \text{dd}^c \log |B|^2, \quad R = dr \wedge \text{dd}^c r.$$

The logarithms are computed in a local homogeneous lift, but their Hessians do not depend on the lift. The forms P, Q are pullbacks of Fubini–Study forms from the two projective lines $\mathbb{P}(\mathbb{C}^2)$. All three forms are semipositive of rank one, and

$$P^2 = Q^2 = R^2 = 0, \quad P \wedge Q \wedge R > 0. \quad (11.39)$$

Indeed, in local coordinates $A = (1, a)$ and $B = \tau(1, b)$, P and Q are positive multiples of $i da \wedge d\bar{a}$ and $i db \wedge d\bar{b}$, while

$$\partial r = \frac{\bar{a} da}{1 + |a|^2} - \frac{d\tau}{\tau} - \frac{\bar{b} db}{1 + |b|^2}.$$

Its $d\tau$ component is nonzero, so the three rank-one forms correspond to independent directions. In particular, for nonnegative x, y, z ,

$$(xP + yQ + zR)^3 = 6xyz P \wedge Q \wedge R, \quad (11.40)$$

and the form is positive exactly when all three coefficients are positive.

Since $dd^c r = P - Q$, the chain rule gives, for a smooth function $G : \mathbb{R} \rightarrow \mathbb{R}$,

$$dd^c G(r) = G'(r)(P - Q) + G''(r)R. \quad (11.41)$$

Let $\sigma(r) = e^r / (1 + e^r)$. Since $\log(|A|^2 + |B|^2) = \log |B|^2 + \log(1 + e^r)$, we have

$$\omega_X = \sigma(r)P + \sigma(-r)Q + \sigma'(r)R. \quad (11.42)$$

A function of r that is constant near each end of $\mathbb{R}$ extends smoothly across $X \setminus U$. A form $xP + yQ + zR$ whose coefficients equal those of (11.42) for $|r| \geq 2$ extends smoothly by ω_X across $X \setminus U$.

11.6.2 The scalar coefficients

On the central interval $-1 \leq r \leq 1$, the coefficients will make a different rank-one factor vanish in each of the two solution forms. Outside a larger interval they coincide with the Fubini–Study coefficients, so the resulting forms extend across the omitted projective lines. Primes denote derivatives with respect to r .

Choose an even smooth function β supported in $[-1, 1]$, strictly positive on $(-1, 1)$, with $\beta' > 0$ on $(-1, 0)$, and normalized by $\int_{-1}^1 \beta = 2$; for instance, a positive multiple of $\exp(-1/(1 - r^2))$ on $(-1, 1)$, extended by zero. Define

$$F(r) = -1 + \int_{-1}^r \beta(t) dt \quad (-1 < r < 1), \quad F = -1 \ (r \leq -1), \quad F = 1 \ (r \geq 1),$$

and put $p = \beta/2$, $q = \beta'/2$. Then F is smooth and odd, p is even, and q is odd, positive on $(-1, 0)$ and negative on $(0, 1)$. Both p and q vanish to infinite order at the endpoints.

Take smooth $a \geq 0$ with $a = 1$ on $(-\infty, -2/3]$ and $a = 0$ on $[-1/3, \infty)$, and put $b(r) = a(-r)$. Choose an even nonnegative $\chi \in C_c^\infty((-1/3, 1/3))$ with $\chi(0) > 0$. On $[-1, 1]$ set

$$z_0 = (q^2 + \chi^2)^{1/2}.$$

It is smooth: the expression under the square root is positive in the interior, and near each endpoint $z_0 = |q|$, where q has a fixed sign. It is positive in the interior and vanishes to infinite order at the endpoints. Also,

$$z_0 \geq |q|, \quad a(z_0 - q) = 0, \quad b(z_0 + q) = 0. \quad (11.43)$$

The first cancellation holds because $\chi = 0$ on the support of a and $q \geq 0$ there; the second follows by reflection.

On $(-\infty, -1]$ choose smooth functions ℓ, s such that $0 \leq \ell \leq 1$, $\ell = 0$ on $(-\infty, -2]$, $\ell = 1$ on $[-3/2, -1]$, while $s > 0$ for $r < -1$, $s = 1$ on $(-\infty, -3/2]$, and s vanishes to infinite order at -1 . Such functions are easily obtained from smooth cutoff functions and a function like $\exp(-1/(r+1)^2)$. Define

$$\begin{aligned} x &= (1 - \ell)\sigma + \ell, & y &= (1 - \ell)\sigma(-r) + \ell s, & z &= (1 - \ell)\sigma' + \ell s & (r \leq -1), \\ x &= p + a, & y &= p + b, & z &= z_0 & (-1 \leq r \leq 1), \end{aligned}$$

and for $r \geq 1$ use $x(r) = y(-r)$, $y(r) = x(-r)$, $z(r) = z(-r)$.

The definitions join smoothly: at -1 both definitions give the values $(1, 0, 0)$, and their differences vanish to infinite order there, since $a = 1$ and $b = 0$ near -1 . The central definitions are symmetric under reflection, so the same holds at 1 . We have

$$x, y, z > 0 \quad \text{for } r \neq \pm 1, \quad (x, y, z)(-1) = (1, 0, 0), \quad (x, y, z)(1) = (0, 1, 0).$$

For $|r| \geq 2$ their values are $(\sigma(r), \sigma(-r), \sigma'(r))$.

11.6.3 Two forms with the same cube

The cancellation identities now turn the scalar coefficients into two semipositive forms with the same cube. Their average is strictly positive except at the two ends of the central interval.

By the extensions described above, the form and the function

$$\omega_0 = x(r)P + y(r)Q + z(r)R, \quad w = F(r)$$

are smooth on X . The form is semipositive, and positive except on the hypersurfaces $M_- = \{r = -1\}$ and $M_+ = \{r = 1\}$. Put

$$H = \frac{1}{2} \text{dd}^c w = p(P - Q) + qR, \quad A_0 = \omega_0 - H, \quad B_0 = \omega_0 + H.$$

For $|r| \geq 1$ we have $H = 0$. On $|r| < 1$,

$$A_0 = aP + (2p + b)Q + (z_0 - q)R, \quad B_0 = (2p + a)P + bQ + (z_0 + q)R.$$

All coefficients are nonnegative, and by (11.40) and (11.43), $A_0^3 = B_0^3 = 0$ on this band. Outside it both cubes equal ω_0^3 . Thus A_0, B_0 are smooth semipositive forms on X with equal cubes. This common top-degree form vanishes on the closed band $|r| \leq 1$ and is positive on its complement, including near $X \setminus U$.

11.6.4 Restoring strict positivity of the background

The forms A_0, B_0 already have the required common measure. We obtain a Hermitian background by adding an exact correction $\text{dd}^c \rho$ to their average ω_0 and subtracting ρ from both potentials. The correction must restore positivity at $M_\pm$ while preserving it in the transition regions.

Take $\kappa \in C_c^\infty((-2, 2))$, equal to one on $[-3/2, 3/2]$. For a parameter $\varepsilon > 0$ to be chosen, set

$$\rho(r) = \varepsilon(r^2 - 1)\kappa(r), \quad \omega = \omega_0 + \text{dd}^c \rho.$$

By (11.41), its coefficients on U are $x + \rho'$, $y - \rho'$ and $z + \rho''$. On $[-3/2, 3/2]$ one has $\rho' = 2\varepsilon r$ and $\rho'' = 2\varepsilon$, so the last coefficient is positive there. For $r \geq 0$, $x + 2\varepsilon r$ is positive, including at $r = 0$ since $x(0) = p(0) > 0$. On $[-3/2, 0]$, the function x has a positive minimum m , so $x + 2\varepsilon r \geq m - 3\varepsilon > 0$ for small ε . Reflection gives the corresponding estimate for $y - 2\varepsilon r$. On the compact region $3/2 \leq |r| \leq 2$, all three original coefficients have a positive minimum and the perturbations are $O(\varepsilon)$. For $|r| \geq 2$ and near $X \setminus U$, the form is exactly ω_X . Hence ω is strictly positive on X for sufficiently small $\varepsilon > 0$.

The form ω is not closed. Indeed, since $\text{d}R = -\text{d}r \wedge (P - Q)$,

$$\text{d}\omega = \text{d}\omega_0 = \text{d}r \wedge ((x' - z)P + (y' + z)Q). \quad (11.44)$$

At $r = 0$, $x' = y' = 0$ and $z = \chi(0) > 0$. Hence $\text{d}\omega = z \text{d}r \wedge (Q - P) \neq 0$ there. The nonzero $\text{d}r$ component used in (11.39) also shows that $\text{d}r \wedge P$ and $\text{d}r \wedge Q$ are linearly independent.

Proof (of Theorem 11.6.1) Set $\tilde{u} = -w/2 - \rho$ and $\tilde{v} = w/2 - \rho$. Since $\text{dd}^c w = 2H$, the construction gives

$$\omega + \text{dd}^c \tilde{u} = A_0 \geq 0, \quad \omega + \text{dd}^c \tilde{v} = B_0 \geq 0.$$

Subtracting their respective suprema gives u, v . Their Hessians are unchanged, and $v - u = w + \text{constant}$ is nonconstant. The function $f = A_0^3/\omega_X^3 = B_0^3/\omega_X^3$ is smooth, nonnegative and nonzero, and it vanishes on the nonempty open band $|r| < 1$. Both potentials are smooth, hence bounded, so they have minimal singularities: for a Hermitian background, the envelope V_ω of Section 1.19 is zero. $\square$

Every Hermitian background on $\mathbb{P}^3$ has the bounded mass property of Definition 6.5.1: since the Fubini–Study form is closed, Stokes’ theorem for bounded potentials shows that all its bounded potentials have the same mass, and Proposi-

tion 6.5.1 shows that the property does not depend on the metric. This applies to all the backgrounds on $\mathbb{P}^3$ constructed below.

The linearized equation also explains why the maximum principle argument fails. The form

$$T = A_0^2 + A_0 \wedge B_0 + B_0^2$$

satisfies $\text{dd}^c w \wedge T = B_0^3 - A_0^3 = 0$, but $T = 0$ on $M_\pm$, where $A_0 = B_0 = \omega_0$ has rank one. Thus the linear equation for w is not elliptic everywhere, even though both potentials and their common density are smooth.

11.6.5 A continuum of radial solutions

The open band where the density vanishes allows more solutions than the two smooth ones constructed above. Writing a further potential as $G(r) - \rho$, with G a function of one real variable, reduces the equation on the band to choosing the slope G' so that one of the three coefficients vanishes. Switching the vanishing coefficient at two suitable levels produces a continuum of $C^{1,1}$ solutions for the same background ω and density f .

Recall that $q = p'$ and $z_0 \geq |q|$. The strict inequality $z_0 > |p'|$ near zero, where $\chi > 0$, gives

$$\int_0^1 z_0(r) dr > \int_0^1 |p'(r)| dr = p(0). \quad (11.45)$$

Proposition 11.6.1 *For the smooth background ω and the smooth density f of Theorem 11.6.1, the equation*

$$\text{MA}_\omega(u) = f\omega_X^3$$

has uncountably many distinct $C^{1,1}$ solutions normalized by $\sup_X u = 0$. If the cutoff κ defining ρ is chosen even, one of them, constructed explicitly, is invariant under the block exchange $\iota[A : B] = [B : A]$.

Proof Consider pairs $-1 < I < 0 < J < 1$ satisfying

$$\int_I^J z_0(r) dr = p(I) + p(J). \quad (11.46)$$

We first show that such pairs exist, with I ranging over an interval. Define

$$K(I, J) = \int_I^J z_0(r) dr - p(I) - p(J).$$

We have $K(0, 0) = -2p(0) < 0$ and $K(0, 1) > 0$ by (11.45). By continuity, there is $\epsilon > 0$ such that $K(I, 0) < 0 < K(I, 1)$ for every $I \in [-\epsilon, 0]$. For $0 < J < 1$,

$$\partial_J K(I, J) = z_0(J) - p'(J) > 0.$$

The intermediate value theorem therefore gives a unique $J = J(I) \in (0, 1)$ satisfying (11.46) for every $I \in [-\epsilon, 0)$; we may assume $\epsilon < 1$.

For any pair satisfying (11.46), define the slope on $[-1, 1]$ by

$$h_{I,J}(r) = \begin{cases} p(r), & -1 \leq r \leq I, \\ p(I) - \int_I^r z_0(s) \, ds, & I \leq r \leq J, \\ -p(r), & J \leq r \leq 1, \end{cases}$$

and extend it by zero outside that interval. The balance identity makes it continuous at J , and continuity at I is immediate. Each piece has bounded derivative, so $h_{I,J}$ is Lipschitz on $\mathbb{R}$; it vanishes to infinite order at ± 1 . Let $G_{I,J}$ be a primitive of $h_{I,J}$. It is $C^{1,1}$ and constant near each end of the real line. Consequently $G_{I,J}(r)$ extends to a $C^{1,1}$ function on X that is smooth near $X \setminus U$.

On the middle interval $[I, J]$ the slope lies between $-p$ and p . Indeed,

$$(h_{I,J} - p)' = -z_0 - p' \leq 0, \quad (h_{I,J} + p)' = -z_0 + p' \leq 0.$$

The first difference vanishes at I , and the second vanishes at J . Since both are nonincreasing, $h_{I,J} \leq p$ and $h_{I,J} \geq -p$ on $[I, J]$.

Put $\tilde{u}_{I,J} = G_{I,J}(r) - \rho$. By (11.41), almost everywhere on U ,

$$\omega + \text{dd}^c \tilde{u}_{I,J} = \omega_0 + \text{dd}^c G_{I,J}(r) = (x + h_{I,J})P + (y - h_{I,J})Q + (z + h'_{I,J})R. \quad (11.47)$$

On $I < r < J$, the first two coefficients are nonnegative because $x = p + a$, $y = p + b$ and $-p \leq h_{I,J} \leq p$, and the third is zero. On $-1 < r < I$, we have $h_{I,J} = p$ and $b = 0$, since $I < 0$; so the second coefficient is zero, and the others are nonnegative because $z_0 + p' \geq 0$. On $J < r < 1$, we have $h_{I,J} = -p$ and $a = 0$; so the first coefficient is zero, and the others are nonnegative because $z_0 - p' \geq 0$. Outside the band, $h_{I,J} = h'_{I,J} = 0$, so the form equals ω_0 .

Formula (11.47) has no additional term supported on the hypersurfaces $r = I$ and $r = J$: the function $G_{I,J}$ is $C^{1,1}$, so its first derivative is continuous at both transition points, and its distributional Hessian is its bounded almost-everywhere Hessian. The preceding coefficient inequalities therefore prove $\omega + \text{dd}^c \tilde{u}_{I,J} \geq 0$ as a current.

By Proposition 1.7.2, its Monge–Ampère measure is the pointwise cube of (11.47), computed almost everywhere. By the rank-one identities (11.39) and (11.40), this cube is zero almost everywhere on the band, since one coefficient vanishes there, and it equals ω_0^3 off the band. These are exactly the values of $f\omega_X^3$ in the preceding construction. Thus $\tilde{u}_{I,J}$ solves the equation, and subtracting its supremum gives a normalized solution $u_{I,J}$.

Different values of $I \in [-\epsilon, 0)$ give different normalized solutions. If $I_1 < I_2 < 0$ and $I_1 < r < I_2$, then the slope belonging to I_2 is $p(r)$, whereas

$$p(r) - h_{I_1, J(I_1)}(r) = \int_{I_1}^r (p'(s) + z_0(s)) \, ds > 0,$$

because $p' > 0$ on $(-1, 0)$. The two primitives therefore do not differ by a constant. Since the interval $[-\epsilon, 0)$ is uncountable, this proves the first assertion. None of these slopes equals p or $-p$ on all of $(-1, 1)$, so the constructed solutions are also distinct from the two smooth solutions of [Theorem 11.6.1](#).

Finally, the function

$$L(t) = \int_0^t z_0(r) dr - p(t), \quad 0 \leq t \leq 1,$$

is negative at zero, positive at one, and strictly increasing on $(0, 1)$. Its unique zero t_* gives a symmetric pair $I = -t_*$, $J = t_*$ satisfying (11.46). Since z_0 and p are even, $h_{I,J}$ is odd: on the middle interval it equals $-\int_0^r z_0(s) ds$. Choose its primitive even. Since ι changes r into $-r$, if ρ is even, the potential $G_{I,J}(r) - \rho$ and its normalization are fixed by ι . This proves the last assertion. $\square$

For these symmetric data, the normalized solutions of the equations with a positive exponent converge, as the exponent tends to zero, to the symmetric solution just constructed; see [Theorem 13.19.1](#).

11.7 Nonuniqueness with a zero set of empty interior

We now keep the Hermitian background of [Theorem 11.6.1](#), but change the density so that it is positive off $M_- \cup M_+$, where $M_{\pm} = \{r = \pm 1\}$. For potentials of the form $G(r) - \rho$, the equation on the middle band becomes a first-order ordinary differential equation for the slope G' . Barriers keep its solutions between the admissible slopes, and infinite-order vanishing at the endpoints then makes their extensions by zero smooth.

Theorem 11.7.1 *There are a smooth nonclosed Hermitian form ω on $\mathbb{P}^3$ and a smooth nonnegative density g , positive off two disjoint smooth real hypersurfaces, such that the equation*

$$\mathrm{MA}_{\omega}(u) = g\omega_X^3$$

has uncountably many distinct smooth solutions normalized by $\sup_X u = 0$. The background ω has bounded mass.

Thus a zero set with empty interior, even one of measure zero, does not ensure uniqueness of smooth normalized solutions.

We use the coefficients of [Section 11.6.2](#), with the explicit choice

$$p(r) = C \exp\left(-\frac{1}{1-r^2}\right), \quad -1 < r < 1, \quad \int_{-1}^1 p(r) dr = 1,$$

extended by zero, where the integral condition determines $C > 0$; then $q = p'$. Fix $0 < s < 1$, and set

$$k_s(r) = (x(r) + sp(r))(y(r) - sp(r))(z(r) + sq(r)).$$

For $|r| > 1$ this is xyz . If $G' = sp$, then the potential $G(r) - \rho$ has $\omega + dd^c(G(r) - \rho) = \omega_0 + sH$. This form is strictly positive for $-1 < r < 1$, since

$$x + sp = a + (1 + s)p > 0, \quad y - sp = b + (1 - s)p > 0, \quad z_0 + sq \geq (1 - s)z_0 > 0.$$

It is also strictly positive outside the closed band, and at $r = \pm 1$ it equals the rank-one form ω_0 . Consequently

$$g\omega_X^3 = (\omega_0 + sH)^3 \quad (11.48)$$

defines a smooth density g that is positive exactly off $M_- \cup M_+$. These hypersurfaces have measure zero and empty interior. On the band $|r| < 1$, a potential $G(r) - \rho$ with slope $h = G'$ solves the equation exactly when $(x + h)(y - h)(z + h') = k_s$, which is the differential equation (11.49) below.

Lemma 11.7.1 *There exists $\eta_0 > 0$ such that for every $0 < \eta < \eta_0$ the initial-value problem*

$$h' = \frac{k_s(r)}{(x(r) + h)(y(r) - h)} - z(r), \quad h(0) = sp(0) - \eta, \quad (11.49)$$

has a smooth solution on $(-1, 1)$ with $-x < h < y$ and $h < sp$. Moreover, on some fixed endpoint neighborhoods there are constants $0 < c_L < s < t < 1$, independent of η , such that

$$c_L p < h < sp \quad \text{near } -1, \quad -tp < h < sp \quad \text{near } 1.$$

Proof The function $h_s = sp$ solves (11.49) and lies strictly between $-x$ and y throughout $(-1, 1)$. Write $F_s(r, h)$ for the right-hand side of the equation, which is smooth on the open domain $-x(r) < h < y(r)$.

Near -1 the coefficients are exactly

$$x = 1 + p, \quad y = p, \quad z = q > 0.$$

For a constant $c \in (-1, 1)$, the product of coefficients for the trial slope cp is

$$k_c = (1 - c^2)(1 + (1 + c)p)pq.$$

Fix $c_L \in (0, s)$. At $p = 0$, the factor preceding pq for $c = c_L$ exceeds that for $c = s$ by $s^2 - c_L^2 > 0$. Thus, on a sufficiently small fixed neighborhood of the left endpoint, $k_{c_L} > k_s$ and

$$F_s(r, c_L p) - (c_L p)' = \frac{k_s - k_{c_L}}{(x + c_L p)(y - c_L p)} < 0. \quad (11.50)$$

Thus $c_L p$ is a lower barrier when the equation is solved backward, that is, toward -1 .

Near 1 the exact coefficients are

$$x = p, \quad y = 1 + p, \quad z = -q > 0,$$

and the trial slope cp has product of coefficients

$$k_c = (1 - c^2)(1 + (1 - c)p)p(-q).$$

Fix $s < t < 1$. At $p = 0$, the factor for $c = s$ exceeds that for $c = -t$ by $t^2 - s^2 > 0$. On a sufficiently small fixed neighborhood of the right endpoint, therefore, $k_s > k_{-t}$, so

$$F_s(r, -tp) - (-tp)' = \frac{k_s - k_{-t}}{(x - tp)(y + tp)} > 0. \quad (11.51)$$

Thus $-tp$ is a lower barrier when the equation is solved forward, toward 1.

Choose $r_L < 0 < r_R$ in these respective neighborhoods. The graph of h_s over $[r_L, r_R]$ is a compact subset of the domain of F_s . Existence and continuous dependence on initial values for smooth ordinary differential equations therefore give $\eta_0 > 0$ such that, for every $0 < \eta < \eta_0$, the solution with initial value $sp(0) - \eta$ exists on $[r_L, r_R]$, stays in the domain, and satisfies

$$h(r_L) > c_L p(r_L), \quad h(r_R) > -tp(r_R).$$

By local uniqueness, two solutions of the equation cannot cross. Since $h(0) < h_s(0)$, we have $h < h_s$ wherever h exists.

Follow the solution backwards from r_L ; it cannot cross $c_L p$. Indeed, at a first crossing point the difference $h - c_L p$ would vanish and be positive immediately to its right, so its derivative there would be nonnegative, whereas (11.50) shows that this derivative is strictly negative. Thus $c_L p < h < sp$ on the part of the interval of existence to the left of r_L . Likewise, (11.51) prevents a first downward crossing of $-tp$ to the right of r_R , giving $-tp < h < sp$ there.

These bounds also show that the maximal interval of existence is all of $(-1, 1)$. Indeed, near a possible endpoint inside $(-1, 1)$, the factors $x + h$ and $y - h$ stay bounded away from zero, so the graph of h stays in a compact subset of the domain of F_s , and the continuation theorem for ordinary differential equations extends the solution beyond that endpoint. Hence the solution exists on $(-1, 1)$ and satisfies the claimed bounds. $\square$

Lemma 11.7.2 *Every solution furnished by Lemma 11.7.1, extended by zero outside $(-1, 1)$, is smooth on $\mathbb{R}$ and vanishes to infinite order at ± 1 .*

Proof Let h be one of the solutions in Lemma 11.7.1. On either endpoint neighborhood put $\xi = h/p$; since $p > 0$ on $(-1, 1)$, this quotient is smooth there, and the trapping bounds place ξ in a fixed compact subinterval of $(-1, 1)$. Define the rational functions

$$R_L(p, \xi) = \frac{(1 - s^2)(1 + (1 + s)p)}{(1 + (1 + \xi)p)(1 - \xi)} - 1,$$

$$R_R(p, \xi) = 1 - \frac{(1 - s^2)(1 + (1 - s)p)}{(1 + \xi)(1 + (1 - \xi)p)}.$$

The explicit formulas for the coefficients near the endpoints give

$$h' = q R_L(p, \xi) \quad \text{on the left,} \quad h' = q R_R(p, \xi) \quad \text{on the right.}$$

Both rational functions are smooth, with all derivatives bounded, on a neighborhood of the relevant set of pairs (p, ξ) with $p \geq 0$ small and ξ in the compact interval above. Writing $R_{L/R}$ for the function corresponding to the endpoint under consideration, we obtain from $h' = p'\xi + p\xi'$ and $q = p'$

$$\xi' = \frac{p'}{p} (R_{L/R}(p, \xi) - \xi). \quad (11.52)$$

For the chosen bump,

$$\frac{p'}{p} = -\frac{2r}{(1-r^2)^2}.$$

This rational function and each of its derivatives grow at most like a power of the inverse distance to the endpoint. Moreover, each derivative of p is p times a rational function with the same property.

An induction using (11.52) shows that every derivative $\xi^{(j)}$ grows at most polynomially in the inverse distance to the endpoint. The case $j = 0$ is the trapping bound on ξ . For the induction step, differentiate the right-hand side of (11.52), including its term $-\xi$, j times. Every resulting term is a product of a derivative of p'/p , a bounded partial derivative of $R_{L/R}$, and derivatives of p and of ξ of order at most j . All of these factors have polynomial bounds, by the induction hypothesis for the derivatives of ξ and since every derivative of p is bounded. This gives the bound for $\xi^{(j+1)}$.

Leibniz' rule for $h = p\xi$ now gives, for each j , constants C_j, N_j such that

$$|h^{(j)}(r)| \leq C_j p(r) (1 - |r|)^{-N_j}$$

near the endpoints. The right-hand side tends to zero at the endpoints, because p decays exponentially in the inverse distance to the endpoint. Thus all derivatives of h tend to zero at ± 1 . Extend each derivative by zero outside $(-1, 1)$. By the mean value theorem, the difference quotient of $h^{(j)}$ at an endpoint tends to the limit of $h^{(j+1)}$, which is zero. Hence these extensions are the successive derivatives of the extension of h , which is therefore smooth and vanishes to infinite order at ± 1 . $\square$

Proof (of Theorem 11.7.1) Let η_0 be as in Lemma 11.7.1, and for $0 < \eta < \eta_0$ denote by h_η the solution with initial value $sp(0) - \eta$. Extend h_η by zero, which gives a smooth function by the preceding lemma, and take a primitive G_η . It is constant near each end of the real line, so $G_\eta(r)$ extends smoothly to all of $\mathbb{P}^3$, including the two omitted projective lines. Set

$$\tilde{u}_\eta = G_\eta(r) - \rho.$$

On the open band,

$$\omega + \text{dd}^c \tilde{u}_\eta = (x + h_\eta)P + (y - h_\eta)Q + (z + h'_\eta)R.$$

The coefficients of P and Q are strictly positive by [Lemma 11.7.1](#), while the equation gives

$$z + h'_\eta = \frac{k_s}{(x + h_\eta)(y - h_\eta)} > 0.$$

Outside the band the form is ω_0 , and on the two boundary hypersurfaces it is also the rank-one form ω_0 , since h_η vanishes to infinite order there. It is therefore semipositive on X , and by [\(11.40\)](#) its cube equals $6k_s P \wedge Q \wedge R = (\omega_0 + sH)^3$ on the band and $\omega_0^3 = (\omega_0 + sH)^3$ elsewhere. Thus its cube is everywhere the measure $g\omega_X^3$ of [\(11.48\)](#). Finally, normalize by subtracting $\sup_X \tilde{u}_\eta$.

Distinct values of η give different slopes at $r = 0$, so the corresponding potentials do not differ by a constant, and their normalized versions are distinct. This gives an uncountable family. The background is that of [Theorem 11.6.1](#), so it has bounded mass. $\square$

The density vanishes to infinite order on the two hypersurfaces. Their complement has three components, and on each of the two outer components, two different solutions differ by a constant, with different constants on the two components. The differential equation on the middle component joins these constants smoothly across the degenerate hypersurfaces. This is why ellipticity at every point of the positive-density set does not give a maximum principle argument across its boundary.

11.8 Quadratic density zeros

Infinite-order vanishing of the density is not needed for smooth nonuniqueness. We change the coefficients of ω_0 so that its coefficient of R stays positive and one of its coefficients of P and Q vanishes quadratically at each of the two hypersurfaces $M_\pm$. The resulting singular differential equation forces the slopes of differences of solutions to decay like $\exp(-A/d)$, where d is the distance to the hypersurface and $A > 0$. The slopes therefore extend smoothly by zero, even though the density vanishes only to finite order.

Theorem 11.8.1 *On $\mathbb{P}^3$ there exist a smooth nonclosed Hermitian form ω and a smooth nonnegative density g such that:*

- (1) *The zero set of g consists of two disjoint smooth real hypersurfaces. Near either hypersurface, g is the square of a smooth defining function times a smooth strictly positive function.*
- (2) *The equation $(\omega + \text{dd}^c u)^3 = g\omega_X^3$ has uncountably many distinct smooth ω -plurisubharmonic solutions normalized by $\sup_X u = 0$.*

The background ω has bounded mass.

We keep the rank-one forms P, Q, R and the function r of [Section 11.6.1](#), and use new scalar coefficients.

Choose a smooth function a valued in $[0, 1]$, equal to one for $r \leq -2/3$ and zero for $r \geq -1/3$, and put $b(r) = a(-r)$. Choose a smooth even cutoff χ valued in $[0, 1]$, zero for $|r| \leq 5/4$ and one for $|r| \geq 3/2$. Set $p(r) = (1 - r^2)^2$ and

$$\begin{aligned} x &= (1 - \chi)(p + a) + \chi\sigma, \\ y &= (1 - \chi)(p + b) + \chi(1 - \sigma), \\ z &= 1 - \chi + \chi\sigma', \quad \omega_0 = xP + yQ + zR. \end{aligned} \tag{11.53}$$

Since these coefficients coincide with those of (11.42) for $|r| \geq 3/2$, the form ω_0 extends by ω_X across the two omitted projective lines. The coefficient z is strictly positive, and x, y are strictly positive except that $y(-1) = 0$ and $x(1) = 0$. Thus ω_0 is positive off $M_{\pm} = \{r = \pm 1\}$ and has rank two there.

Choose a smooth cutoff $\kappa \in C_c^\infty((-2, 2))$ equal to one on $[-3/2, 3/2]$. For a parameter $\varepsilon > 0$ to be chosen, define the correction

$$\rho = \varepsilon(r^2 - 1)\kappa(r), \quad \omega = \omega_0 + \text{dd}^c \rho.$$

For sufficiently small $\varepsilon > 0$, the form ω is strictly positive. Indeed, on $[-3/2, 3/2]$ its coefficients are $x + 2\varepsilon r$, $y - 2\varepsilon r$ and $z + 2\varepsilon$. The first is positive for $r \geq 0$, and on $[-3/2, 0]$ the function x has a positive minimum, so it remains positive for small ε . Reflection gives the positivity of the second coefficient, and that of the third is immediate. On $3/2 \leq |r| \leq 2$, the form ω_0 is strictly positive on a compact set and the correction is $O(\varepsilon)$. Near the projective ends there is no correction. The form ω is not closed: at $r = 0$, $x' = y' = 0$ and $z = 1$, so by (11.44)

$$d\omega = dr \wedge ((x' - z)P + (y' + z)Q) \neq 0.$$

Define the density g by

$$g\omega_X^3 = \omega_0^3.$$

It is smooth and positive exactly off $M_- \cup M_+$. By (11.42) and (11.40), $g = xyz/(\sigma(r)(1 - \sigma(r))\sigma'(r))$. Near either hypersurface, $xyz = (1 + p)p$, and hence

$$g(r) = \frac{(1 + p(r))(1 - r^2)^2}{\sigma(r)(1 - \sigma(r))\sigma'(r)}.$$

The denominator is smooth and strictly positive at ± 1 , and $1 - r^2$ is a defining function for $M_{\pm}$ near these hypersurfaces. This proves the asserted quadratic vanishing. The potential $-\rho$ is one smooth solution.

Lemma 11.8.1 *For every sufficiently small $\eta > 0$, the equation*

$$h' = \frac{xyz}{(x + h)(y - h)} - z, \quad h(0) = -\eta \tag{11.54}$$

has a smooth solution on $(-1, 1)$ with $-x < h < y$ and $h < 0$. There are a constant $0 < c < 1$ and fixed neighborhoods of both endpoints, independent of η , on which

$$-cp < h < 0.$$

Every such solution, extended by zero, is a smooth function on $\mathbb{R}$ that vanishes to infinite order at ± 1 .

Proof The right-hand side $F(r, h)$ is smooth on $-x < h < y$, and $h = 0$ is a solution. Near -1 , $(x, y, z) = (1 + p, p, 1)$; near 1 , $(x, y, z) = (p, 1 + p, 1)$. Fix $0 < c < 1$. For the trial function $-cp$, near the left endpoint

$$F(r, -cp) + cp' = \frac{1 + p}{(1 + (1 - c)p)(1 + c)} - 1 + cp' \longrightarrow -\frac{c}{1 + c} < 0,$$

whereas near the right endpoint

$$F(r, -cp) + cp' = \frac{1 + p}{(1 - c)(1 + (1 + c)p)} - 1 + cp' \longrightarrow \frac{c}{1 - c} > 0.$$

as $r \rightarrow \pm 1$, since $p, p' \rightarrow 0$ at both endpoints. The strict inequalities therefore hold on fixed neighborhoods of the endpoints, and $-cp$ is a lower barrier for the equation solved backwards near -1 and forwards near 1 .

Choose a compact interval $[r_L, r_R] \ni 0$ with endpoints in those neighborhoods. Continuous dependence on initial values, around the solution $h = 0$, gives $\eta_0 > 0$ such that for every $0 < \eta < \eta_0$ the solution exists on $[r_L, r_R]$, stays in the domain of F , and lies above $-cp$ at r_L and r_R . By uniqueness of solutions, it cannot meet the solution zero, so $h < 0$. The barrier argument used in the proof of [Lemma 11.7.1](#) then gives $-cp < h < 0$ near both ends. On each compact subinterval of $(-1, 1)$ the trapped graph stays at a positive distance from the boundary of the domain of F ; hence, by the continuation theorem, the solution exists on all of $(-1, 1)$.

The equation factors as

$$h' = h L(r, h), \quad L(r, h) = \frac{z(x - y + h)}{(x + h)(y - h)}. \quad (11.55)$$

Since $h < 0$, we have $(\log(-h))' = L(r, h)$. Near the left endpoint, the trapping bounds and the explicit coefficients imply

$$L(r, h) = \frac{1 + h}{(1 + p + h)(p - h)} \geq \frac{C_1}{p}$$

after shrinking that neighborhood, with $C_1 > 0$. Near the right endpoint they give

$$L(r, h) = \frac{-1 + h}{(p + h)(1 + p - h)} \leq -\frac{C_2}{p}, \quad C_2 > 0.$$

Indeed, on the left, $1 + h \geq 1 - cp \geq 1/2$ and the denominator is at most $(1 + p)(1 + c)p$; on the right, the numerator is at most -1 , and the denominator is at most $p(1 + (1 + c)p)$. Since p is comparable to the square of the distance $d = 1 - |r|$ to the endpoint, integrating these inequalities backwards on the left and forwards on the right gives,

for some $A > 0$,

$$|h(r)| \leq Ce^{-A/d} \quad (11.56)$$

near either endpoint. The constants may depend on the solution; uniformity in η is not needed for the smooth extension.

It remains to control all derivatives. On the trapped graph, all partial derivatives in (r, h) of the rational function L grow at most polynomially in d^{-1} . Indeed, near an endpoint x, y are polynomials in $r, z = 1$, h is bounded, and of the two factors in the denominator, one is bounded below by a positive constant and the other by $(1 - c)p$. Repeated differentiation of the quotient therefore only introduces finite powers of p^{-1} .

Inductively, for every $j \geq 0$ there are constants C_j, N_j with

$$|h^{(j)}(r)| \leq C_j e^{-A/d} d^{-N_j}.$$

The case $j = 0$ is (11.56). Differentiate $h' = hL(r, h(r))$ j times. Every resulting term is the product of a derivative of the factor h , of order at most j , and a derivative of the composite function $L(r, h(r))$. The latter involves only partial derivatives of L and derivatives of h of order at most j , which are polynomially bounded by the induction hypothesis, while the first factor has the exponential bound. This proves the case $j + 1$. All derivatives of h therefore tend to zero at ± 1 . Extending them by zero and applying the mean value theorem to the difference quotients at the endpoints, as in Lemma 11.7.2, shows that the extension of h by zero is smooth and vanishes to infinite order at ± 1 . $\square$

Proof (of Theorem 11.8.1) Let $\eta_0 > 0$ be such that Lemma 11.8.1 applies for $0 < \eta < \eta_0$, and let h_η denote the solution with $h_\eta(0) = -\eta$. Take a primitive G_η of its extension by zero. Since G_η is constant near each end of the real line, $G_\eta(r)$ defines a smooth function on X . The potential $u_\eta = G_\eta(r) - \rho$ satisfies

$$\omega + dd^c u_\eta = (x + h_\eta)P + (y - h_\eta)Q + (z + h'_\eta)R.$$

Inside the band, the first two coefficients are positive by the lemma, and the equation gives

$$z + h'_\eta = \frac{xyz}{(x + h_\eta)(y - h_\eta)} > 0.$$

Outside the band the form is ω_0 , and on the two boundary hypersurfaces it is also the rank-two form ω_0 , since h_η vanishes to infinite order there. Thus it is semipositive on X , and by (11.40) its cube is $6xyzP \wedge Q \wedge R = \omega_0^3 = g\omega_X^3$. Different initial values give potentials that do not differ by constants, so after normalization by the supremum we obtain an uncountable family. Bounded mass follows from Proposition 6.5.1, as for Theorem 11.6.1. $\square$

At each of the hypersurfaces $M_\pm$, the difference of two of these solutions agrees to infinite order with a constant, because its derivative is a difference of slopes that vanish to infinite order there. The constants at the two hypersurfaces need not agree.

Thus the singular differential equation produces differences that are flat at $M_{\pm}$, even though the density has only quadratic zeros.

11.9 A real analytic density

The last construction prescribes a globally real analytic density before the background is chosen. The density is a polynomial in a real analytic function on projective space. We first choose a symmetric pair of perturbations, depending only on r , whose determinants equal that density, and then extend the construction across the projective ends by patching coefficients while preserving the determinant. The two hypersurfaces on which the density vanishes quadratically still separate regions where the difference of the two solutions takes different extremal values.

Theorem 11.9.1 *On $X = \mathbb{P}^3$, with block homogeneous coordinates $[A : B]$ and Fubini–Study form ω_X , put*

$$t = \frac{|A|^2}{|A|^2 + |B|^2}, \quad a = \frac{1}{1 + e}, \quad b = \frac{e}{1 + e}, \quad f_*(t) = (t - a)^2(t - b)^2.$$

There exist a smooth nonclosed Hermitian form ω and distinct smooth ω -plurisubharmonic functions u, v , normalized by $\sup_X u = \sup_X v = 0$, with

$$(\omega + dd^c u)^3 = (\omega + dd^c v)^3 = f_*(t)\omega_X^3. \quad (11.57)$$

Both solution forms are positive away from the two connected real analytic hypersurfaces $\{t = a\}$, $\{t = b\}$, and have complex rank two on them. The density is real analytic on X , and it vanishes exactly to second order in the direction transverse to these hypersurfaces. For every $n \geq 4$ the same assertions hold on $\mathbb{P}^3 \times \mathbb{P}^{n-3}$, with the pulled-back density and the product Fubini–Study volume, and with rank $n - 1$ on the two product hypersurfaces.

Proof We use the forms P, Q, R and the function r of [Section 11.6.1](#). By (11.40), the construction reduces to finding scalar coefficients with a prescribed product. By (11.42),

$$\omega_X^3 = 6(\sigma')^2 P \wedge Q \wedge R, \quad \sigma' = \sigma(r)\sigma(-r) > 0. \quad (11.58)$$

11.9.1 Prescribing the determinant

On U , one has $t = \sigma(r)$. We first construct two triples of coefficients, positive on the middle band, with product $f_*(\sigma)(\sigma')^2$. At each endpoint of the band, exactly one of the coefficients of P and Q will vanish.

Put $d_*(r) = f_*(\sigma(r))(\sigma'(r))^2$. Since $a = \sigma(-1)$, $b = \sigma(1)$, define the positive smooth divided differences

$$k_-(r) = \int_0^1 \sigma'(-1 + s(r+1)) \, ds, \quad k_+(r) = \int_0^1 \sigma'(1 + s(r-1)) \, ds,$$

and $H_*(r) = k_-(r)k_+(r)\sigma'(r) > 0$. The fundamental theorem of calculus gives

$$\sigma(r) - a = (r+1)k_-(r), \quad \sigma(r) - b = (r-1)k_+(r), \quad d_* = (1-r^2)^2 H_*^2. \quad (11.59)$$

These formulas show that H_* is smooth and positive also at the endpoints, without any division by a vanishing function. The symmetry $\sigma(-r) = 1 - \sigma(r)$ makes d_* , and hence H_* , even.

Choose the function

$$p(r) = \begin{cases} e^{-1/(1-r^2)}, & |r| < 1, \\ 0, & |r| \geq 1, \end{cases} \quad q = p'.$$

All its derivatives vanish at $r = \pm 1$: each derivative is a finite sum of polynomials in r times powers of $(1-r^2)^{-1}$, multiplied by the exponential, and the exponential factor dominates every such power. On $|r| < 1$, $q = -2rp/(1-r^2)^2$. Define

$$z_b = \sqrt{q^2 + 2H_*^2}, \quad S_* = \sqrt{r^2 + 4p^2 + 2z_b(1-r^2)^2}, \quad (11.60)$$

$$x_b = (S_* - r)/2, \quad y_b = (S_* + r)/2. \quad (11.61)$$

Both radicands are strictly positive everywhere, so these formulas define smooth functions on $\mathbb{R}$, including at the endpoints. They satisfy

$$z_b > |q|, \quad x_b - y_b = -r, \quad x_b y_b = p^2 + \frac{z_b}{2}(1-r^2)^2. \quad (11.62)$$

The coefficients x_b, y_b are nonnegative, positive away from the endpoints, with values $(1, 0)$ at -1 and $(0, 1)$ at 1 . On the open band,

$$S_*^2 - (2p + |r|)^2 = 2(1-r^2)^2(z_b - |q|) > 0,$$

so $x_b > p, y_b > p$. Consequently both triples

$$(x_b - p, y_b + p, z_b - q), \quad (x_b + p, y_b - p, z_b + q) \quad (11.63)$$

are strictly positive there.

We now verify that the two triples have the same product. Set $D_* = x_b y_b - p^2$, $E_* = p(x_b - y_b) = -rp$. Equations (11.62) and the formula for q give

$$D_* = (z_b/2)(1-r^2)^2, \quad qD_* = z_b E_*.$$

The two products in (11.63) therefore equal

$$(D_* + E_*)(z_b - q) = (D_* - E_*)(z_b + q) = \frac{D_*}{z_b}(z_b^2 - q^2) = d_*. \quad (11.64)$$

For $|r| \geq 1$, $p = q = 0$ and the same identity reads $x_b y_b z_b = d_*$. Thus both triples have exactly the prescribed product, and at the endpoints exactly one of their entries vanishes.

11.9.2 Extension over the projective ends

The coefficients just constructed have the right product but need not extend across the projective ends. Away from the zero levels of $f_*(t)$, we interpolate the coefficients of P and Q to those of $f_*(t)^{1/3} \omega_X$, and determine the coefficient of R by the prescribed product.

Choose a smooth even cutoff $0 \leq \eta \leq 1$, equal to one on $|r| \leq 3/2$ and zero on $|r| \geq 2$. On $|r| < 3/2$ set $(x, y, z) = (x_b, y_b, z_b)$. On $|r| > 5/4$, where $f_*(\sigma(r)) > 0$, put

$$\begin{aligned}\kappa &= f_*(\sigma(r))^{1/3}, \\ x &= \eta x_b + (1 - \eta) \kappa \sigma(r), \\ y &= \eta y_b + (1 - \eta) \kappa \sigma(-r), \quad z = d_*/(xy).\end{aligned}$$

These coefficients are smooth and positive on the outer region. On the overlap $5/4 < |r| < 3/2$, we have $\eta = 1$, $p = q = 0$ and $x_b y_b z_b = d_*$, so the two definitions agree. For $|r| \geq 2$ they equal $\kappa(\sigma(r), \sigma(-r), \sigma'(r))$. Thus

$$\omega_0 = xP + yQ + zR$$

extends smoothly across both omitted projective lines, being equal near them to $f_*(t)^{1/3} \omega_X$, which is smooth and positive there since $f_*(0) = f_*(1) = a^2 b^2 > 0$. On X , the form ω_0 is semipositive, positive away from $r = \pm 1$, and of rank two on these levels.

The function

$$F(r) = 2 \int_0^r p(s) \, ds$$

is constant on each of the intervals $(-\infty, -1]$ and $[1, \infty)$, and so $F(r)$ extends to a smooth nonconstant function on X . By (11.41), half of its complex Hessian is $H_0 = \text{dd}^c F/2 = p(P - Q) + qR$. By (11.64) and (11.58), the forms $A_0 = \omega_0 - H_0$, $B_0 = \omega_0 + H_0$ satisfy

$$A_0^3 = B_0^3 = f_*(t) \omega_X^3$$

on U , and hence on X . Their ranks and positivity were determined above, after (11.63). The construction is symmetric: $x(-r) = y(r)$, and z is even.

11.9.3 A positive equation background

As in the first example, an exact correction makes the average form strictly positive without changing the two solution forms. Here the coefficient of R is already positive, and the correction restores the missing coefficient of P or Q at each endpoint. Let $\varepsilon > 0$ be a parameter, restricted below.

Let $h(r) = (r^2 - 1)\eta(r)$, extend it by zero on the tails, and set $\rho = \varepsilon h$. The coefficients of $\omega = \omega_0 + \text{dd}^c \rho$ are

$$(x + \varepsilon h', y - \varepsilon h', z + \varepsilon h''). \quad (11.65)$$

On $|r| \leq 3/2$, we have $h' = 2r$ and $h'' = 2$. For $0 \leq r \leq 3/2$, $x + 2\varepsilon r > 0$, since the only zero of x there is at $r = 1$, where the correction is positive. On $[-3/2, 0]$, x has a positive minimum m_0 , so positivity holds if $3\varepsilon < m_0$. Reflection proves positivity of the second coefficient, and the third is $z + 2\varepsilon > 0$. On the compact transition region $3/2 \leq |r| \leq 2$, all original coefficients have a common positive lower bound m_1 . If M_1 bounds $|h'| + |h''|$, taking also $\varepsilon < m_1/(M_1 + 1)$ preserves their positivity there. For $|r| \geq 2$, the background equals $f_*(t)^{1/3}\omega_X > 0$. Hence ω is strictly positive on X .

The correction is exact, so $d\omega = d\omega_0$. At $r = 0$, where $x = x_b$ and $y = y_b$, evenness of S_* gives $x'(0) = -1/2$ and $y'(0) = 1/2$. Hence (11.44) gives

$$d\omega_0 = (z_b(0) + 1/2) dr \wedge (Q - P) \neq 0.$$

Indeed, if $dr \wedge (Q - P) = 0$, wedging with P and $\text{d}^c r$ would contradict $P \wedge Q \wedge R > 0$. Thus the Hermitian background ω is not closed.

Now put $\tilde{u} = -F/2 - \rho$ and $\tilde{v} = F/2 - \rho$. Then $\omega + \text{dd}^c \tilde{u} = A_0$, $\omega + \text{dd}^c \tilde{v} = B_0$. Subtracting their respective suprema gives u, v with $\sup_X u = \sup_X v = 0$, and (11.57) holds. Their difference is nonconstant because F is nonconstant.

11.9.4 Zeros and higher dimensions

It remains to examine the regularity of the density and the geometry of its zero levels. Taking a product with projective space then preserves the equality of the Monge–Ampère measures and gives examples in every higher dimension.

The function t is real analytic in every affine chart of X , being a quotient of real polynomials with positive denominator. Hence $f_*(t)$ is real analytic on X . Its two zero levels are regular hypersurfaces because $t = \sigma(r)$, $\sigma' > 0$, and $dr \neq 0$. Each level is connected, since it is the quotient of the product of two three-spheres of fixed nonzero radii by the diagonal action of the circle. Each level is compact and has zero volume. The divided differences in (11.59) show near the two levels that

$$f_*(\sigma(r)) = (r + 1)^2 g_-(r), \quad f_*(\sigma(r)) = (r - 1)^2 g_+(r), \quad (11.66)$$

respectively, with smooth strictly positive functions $g_{\pm}$.

For $n \geq 4$, let θ be the Fubini–Study form on $Y = \mathbb{P}^{n-3}$, let $\pi_1 : X \times Y \rightarrow X$ and $\pi_2 : X \times Y \rightarrow Y$ be the projections, and set, on $X \times Y$,

$$\omega_n = \pi_1^* \omega + \pi_2^* \theta, \quad \Omega_n = \pi_1^* \omega_X + \pi_2^* \theta, \quad u_n = \pi_1^* u, \quad v_n = \pi_1^* v.$$

In the expansion of an n -fold product, only the terms with exactly three factors pulled back from X survive. Consequently

$$(\omega_n + \text{dd}^c u_n)^n = \binom{n}{3} \pi_1^*(A_0^3) \wedge \pi_2^*(\theta^{n-3}) = f_*(\pi_1^* t) \Omega_n^n,$$

and the same holds for v_n . On the two product levels, the solution forms have rank $2 + (n - 3) = n - 1$. Restriction to a slice $X \times \{y\}$ recovers $d\omega \neq 0$, so ω_n is not closed. Normalization, distinctness and real analyticity are preserved by pullback. $\square$

Write Vol for the volume with respect to ω_X^3 , or Ω_n^n in dimension n . The quadratic zeros complete the proof of the sharpness assertion in [Theorem 11.1.2](#). In finitely many tubular charts around the zero levels, the density is bounded above and below by positive multiples of the square of a real transverse coordinate, and the volume form has a bounded positive density with respect to coordinate volume. Away from these charts, the density is bounded below by a positive constant. Thus, for $s > 0$ and $\alpha > 0$,

$$\text{Vol}\{f_* \leq s\} \asymp \sqrt{s} \quad (s \downarrow 0), \quad f_*^{-\alpha} \in L^1 \iff \alpha < \frac{1}{2}. \quad (11.67)$$

Thus, for every $0 < \alpha < 1/2$ and every dimension $n \geq 3$, there are smooth examples of nonuniqueness whose density f satisfies $f^{-\alpha} \in L^1$; this condition is weaker than the hypothesis $f^{-1/2} \in L^1$ of [Theorem 11.1.2](#).

Remark 11.9.1 For this example, the positive-density set $\{f_*(t) > 0\}$ has three components: the middle band and the two outer regions. The two solution forms have the same missing direction on each zero level, so $E_{\text{unif}} = \{f_*(t) > 0\}$. The maximum and the minimum of the difference of the two potentials are attained on the two outer components, whose closures are disjoint, in accordance with [Theorem 11.1.1](#). Although the closure of the middle component meets both outer closures, the extremal values do not propagate through the middle component.

Part III
Relative singularities and equations

Chapter 12

Envelopes and volumes of singularities

Throughout this chapter, X is a connected compact complex manifold of dimension $n \geq 1$, with an auxiliary Hermitian metric ω and a smooth positive volume form dV , and θ denotes a smooth real $(1, 1)$ -form on X whose positivity is specified in each section.

In a closed background, the non-pluripolar Monge–Ampère mass of a potential depends only on its singularity type; this is what makes mass a tool for comparing singularities. In a nonclosed background, a bounded change of the potential can change the mass, and a singularity type may contain potentials of different, even infinite, masses. This chapter opens the part of the book on relative singularities and the equations they govern, and introduces two kinds of invariants that take this into account.

The first records the variation of mass: the lower and upper volumes $\underline{\text{vol}}_\theta(u)$ and $\overline{\text{vol}}_\theta(u)$ of a potential u are the infimum and the supremum of the masses of all potentials of the same singularity type. The second replaces a mass condition by a condition on envelopes. Fix a reference potential φ . Stretching a potential u away from φ by a factor $b \geq 1$ gives the obstacle $bu - (b - 1)\varphi$, which is more singular than u where u lies below φ . The *relative envelope class* $\mathcal{E}_\varphi$ consists of the potentials u at least as singular as φ for which every such stretched obstacle lies above some θ -plurisubharmonic function. This class is convex and stable under finite rooftops, its members have the same singularity envelope as φ , and its definition involves no mass.

The main tool is the contact property of envelopes: the Monge–Ampère measure of an envelope is carried by the set where it touches its obstacle. Together with ordered contact, it gives the domination principle for bounded potentials in a semipositive background and bounds the measures of rooftop envelopes. For envelopes of logarithmic growth on $\mathbb{C}^n$, which correspond to envelopes on $\mathbb{P}^n$, we also examine how the contact of the regularized envelope with its obstacle depends on the growth allowance.

In a semipositive big background, the contact property also produces positive mass. Let φ be a model reference, that is, a fixed point of the singularity envelope that admits a competitor in a smaller background. Every member u of $\mathcal{E}_\varphi$ then has a competitor in a background $a\theta$ with $0 < a < 1$, and an envelope in the remaining

big background $(1 - a)\theta$ has positive mass, which it transfers to u on the contact set. The argument uses only that each bounded potential has positive mass, so it applies even when the infimum of these masses is zero. Conversely, if the Hermitian metric ω does not have the bounded mass property of [Definition 6.5.1](#), the relative envelope class of the zero potential contains potentials of infinite mass. Envelope conditions and mass bounds are therefore different requirements, and this distinction is essential for the equations with prescribed singularities in the next chapter.

We use the following notation from [Chapter 1](#). For quasi-plurisubharmonic functions u, v , we write $u \preceq v$ if $u \leq v + C$ for a constant C , and $u \sim v$ if $u \preceq v$ and $v \preceq u$; the equivalence class of u is its *singularity type* ([Definition 1.12.1](#)). For an obstacle f , the envelope $P_\theta(f)$ is the upper semicontinuous regularization of the supremum of all $v \in \text{PSH}(X, \theta)$ with $v \leq f$ quasi-everywhere; it may be identically $-\infty$, and then it does not belong to $\text{PSH}(X, \theta)$. For $u, v \in \text{PSH}(X, \theta)$, the rooftop envelope is $P_\theta(u, v) = P_\theta(\min(u, v))$, and $V_\theta = P_\theta(0)$ is the potential with minimal singularities; see [Section 1.19](#). The singularity envelope $P_\theta[u]$, its variant $P_{\theta, F}[u]$ with a smooth obstacle F , and envelope fixed points, that is, potentials with $P_\theta[u] = u$, are defined in [Definition 1.19.1](#). We write $\theta_u = \theta + \text{dd}^c u$ and $\omega_u = \omega + \text{dd}^c u$. For $u \in \text{PSH}(X, \theta)$, $\text{MA}_\theta(u)$ denotes the extended Monge–Ampère measure $\text{MA}_\theta^{\text{ext}}(u)$ of [Theorem 6.1.1](#). It is the Bedford–Taylor measure $(\theta + \text{dd}^c u)^n$ when u is bounded, it puts no mass on pluripolar sets, and its total mass, the *extended mass* of u , may be infinite.

12.1 Contact sets

The Monge–Ampère measure of an envelope is concentrated on the contact set, where the envelope meets its obstacle. For a smooth obstacle and a Hermitian background, the envelope is the uniform limit of solutions of exponential equations whose densities tend to zero wherever the envelope stays strictly below the obstacle. Continuity of bounded products then carries this property to quasi-continuous obstacles, first bounded ones, through monotone approximation, and then general ones, through truncation.

Proposition 12.1.1 *Let $f \in C^\infty(X, \mathbb{R})$. For $\beta > 0$, denote by u_β the smooth strictly ω -plurisubharmonic solution of*

$$\omega_{u_\beta}^n = e^{\beta(u_\beta - f)} \omega^n.$$

As $\beta \rightarrow +\infty$, these solutions converge uniformly to $p = P_\omega(f)$. Moreover,

$$\mathbf{1}_{\{p < f\}} \omega_p^n = 0.$$

Proof The solutions exist by [Theorem 9.6.1](#). Choose $A \geq 0$ with $\text{dd}^c f \leq A\omega$. At a maximum point of $u_\beta - f$, the second derivative test gives

$$\omega_{u_\beta} \leq \omega + \text{dd}^c f \leq (1 + A)\omega.$$

Evaluating the equation at this point, we obtain

$$u_\beta \leq f + \frac{C_f}{\beta}, \quad C_f = n \log(1 + A).$$

Thus $u_\beta - C_f/\beta$ is a competitor for $P_\omega(f)$, and $u_\beta \leq p + C_f/\beta$.

For the lower bound, note that p is continuous by [Proposition 1.19.1](#), and choose smooth strictly ω -plurisubharmonic functions $v_j \downarrow p$ by [Theorem 1.11.1](#); by Dini's theorem the convergence is uniform. For any $\delta > 0$, choose j so that

$$p \leq v_j \leq p + \delta/2.$$

Then $v_j - \delta \leq f$, since $p \leq f$. Since $\omega_{v_j} > 0$ and X is compact, there is $c_j > 0$ such that $\omega_{v_j}^n \geq c_j \omega^n$. Put $C_j = \max(0, -\log c_j)$. The function

$$w_{j,\beta} = v_j - \delta - C_j/\beta$$

satisfies

$$\omega_{w_{j,\beta}}^n = \omega_{v_j}^n \geq e^{-C_j} \omega^n \geq e^{\beta(w_{j,\beta} - f)} \omega^n.$$

Exponential comparison, [Corollary 10.2.2](#) with $\lambda = \beta$, gives $w_{j,\beta} \leq u_\beta$. Consequently

$$p - \delta - C_j/\beta \leq u_\beta \leq p + C_f/\beta.$$

Letting first $\beta \rightarrow \infty$ with j fixed, so that no lower bound for c_j uniform in j is needed, and then $\delta \downarrow 0$, we obtain uniform convergence. Bounded Bedford–Taylor continuity then gives weak convergence of the measures.

On a compact subset of the open set $\{p < f\}$, uniform convergence gives $u_\beta - f \leq -\epsilon$ for some $\epsilon > 0$ and all large β . There the measures $\omega_{u_\beta}^n$ have densities at most $e^{-\beta\epsilon}$ with respect to ω^n . Testing against continuous functions with compact support in $\{p < f\}$ and passing to the limit gives $\omega_p^n = 0$ on this open set. $\square$

Proposition 12.1.2 *If f is bounded and lower semicontinuous, then $P_\omega(f)$ is bounded, lies below f quasi-everywhere, and its Monge–Ampère measure is concentrated on $\{P_\omega(f) = f\}$.*

Proof Suppose first that f is continuous. Choose smooth functions $f_j \rightarrow f$ uniformly. The Lipschitz bound for envelopes in [Proposition 1.19.1](#) gives $p_j = P_\omega(f_j) \rightarrow p = P_\omega(f)$ uniformly. Every compact subset of the open set $\{p < f\}$ has a neighborhood on which $p_j < f_j$ for all large j . The preceding proposition and convergence of bounded products then give $\omega_p^n = 0$ on $\{p < f\}$.

For lower semicontinuous f , choose continuous functions $f_j \uparrow f$ with common upper and lower bounds. For example, for a fixed distance d inducing the topology of X , one may take

$$f_j(x) = \inf_{y \in X} (f(y) + jd(x, y)).$$

These functions are Lipschitz and increase to f : if convergence failed at x , approximate minimizers y would approach x , contradicting lower semicontinuity of f at x .

The functions $p_j = P_\omega(f_j)$ increase and stay bounded, so the regularized limit $p_\infty = (\lim_j p_j)^*$ is a bounded ω -plurisubharmonic function. It agrees with $\lim_j p_j$ outside a pluripolar set, and since each p_j lies below $f_j \leq f$ outside a pluripolar set, we obtain $p_\infty \leq f$ quasi-everywhere. Thus $p_\infty \leq P_\omega(f)$.

For fixed k , the set $\{p_\infty < f_k\}$ is open, since p_∞ is upper semicontinuous and f_k is continuous. If $j \geq k$, then $p_j \leq p_\infty < f_k \leq f_j$ there, so the continuous case gives $\omega_{p_j}^n = 0$ on that open set. Bedford–Taylor continuity along increasing sequences applies after adding a fixed smooth local function whose Hessian dominates ω and expanding with respect to the resulting smooth form. Together with the lower semicontinuity of the mass of open sets under weak convergence, it yields

$$\omega_{p_\infty}^n(\{p_\infty < f_k\}) = 0.$$

Taking the union over k gives zero measure on $\{p_\infty < f\}$, hence also on $\{p_\infty < P_\omega(f)\}$ outside a pluripolar set, since $P_\omega(f) \leq f$ quasi-everywhere. Bounded measures of this kind do not charge pluripolar sets, so the domination principle, [Theorem 10.2.2](#), gives $p_\infty \geq P_\omega(f)$. The two functions are therefore equal, and the assertion follows. $\square$

Theorem 12.1.1 *Let $\theta \geq 0$ be smooth and let f be bounded and quasi-continuous. Then $p = P_\theta(f)$ is bounded, $p \leq f$ quasi-everywhere, and*

$$\mathbf{1}_{\{p < f\}} \mathbf{MA}_\theta(p) = 0.$$

Proof First suppose that $\theta = \omega$ is Hermitian. Choose bounded lower semicontinuous functions $f_j \downarrow f$ quasi-everywhere, with common bounds, as in [Lemma 1.8.2](#). The bounded functions $p_j = P_\omega(f_j)$ decrease to p . Indeed, their limit is a competitor for p , since it lies below f quasi-everywhere, and the reverse inequality follows from monotonicity.

For fixed k , put $H_k = \min\{1, (f - p_k)_+\}$, a bounded quasi-continuous function. Where $H_k > 0$ and $j \geq k$, we have $p_j \leq p_k < f \leq f_j$ outside a pluripolar set. The lower semicontinuous case therefore gives

$$\int_X H_k \omega_{p_j}^n = 0.$$

The convergence of bounded products against quasi-continuous weights in [Section 1.8](#) gives $\int_X H_k \omega_p^n = 0$. Since the sets $\{p_k < f\}$ increase to $\{p < f\}$, this proves the assertion for Hermitian θ .

For general semipositive θ , set $\theta_j = \theta + j^{-1}\omega$. The functions $p_j = P_{\theta_j}(f)$ have the common bounds $\inf_X f \leq p_j \leq \sup_X f$ and decrease. Their limit is θ -plurisubharmonic by distributional convergence and lies below f quasi-everywhere, so it is at most $p = P_\theta(f)$; since $p \leq p_j$ for all j , it equals p . For each fixed k , the same coefficient $H_k = \min\{1, (f - p_k)_+\}$ gives

$$\int_X H_k \mathbf{MA}_{\theta_j}(p_j) = 0 \quad (j \geq k).$$

All p_j are bounded potentials for the fixed Hermitian form $\theta + \omega$. Expanding the products with background θ_j with respect to this fixed background, we may use convergence of bounded products and uniform capacity bounds to pass the last identity to the limit, with the quasi-continuous weight H_k ; this gives $\int_X H_k \mathbf{MA}_\theta(p) = 0$. Exhausting $\{p < f\}$ as before completes the proof. $\square$

Theorem 12.1.2 *Let θ be smooth and semipositive, and let f be a quasi-continuous obstacle. If $p = P_\theta(f)$ is not identically $-\infty$, then $p \leq f$ quasi-everywhere and*

$$\mathbf{1}_{\{p < f\}} \mathbf{MA}_\theta(p) = 0.$$

Here the total extended mass of p may be infinite.

Proof The local envelope theorem, applied to a countable family realizing the supremum (Choquet's lemma), gives $p \leq f$ outside a pluripolar set. Choose $M > \sup_X p$ and replace f by $\min(f, M)$. This does not change the envelope, since p itself is a competitor for the smaller obstacle. Since $p < M$, the contact set is also unchanged, so it suffices to prove the theorem for the smaller obstacle; that is, we may assume that f is bounded above.

Set $f_j = \max(f, -j)$ and $p_j = P_\theta(f_j)$. The constants $-j$ are competitors, so p_j is bounded. **Theorem 12.1.1** gives $p_j \leq f_j$ quasi-everywhere and

$$\mathbf{1}_{\{p_j < f_j\}} \mathbf{MA}_\theta(p_j) = 0.$$

The sequence p_j decreases and stays above p . Its limit is therefore θ -plurisubharmonic, it lies below f quasi-everywhere, and so it is a competitor for p . Hence $p_j \downarrow p$.

Fix an integer $k \geq 1$ and $C > 0$, and define the bounded nonnegative quasi-continuous function

$$H_{k,C} = \min\{1, (f - p_k)_+\} \min\{1, (p + C)_+\}.$$

Its values on pluripolar sets are immaterial. Where this coefficient is positive, $p_k < f$ and $p > -C$. For $j \geq k$, we then have $p_j \leq p_k < f \leq f_j$ and $p_j \geq p > -C$ there. Plurifine locality and **Theorem 12.1.1** therefore imply

$$\int_X H_{k,C} \mathbf{MA}_\theta(\max(p_j, -C)) = 0.$$

The truncated potentials are uniformly bounded and decrease to $\max(p, -C)$, so their measures converge weakly by bounded Bedford–Taylor continuity. The uniform capacity bounds and the weighted convergence in **Section 1.8** also allow testing against $H_{k,C}$. Hence the last identity holds with p in place of p_j . By plurifine locality, this says that the extended measure of p vanishes on $\{p_k < f\} \cap \{p > -C\}$. Off the pole set of p , these sets increase to $\{p < f\}$ as first k and then C tend to infinity.

Continuity of positive measures along increasing sequences proves the assertion, even if the total extended mass is infinite. $\square$

For a smooth big background, constants need not be competitors, and a strictly θ -plurisubharmonic barrier with poles replaces the constant lower truncations. The same contact property for quasi-continuous obstacles finite almost everywhere is proved in this setting in [Theorem 13.7.2](#). Combined with ordered contact, either contact theorem controls the measures of rooftop envelopes. In the following bound, the strict inequality in the first term assigns the common contact set $\{p = u = v\}$ to the second term.

Proposition 12.1.3 *Let θ be a smooth real $(1, 1)$ -form that is semipositive or big, and let $u, v \in \text{PSH}(X, \theta)$. If $p = P_\theta(u, v)$ is not identically $-\infty$, then*

$$\text{MA}_\theta(p) \leq \mathbf{1}_{\{p=u<v\}} \text{MA}_\theta(u) + \mathbf{1}_{\{p=v\}} \text{MA}_\theta(v).$$

Proof The envelope lies below both obstacles quasi-everywhere, hence everywhere, since the obstacles are upper semicontinuous. By the contact theorem ([Theorem 12.1.2](#) or [Theorem 13.7.2](#)), its measure is carried by $\{p = \min(u, v)\}$. Partition this set into $\{p = u < v\}$ and $\{p = v\}$, and apply [Proposition 6.2.1](#) on each part. All measures vanish on the pluripolar pole sets, which can therefore be discarded throughout. $\square$

Proposition 12.1.4 *Let θ be smooth and semipositive. Every envelope fixed point φ satisfies*

$$\text{MA}_\theta(\varphi) \leq \mathbf{1}_{\{\varphi=0\}} \theta^n.$$

In particular, its extended mass is finite.

Proof Since $\varphi = P_\theta[\varphi] \leq 0$, the function φ is a competitor for $P_\theta(\varphi + 1, 0)$. This rooftop is also a competitor for $P_\theta[\varphi] = \varphi$, being at most $\varphi + 1$ and at most zero, so it equals φ . Now apply [Proposition 12.1.3](#) with $u = \varphi + 1$ and $v = 0$. The contact set $\{\varphi = \varphi + 1 < 0\}$ is contained in the pole set of φ , which the extended measure does not charge. Only contact with zero contributes, and this gives the asserted bound. $\square$

12.1.1 Affine growth and projective envelopes

The contact property concerns the regularized envelope. For the classical weighted extremal functions on $\mathbb{C}^n$, the obstacle is imposed at every point of a compact set, and one may ask when the regularized envelope still touches the obstacle there. Compactifying $\mathbb{C}^n$ to $\mathbb{P}^n$ turns the logarithmic growth allowance into a semipositive background. This correspondence distinguishes contact of the raw supremum with the obstacle from contact of its upper semicontinuous regularization, and it shows how both depend on the growth allowance.

In the rest of this section we work on $\mathbb{C}^n$ and on $\mathbb{P}^n$ rather than on X . Write $\chi(z) = \log(1 + \|z\|^2)$ on $\mathbb{C}^n$, and let ω_{FS} be the Fubini–Study form on $\mathbb{P}^n$ with this local potential, so that $\int_{\mathbb{P}^n} \omega_{\text{FS}}^n = 1$ with our normalization of dd^c . For $\delta > 0$ put

$$\theta_\delta = \frac{\delta}{2} \omega_{\text{FS}}, \quad \mathcal{L}_\delta = \{u \in \text{PSH}(\mathbb{C}^n) : u(z) \leq \delta \log^+ \|z\| + C_u\}.$$

Here $\log^+ = \max(\log, 0)$, and C_u is a constant depending on u . Thus $\mathcal{L}_\delta$ is the class of plurisubharmonic functions of logarithmic growth at most δ . Let $\mathcal{L}_\delta^+$ consist of the members of $\mathcal{L}_\delta$ that are also bounded below by $\delta \log^+ \|z\| - C$ for some constant C .

Lemma 12.1.1 *The map $u \mapsto u - \delta\chi/2$, followed by the canonical extension across the hyperplane at infinity, is a bijection from $\mathcal{L}_\delta$ onto $\text{PSH}(\mathbb{P}^n, \theta_\delta)$.*

Proof Use homogeneous coordinates $[Z_0 : \cdots : Z_n]$ and the affine chart $Z_0 \neq 0$. On a chart $Z_i \neq 0$ meeting $H = \{Z_0 = 0\}$, the local plurisubharmonic representative of $p = u - \delta\chi/2$ is

$$p + \frac{\delta}{2} \log \frac{\sum_{j=0}^n |Z_j|^2}{|Z_i|^2} = u + \delta \log |Z_0/Z_i|.$$

This function is locally bounded above near H , by the growth bound on u , because the norm of the affine coordinates is at most a constant, depending on the chart, divided by $|Z_0/Z_i|$. By Lemma 1.3.7, it therefore extends canonically across H . Since the local potentials of θ_δ differ by smooth functions on overlaps, the extensions agree there.

Conversely, every $p \in \text{PSH}(\mathbb{P}^n, \theta_\delta)$ is bounded above, since $\mathbb{P}^n$ is compact. The function $u = p + \delta\chi/2$ is plurisubharmonic on the affine chart, and

$$0 \leq \frac{1}{2}\chi - \log^+ \|z\| \leq \frac{1}{2} \log 2$$

gives the required growth bound. Neither function is identically $-\infty$ on the affine chart. Uniqueness of the canonical extension shows that the two maps are inverse to each other. $\square$

Fix a non-pluripolar compact set $K \subset \mathbb{C}^n$ and a bounded real function ψ on K . Define the raw and the regularized envelope

$$V_\delta = \sup\{u \in \mathcal{L}_\delta : u|_K \leq \psi\}, \quad F_\delta = V_\delta^*,$$

where the obstacle condition is imposed at every point of K . On $\mathbb{P}^n$ put

$$G_\delta = \sup\{p \in \text{PSH}(\mathbb{P}^n, \theta_\delta) : p|_K \leq \psi - \delta\chi/2\}.$$

Proposition 12.1.5 *The regularized envelope G_δ^* on $\mathbb{P}^n$ is bounded and θ_δ -plurisubharmonic. On the affine chart,*

$$V_\delta = \frac{\delta}{2}\chi + G_\delta, \quad F_\delta = \frac{\delta}{2}\chi + G_\delta^* \in \mathcal{L}_\delta^+. \quad (12.1)$$

Moreover, $V_\delta = F_\delta$ almost everywhere.

Proof By Lemma 12.1.1, the map $u \mapsto u - \delta\chi/2$ is a bijection between the two families of competitors, which proves the identity for V_δ . Constants below $\inf_K(\psi - \delta\chi/2)$ are competitors for G_δ .

Since all competitors for G_δ lie below the constant $\sup_K(\psi - \delta\chi/2)$ on K , Lemma 1.19.1 gives a common upper bound for them. Together with a constant competitor, the upper-envelope theorem shows that G_δ^* is bounded and θ_δ -plurisubharmonic. Addition of the smooth function $\delta\chi/2$ in (12.1) commutes with regularization, and the two-sided bounds for G_δ^* give $F_\delta \in \mathcal{L}_\delta^+$.

Locally, adding a potential of θ_δ makes the competitors plurisubharmonic. The upper-envelope theorem recalled in Chapter 1 shows that regularization changes their supremum only on a pluripolar set. Thus $G_\delta = G_\delta^*$ almost everywhere, and adding $\delta\chi/2$ gives the same assertion for V_δ . $\square$

The regularized envelope does not change if the obstacle is imposed only outside a pluripolar subset of K . Within the growth class this can be seen directly: a function in $\mathcal{L}_\delta$ with poles on the exceptional set repairs each competitor.

Lemma 12.1.2 *For every pluripolar set $E \subseteq \mathbb{C}^n$ and every $\delta > 0$, there is $b \in \mathcal{L}_\delta$ with $b = -\infty$ on E . Given a non-pluripolar compact set K , it can be chosen with $b \leq 0$ on K .*

Proof Put $E_j = E \cap \overline{B}(0, j)$. Each E_j is pluripolar as a subset of $\mathbb{P}^n$: it is locally pluripolar near every affine point, and a neighborhood of the hyperplane at infinity does not meet this bounded set. By Josefson's theorem on compact manifolds, [Xia, Theorem 1.1.5], there is a quasi-plurisubharmonic function on $\mathbb{P}^n$, not identically $-\infty$, that equals $-\infty$ on E_j . Rescaling it so that it becomes θ_1 -plurisubharmonic and subtracting its supremum gives

$$p_j \in \text{PSH}(\mathbb{P}^n, \theta_1), \quad p_j \leq 0, \quad p_j|_{E_j} = -\infty.$$

The L^1 norms of these normalized potentials are uniformly bounded by Theorem 1.4.1. The partial sums

$$p_N = \sum_{j=1}^N 2^{-j} p_j$$

decrease, have uniformly bounded L^1 norms, and remain θ_1 -plurisubharmonic because $\theta_1 \geq 0$ and the coefficients sum to at most one. By Corollary 1.4.1, their limit p belongs to $\text{PSH}(\mathbb{P}^n, \theta_1)$. Every point of E is a pole of one of the summands, hence $p = -\infty$ on E . By Lemma 12.1.1,

$$b = \delta(p + \chi/2) \in \mathcal{L}_\delta$$

has the required properties. Its supremum on K is finite, since b is bounded above on the compact set K and is not identically $-\infty$ on K , which is non-pluripolar. Subtracting this supremum gives $b \leq 0$ on K . $\square$

Corollary 12.1.1 *The envelope F_δ is unchanged if $u|_K \leq \psi$ is imposed only quasi-everywhere, or only on $K \setminus E$ for any pluripolar $E \subseteq K$.*

Proof Let $u \in \mathcal{L}_\delta$ satisfy $u \leq \psi$ on $K \setminus E$, where E is pluripolar. Choose b as in the lemma, with $b = -\infty$ on E and $b \leq 0$ on K , and put $m = \inf_K \psi$. For $\epsilon > 0$ define

$$u_\epsilon = \frac{u + \epsilon b + \epsilon m}{1 + \epsilon}.$$

This function belongs to $\mathcal{L}_\delta$. On $K \setminus E$, the inequalities $u \leq \psi$, $b \leq 0$ and $m \leq \psi$ give $u_\epsilon \leq \psi$, and on E the pole of b gives $u_\epsilon = -\infty$. Thus u_ϵ is a competitor for V_δ , so $u_\epsilon \leq F_\delta$; moreover, $u_\epsilon \rightarrow u$ almost everywhere as $\epsilon \downarrow 0$. By Lemma 1.3.3, $u \leq F_\delta$ everywhere. Taking the supremum over u and regularizing proves the asserted equalities.

Alternatively, apply Proposition 1.19.2 on $\mathbb{P}^n$ with the big background θ_δ and the bounded obstacle $\psi - \delta\chi/2$, and then use (12.1). $\square$

These equalities concern regularized envelopes. The raw envelope V_δ is still defined with the obstacle imposed at every point of K .

Changing δ changes both the background θ_δ and the obstacle $\psi - \delta\chi/2$. Nevertheless, the set of parameters for which contact holds has a simple structure. Put

$$\Lambda = \{\delta > 0 : V_\delta|_K = \psi\}, \quad \Lambda_{\text{reg}}(a) = \{\delta \in \Lambda : F_\delta(a) = \psi(a)\} \quad (a \in K).$$

The parameters $\delta \in \Lambda$ are those for which the raw envelope touches the obstacle at every point of K ; we say that *raw contact* holds for them. For $a \in K$, the parameters in $\Lambda_{\text{reg}}(a)$ are those for which, in addition, the regularized envelope touches the obstacle at a ; we say that *regular contact* holds at a .

Theorem 12.1.3 *The set Λ is empty, $(0, \infty)$, or $[\lambda, \infty)$ for some $\lambda > 0$. If $\Lambda = [\lambda, \infty)$, each $\Lambda_{\text{reg}}(a)$ is empty, $\{\lambda\}$, or Λ . If $\Lambda = (0, \infty)$, each $\Lambda_{\text{reg}}(a)$ is empty or Λ . The same alternatives hold for $\bigcap_{a \in K} \Lambda_{\text{reg}}(a)$.*

Proof Let $m = \inf_K \psi$. Inclusion of the growth classes and scaling of competitors give, for $0 < \alpha < \beta$,

$$0 \leq V_\beta - V_\alpha \leq \frac{\beta - \alpha}{\alpha} (V_\alpha - m). \quad (12.2)$$

Indeed, if u is a competitor for V_β , then $(\alpha/\beta)(u - m) + m$ is a competitor for V_α , since $\psi \geq m$. The constant m is also a competitor, so all terms are finite and the right-hand side is nonnegative. The estimate shows that $V_\delta(z)$ depends continuously

on $\delta > 0$ at every point z . Since $V_\delta \leq \psi$ on K and V_δ increases with δ , the set Λ is closed upwards, and by continuity it is relatively closed in $(0, \infty)$. This proves the three possible forms of Λ .

For $0 \leq t \leq 1$, convex combinations of competitors give

$$V_{(1-t)\alpha+t\beta} \geq (1-t)V_\alpha + tV_\beta.$$

By the preceding proposition, the same inequality holds for the regularized envelopes almost everywhere, and hence everywhere by [Lemma 1.3.3](#). Thus $F_\delta(z)$ is a concave nondecreasing function of δ at every point z .

For $a \in K$ and $\delta \in \Lambda$, the defect $d_\delta = F_\delta(a) - \psi(a)$ is nonnegative, concave and nondecreasing in δ . Suppose $d_\alpha = 0$, and that there is $\eta \in \Lambda$ with $\eta < \alpha$. For every $\beta > \alpha$, write α as a convex combination of η and β with positive weights. Concavity then forces both nonnegative defects d_η and d_β to vanish, and monotonicity gives $d_\delta = 0$ for all $\delta \in \Lambda$ with $\delta < \alpha$. Hence a zero of the defect at a parameter other than the smallest element of Λ forces every defect to vanish. This proves the alternatives for each $\Lambda_{\text{reg}}(a)$, and intersecting them gives the alternatives for $\bigcap_{a \in K} \Lambda_{\text{reg}}(a)$. $\square$

Thus raw contact persists as the growth allowance increases, whereas regular contact at a point may hold only at the smallest contact parameter. The correspondence with $\mathbb{P}^n$ keeps the background and the obstacle matched throughout this variation.

12.1.1.1 Growth slopes and supporting probabilities

By concavity, the rate at which F_δ grows when the growth allowance δ is increased is at least its rate of growth for large δ , and the latter is the classical extremal function of K , without weight. For continuous weights, supporting probabilities express the initial rate of growth through tests by functions of the fixed class $\mathcal{L}_1$.

When the weight varies, we write $V_{\delta,q}$ and $F_{\delta,q} = V_{\delta,q}^*$ for the raw and regularized envelopes defined as above, with a bounded obstacle q on the fixed compact set K in place of ψ . Thus $F_\delta = F_{\delta,\psi}$. Set

$$V_K = V_{1,0}, \quad V_K^* = F_{1,0}, \quad m = \inf_K \psi, \quad M = \sup_K \psi.$$

Thus V_K^* is the extremal function of K . Since the constant 0 is a competitor for V_K , and since competitors can be scaled and translated by constants, we have $V_K^* \geq 0$ and

$$\delta V_K^* + m \leq F_\delta \leq \delta V_K^* + M. \quad (12.3)$$

Lemma 12.1.3 *For $0 < \alpha < \beta$, one has on $\mathbb{C}^n$*

$$(\beta - \alpha)V_K^* \leq F_\beta - F_\alpha \leq \frac{\beta - \alpha}{\alpha}(F_\alpha - m). \quad (12.4)$$

Proof If u is a competitor for $V_\alpha = V_{\alpha,\psi}$ and v is a competitor for $V_K = V_{1,0}$, then $u + (\beta - \alpha)v$ is a competitor for V_β . Taking the suprema over u and v independently

gives

$$V_\beta \geq V_\alpha + (\beta - \alpha)V_K.$$

By [Proposition 12.1.5](#), the raw envelopes agree almost everywhere with their regularizations, so this inequality holds almost everywhere for the regularizations, and hence everywhere by [Lemma 1.3.3](#). This is the first inequality. The same argument applied to [\(12.2\)](#) gives the second. $\square$

Proposition 12.1.6 *For every $a \in \mathbb{C}^n$ and $\tau > 0$, the right derivative*

$$D_\tau(a) = \lim_{h \downarrow 0} \frac{F_{\tau+h}(a) - F_\tau(a)}{h}$$

exists and is finite. The difference quotients decrease as $h > 0$ increases, and

$$V_K^*(a) \leq \frac{F_{\tau+h}(a) - F_\tau(a)}{h} \leq D_\tau(a) \leq \frac{F_\tau(a) - m}{\tau}. \quad (12.5)$$

As $h \rightarrow \infty$, they converge to $V_K^(a)$, with the error bound*

$$0 \leq \frac{F_{\tau+h}(a) - F_\tau(a)}{h} - V_K^*(a) \leq \frac{M - m}{h}. \quad (12.6)$$

Moreover, $D_\tau(a) = V_K^(a)$ if and only if*

$$F_\delta(a) = F_\tau(a) + (\delta - \tau)V_K^*(a) \quad (\delta \geq \tau). \quad (12.7)$$

Proof For $0 < h_1 < h_2$, concavity of $F_\delta(a)$ gives

$$F_{\tau+h_1}(a) - F_\tau(a) \geq \frac{h_1}{h_2} (F_{\tau+h_2}(a) - F_\tau(a)).$$

Thus the difference quotients decrease with h . [Lemma 12.1.3](#) bounds them between $V_K^*(a)$ and $(F_\tau(a) - m)/\tau$, which proves the existence and finiteness of $D_\tau(a)$ and [\(12.5\)](#). Combining the lower bound for the increments with [\(12.3\)](#) gives [\(12.6\)](#), with a bound independent of a . If $D_\tau(a) = V_K^*(a)$, then by [\(12.5\)](#) every difference quotient equals $V_K^*(a)$, which gives [\(12.7\)](#). Conversely, that formula gives $D_\tau(a) = V_K^*(a)$. $\square$

Corollary 12.1.2 *Let $a \in K$ and $\tau \in \Lambda_{\text{reg}}(a)$. Regular contact at a holds for every $\delta > \tau$ if and only if $D_\tau(a) = 0$. If $D_\tau(a) > 0$, regular contact at a fails for every $\delta > \tau$, and τ is the smallest element of Λ .*

Proof At τ one has $F_\tau(a) = \psi(a)$, and raw contact holds for all $\delta \geq \tau$ by [Theorem 12.1.3](#). If $D_\tau(a) = 0$, then by [\(12.5\)](#) every difference quotient at τ vanishes, so $F_\delta(a) = \psi(a)$ for all $\delta > \tau$. If $D_\tau(a) > 0$, then $F_\delta(a) > \psi(a)$ for all δ slightly larger than τ , and by monotonicity for all $\delta > \tau$. In this case $\Lambda_{\text{reg}}(a)$ contains τ but no larger parameter, so by [Theorem 12.1.3](#) it equals $\{\lambda\}$, where $\lambda = \tau$ is the smallest element of Λ . $\square$

Assume now that the weights are continuous. If the obstacle is imposed only quasi-everywhere on K , the regularized envelope itself becomes a competitor, so the supremum needs no regularization; a constraint imposed at every point would miss the values created by regularization. Indeed, for $q \in C(K, \mathbb{R})$,

$$F_{\delta,q}(z) = \sup\{u(z) : u \in \mathcal{L}_\delta, u \leq q \text{ q.e. on } K\}. \quad (12.8)$$

The envelope $F_{\delta,q}$ itself is a competitor on the right, since it agrees with the raw envelope off a pluripolar set by [Proposition 12.1.5](#). Conversely, the argument of [Corollary 12.1.1](#) shows that every competitor on the right lies below $F_{\delta,q}$ everywhere.

For $a \in \mathbb{C}^n$, let $\mathcal{J}_a(K)$ be the set of *supporting pairs* (μ, c) , where μ is a Borel probability measure on K and $c \geq 0$, such that

$$u(a) \leq \int_K f \, d\mu + c \quad (12.9)$$

whenever $u \in \mathcal{L}_1$, $f \in C(K, \mathbb{R})$ and $u \leq f$ quasi-everywhere on K . We call μ a *supporting probability* at a .

Theorem 12.1.4 *For every $a \in \mathbb{C}^n$, $q \in C(K, \mathbb{R})$ and $\delta > 0$,*

$$F_{\delta,q}(a) = \min_{(\mu,c) \in \mathcal{J}_a(K)} \left(\int_K q \, d\mu + \delta c \right). \quad (12.10)$$

In particular, $\mathcal{J}_a(K)$ is nonempty and

$$\min_{(\mu,c) \in \mathcal{J}_a(K)} c = V_K^*(a).$$

Proof On the real Banach space $C(K)$, put $T(f) = F_{1,f}(a)$. By [\(12.8\)](#), T is concave, since convex combinations of competitors are competitors. Comparison of obstacles and translation by constants show that T is nondecreasing and satisfies

$$T(f+t) = T(f) + t, \quad |T(f) - T(g)| \leq \|f - g\|_\infty.$$

Fix $f_0 \in C(K)$. The directional derivative of the convex Lipschitz function $-T$ at f_0 is finite and sublinear. By the Hahn–Banach theorem, there is a continuous linear functional dominated by it, and since difference quotients of a convex function are monotone, this functional supports $-T$ at f_0 . Changing the sign, we obtain a continuous linear functional ℓ with

$$T(f) \leq T(f_0) + \ell(f - f_0) \quad (f \in C(K)).$$

Testing $f = f_0 + th$ with $h \geq 0$ and $t > 0$, and using monotonicity, gives $\ell(h) \geq 0$. Testing with $f = f_0 \pm t$ gives $\ell(1) = 1$. By the Riesz representation theorem, $\ell(f) = \int_K f \, d\mu$ for a Borel probability measure μ on K . Set $c = T(f_0) - \int_K f_0 \, d\mu$. The supporting inequality at $f = 0$ gives $c \geq T(0) = V_K^*(a) \geq 0$. Together with [\(12.8\)](#), it shows that $(\mu, c) \in \mathcal{J}_a(K)$ and

$$T(f_0) = \int_K f_0 \, d\mu + c.$$

Conversely, applying (12.9) to $u = F_{1,f_0}$, which lies below f_0 quasi-everywhere on K , shows that $T(f_0) \leq \int_K f_0 \, d\mu + c$ for every pair in $\mathcal{J}_a(K)$. This proves (12.10) for $\delta = 1$, with the minimum attained. The identity $F_{\delta,q} = \delta F_{1,q/\delta}$ gives the general case, and the zero obstacle gives the last assertion. $\square$

Theorem 12.1.5 *If $\psi \in C(K, \mathbb{R})$, then for every $a \in \mathbb{C}^n$ and $\tau > 0$,*

$$D_\tau(a) = \min \left\{ c : (\mu, c) \in \mathcal{J}_a(K), \int_K \psi \, d\mu + \tau c = F_\tau(a) \right\}. \quad (12.11)$$

Consequently, $D_\tau(a) = V_K^(a)$ if and only if there is a Borel probability measure μ on K such that*

$$(\mu, V_K^*(a)) \in \mathcal{J}_a(K), \quad \int_K \psi \, d\mu = F_\tau(a) - \tau V_K^*(a).$$

Proof Each defining inequality of $\mathcal{J}_a(K)$ is preserved under weak convergence of the probability measures and convergence of the constants, because the test function f is continuous. Since the Borel probability measures on the compact metric space K form a weakly compact set, the pairs in $\mathcal{J}_a(K)$ with $c \leq C$ form a compact set for each finite C .

Call a pair in $\mathcal{J}_a(K)$ *active* at τ if it satisfies the equality in (12.11). Such pairs exist by Theorem 12.1.4, and since $\int_K \psi \, d\mu \geq m = \inf_K \psi$, they satisfy

$$0 \leq c \leq \frac{F_\tau(a) - m}{\tau}.$$

The set of active pairs is therefore compact, and the minimum of c over it is attained. By Theorem 12.1.4 at $\tau + h$, each active pair gives $F_{\tau+h}(a) \leq F_\tau(a) + hc$, hence $D_\tau(a) \leq c$.

Conversely, for $h > 0$ choose a pair (μ_h, c_h) attaining the minimum in (12.10) at $\tau + h$, with $q = \psi$. The representation at τ gives

$$F_\tau(a) \leq \int_K \psi \, d\mu_h + \tau c_h = F_{\tau+h}(a) - hc_h.$$

Thus $0 \leq c_h \leq (F_{\tau+h}(a) - F_\tau(a))/h$, and these constants are bounded by (12.5). Along a sequence $h \downarrow 0$, compactness gives a limiting pair $(\mu, c) \in \mathcal{J}_a(K)$. The same bound makes $F_{\tau+h}(a) \rightarrow F_\tau(a)$ and $hc_h \rightarrow 0$, and continuity of ψ then gives $\int_K \psi \, d\mu + \tau c = F_\tau(a)$. Thus the limit pair is active, and it satisfies $c \leq D_\tau(a)$. This proves (12.11). Finally, every pair has $c \geq V_K^*(a)$ by Theorem 12.1.4, so the attainment of the minimum gives the stated criterion. $\square$

At a point a of regular contact, $F_\tau(a) = \psi(a)$, so the criterion involves only the original weight and tests by functions in $\mathcal{L}_1$. If the defining tests instead required

$u \leq f$ at every point of K , the pair $(\delta_a, 0)$, where δ_a is the unit point mass at $a \in K$, would always be allowed; the resulting infimum would be at most $\psi(a)$ and would not detect a defect created by regularization.

12.1.1.2 Variation of continuous weights

Supporting probabilities also describe how the envelope responds to changes of the weight, jointly with changes of the growth allowance. Keep the non-pluripolar compact set $K \subset \mathbb{C}^n$ fixed. For $a \in \mathbb{C}^n$, $\delta > 0$ and $q \in C(K, \mathbb{R})$, let

$$\mathcal{J}_a^{\text{act}}(\delta, q) = \left\{ (\mu, c) \in \mathcal{J}_a(K) : \int_K q \, d\mu + \delta c = F_{\delta, q}(a) \right\}. \quad (12.12)$$

be the set of pairs that are active at (δ, q) . We give the weights the uniform norm, the probability measures the weak topology, and the constants the usual topology of $\mathbb{R}$.

Lemma 12.1.4 *The set $\mathcal{J}_a^{\text{act}}(\delta, q)$ is nonempty, convex and compact. For $\delta, \eta \geq \epsilon > 0$ and $p, q \in C(K, \mathbb{R})$,*

$$|F_{\eta, p}(a) - F_{\delta, q}(a)| \leq \|p - q\|_{\infty} + |\eta - \delta| \left(V_K^*(a) + \frac{\text{osc}_K q}{\epsilon} \right). \quad (12.13)$$

If $\delta_j \rightarrow \delta > 0$, $q_j \rightarrow q$ uniformly and $(\mu_j, c_j) \in \mathcal{J}_a^{\text{act}}(\delta_j, q_j)$, then these pairs have a convergent subsequence, and every subsequential limit belongs to $\mathcal{J}_a^{\text{act}}(\delta, q)$.

Proof Nonemptiness follows from **Theorem 12.1.4**. Since the test functions are continuous, $\mathcal{J}_a(K)$ is closed and convex, and the equality defining active pairs is a closed affine condition. For an active pair, (12.3), applied with the weight q , gives

$$0 \leq c \leq \frac{F_{\delta, q}(a) - \inf_K q}{\delta} \leq V_K^*(a) + \frac{\text{osc}_K q}{\delta}.$$

The pairs in $\mathcal{J}_a(K)$ with bounded constants form a compact set, as in the proof of **Theorem 12.1.5**; hence the set of active pairs is compact.

With q fixed, **Lemma 12.1.3** and (12.3), applied with the weight q , bound $|F_{\eta, q}(a) - F_{\delta, q}(a)|$ by $|\eta - \delta|(V_K^*(a) + \text{osc}_K q/\epsilon)$. Comparison of obstacles and translation by constants bound $|F_{\eta, p}(a) - F_{\eta, q}(a)|$ by $\|p - q\|_{\infty}$. Adding these bounds gives (12.13).

For the sequence in the statement, the constants c_j have a common bound, by the estimate above, because the weights q_j are uniformly bounded and the parameters δ_j are bounded below by a positive constant. Weak compactness of probability measures gives a convergent subsequence of pairs, and its limit belongs to $\mathcal{J}_a(K)$, which is closed. The estimate (12.13) gives $F_{\delta_j, q_j}(a) \rightarrow F_{\delta, q}(a)$, while uniform convergence of the q_j and weak convergence of the μ_j give $\int_K q_j \, d\mu_j \rightarrow \int_K q \, d\mu$. Passing to the limit in the equality defining active pairs proves the last assertion. $\square$

Proposition 12.1.7 *For $r \in C(K, \mathbb{R})$ and $s \in \mathbb{R}$, one has*

$$\lim_{h \downarrow 0} \frac{F_{\delta+hs, q+hr}(a) - F_{\delta, q}(a)}{h} = \min_{(\mu, c) \in \mathcal{J}_a^{\text{act}}(\delta, q)} \left(\int_K r \, d\mu + sc \right). \quad (12.14)$$

The same limit holds along any sequence $h_j \downarrow 0$ if s, r in the difference quotient are replaced by s_j, r_j , where $s_j \rightarrow s$ and $r_j \rightarrow r$ uniformly. Thus the one-sided directional derivative is stable under convergence of the directions.

Proof By compactness of the set of active pairs, the minimum on the right is attained. For a fixed pair (μ, c) active at (δ, q) , the representation (12.10) at the perturbed parameters gives

$$F_{\delta+hs, q+hr}(a) \leq F_{\delta, q}(a) + h \left(\int_K r \, d\mu + sc \right).$$

Choosing an active pair that attains the minimum on the right, we see that the upper limit of the difference quotients is at most this minimum. Conversely, choose a pair (μ_h, c_h) active at $(\delta + hs, q + hr)$. The representation at (δ, q) gives

$$\frac{F_{\delta+hs, q+hr}(a) - F_{\delta, q}(a)}{h} \geq \int_K r \, d\mu_h + sc_h.$$

The estimate (12.13) bounds the difference quotients. Along a sequence of values of h realizing their lower limit, Lemma 12.1.4 gives a subsequence of pairs converging to a pair active at (δ, q) . For this pair, $\int_K r \, d\mu + sc$ is at least the minimum on the right. This proves (12.14).

For convergent directions, the same two inequalities hold. The fixed active pair attaining the minimum gives an upper bound with the right limit. The active pairs at the perturbed parameters still have uniformly bounded constants, and their subsequential limits are active at (δ, q) . Uniform convergence of the r_j controls the integrals $\int_K r_j \, d\mu_{h_j}$, and $s_j \rightarrow s$ controls the terms $s_j c_{h_j}$. The lower bound therefore has the same limit. Note that all perturbed growth allowances $\delta + h_j s_j$ are positive for small h_j . $\square$

Corollary 12.1.3 *For fixed a and q , the function $\delta \mapsto F_{\delta, q}(a)$ has finite left and right derivatives $D_{\delta, q}^-(a)$ and $D_{\delta, q}^+(a)$ at every positive parameter, with*

$$D_{\delta, q}^-(a) = \max_{\mathcal{J}_a^{\text{act}}(\delta, q)} c, \quad D_{\delta, q}^+(a) = \min_{\mathcal{J}_a^{\text{act}}(\delta, q)} c. \quad (12.15)$$

It is differentiable exactly when all active pairs have the same constant c . For each fixed a, q , the set of positive parameters where it fails to be differentiable is at most countable.

Proof Apply (12.14) with $r = 0$ and $s = \pm 1$. The direction $s = -1$ gives minus the left derivative, which proves (12.15). Concavity gives

$$D_{\alpha, q}^+(a) \geq D_{\beta, q}^-(a) \quad (0 < \alpha < \beta).$$

Hence the open intervals $(D_{\delta,q}^+(a), D_{\delta,q}^-(a))$, which are nonempty exactly at the parameters where differentiability fails, are pairwise disjoint. Choosing a rational number in each of them proves countability. $\square$

Corollary 12.1.4 *For fixed a and $\delta > 0$, the map $q \mapsto F_{\delta,q}(a)$ on $C(K, \mathbb{R})$ is Gâteaux differentiable at q if and only if all pairs active at (δ, q) have the same probability measure μ . In that case its derivative is*

$$r \mapsto \int_K r \, d\mu.$$

Proof With $s = 0$, (12.14) shows that the right derivative in the direction r is the minimum of $\int_K r \, d\mu$ over active pairs, and the direction $-r$ shows that the left derivative is the maximum. If all active pairs have the same probability measure, these values agree and define a continuous linear derivative. Conversely, if the map is Gâteaux differentiable, the minimum and the maximum agree for every continuous r . Continuous functions separate Borel probability measures on K , so all active pairs have the same probability measure; their constant is then determined by (12.12), since $\delta > 0$. $\square$

Example 12.1.1 Let $D \subset \mathbb{C}$ be the open unit disk, let $K = \overline{D}$, and fix $\delta > 0$. For $q_t(z) = -t|z|^2$,

$$F_{\delta,q_t}(0) = \begin{cases} -t, & t \geq 0, \\ 0, & -\delta/2 \leq t \leq 0. \end{cases} \quad (12.16)$$

Thus the map $q \mapsto F_{\delta,q}(0)$ is not Gâteaux differentiable at $q = 0$, and there are active pairs at $(\delta, 0)$ with different probability measures.

Proof For $t \geq 0$, each competitor is at most $-t$ on the unit circle, so the maximum principle for subharmonic functions bounds it by $-t$ on D . This bound persists after regularization on D , and the constant $-t$ is a competitor. Hence $F_{\delta,q_t}(0) = -t$.

For $t = -b$ with $0 \leq b \leq \delta/2$, define

$$u_b(z) = \begin{cases} b|z|^2, & |z| \leq 1, \\ b + \delta \log |z|, & |z| > 1. \end{cases}$$

This function is continuous and subharmonic: its Laplacian has density $4b$ inside the disk, density zero outside, and a nonnegative contribution on the circle coming from the jump $\delta - 2b \geq 0$ of the radial derivative. It belongs to $\mathcal{L}_\delta$ and equals q_{-b} on K . Hence $F_{\delta,q_{-b}}(0) \geq u_b(0) = 0$. On D the raw envelope is at most the continuous function $b|z|^2$, so its regularization at zero is at most zero. This proves (12.16). In particular, the right and left derivatives in t at $t = 0$ are -1 and 0 , and Corollary 12.1.4, applied in the direction $r = -|z|^2$, gives the final assertion. $\square$

12.1.1.3 Local regularity and strict weights

Whether the regularized envelope touches the obstacle at a point $a \in K$ depends only on the parts of K near a . Without weight, this local regularity is detected by the relative extremal function $h_{E,B}$ of [Definition 1.6.1](#), for compact pieces E of K near a and small balls B centered at a . If the weight extends to a global function whose complex Hessian has a strict lower bound near a , a failure of this regularity produces a quantitative defect of the weighted envelope.

For a non-pluripolar compact set $E \subset \mathbb{C}^n$, write V_E and V_E^* for the raw and regularized envelopes of growth one with zero obstacle on E ; thus $V_K = V_{1,0}$ as before. For other weights and growth allowances, write $F_{\delta,E,q}$ for the regularized envelope with growth allowance δ and obstacle q imposed at every point of E .

Lemma 12.1.5 *Let $a \in \mathbb{C}^n$, $0 < r < R$ and $B = B(a, R)$, and let $E \subseteq \overline{B}(a, r)$ be compact. If E is pluripolar, then $h_{E,B}^* = 0$ on B . If E is non-pluripolar, then*

$$h_{E,B}^*(a) = -1 \iff V_E^*(a) = 0.$$

Proof In the pluripolar case, choose $b \in \mathcal{L}_1$ with $b = -\infty$ on E by [Lemma 12.1.2](#), and a finite upper bound C for b on B . The functions

$$u_\epsilon = \max\{-1, \epsilon(b - C)\}$$

are competitors for $h_{E,B}$, and they tend to zero almost everywhere as $\epsilon \downarrow 0$. Hence $h_{E,B}^* \geq 0$ almost everywhere, and then everywhere by [Lemma 1.3.3](#). Since $h_{E,B}^* \leq 0$, it vanishes.

Now suppose that E is non-pluripolar. [Proposition 12.1.5](#) gives a finite upper bound $M \geq 1$ for V_E^* on B . For each competitor v for V_E , the function $\max(-1, v/M - 1)$ is a competitor for $h_{E,B}$. Taking suprema and regularizing gives

$$h_{E,B}^*(a) \geq \max\{-1, V_E^*(a)/M - 1\}.$$

As $V_E^* \geq 0$, the equality $h_{E,B}^*(a) = -1$ forces $V_E^*(a) = 0$.

For the converse, choose $r < R_0 < R$ and $k > 0$ with $k \log(R_0/r) > 1$. The plurisubharmonic function

$$L(z) = k \log(\|z - a\|/r)$$

belongs to $\mathcal{L}_k$ and equals $-\infty$ at a . For a competitor u for $h_{E,B}$, define $W = \max(u + 1, L)$ on B and $W = L$ outside B . On the collar $R_0 < \|z - a\| < R$ we have $L > 1 \geq u + 1$, so the two definitions agree there, and W is plurisubharmonic by [Lemma 1.3.2](#). On E one has $u = -1$ and $L \leq 0$, so $W = 0$; on the ball $B(a, r)$ one has $L < 0 \leq u + 1$, so $W = u + 1$. Hence W/k is a competitor for V_E , with k independent of u . Taking the supremum over u and regularizing at a gives

$$V_E^*(a) \geq (1 + h_{E,B}^*(a))/k.$$

Thus $V_E^*(a) = 0$ forces $h_{E,B}^*(a) = -1$. $\square$

Let $K \subset \mathbb{C}^n$ again be a non-pluripolar compact set. For $a \in K$ and $r > 0$, put $K_r = K \cap \overline{B}(a, r)$.

Definition 12.1.1 The compact set K is *locally pluriregular* at $a \in K$ if every K_r , $r > 0$, is non-pluripolar and $V_{K_r}^*(a) = 0$. For $\delta > 0$ and a bounded function q on K , it is *locally (δ, q) -regular* at a if $F_{\delta, K_r, q}(a) = q(a)$ for every $r > 0$.

It suffices to check arbitrarily small radii, since envelopes decrease as the compact set increases. By **Lemma 12.1.5**, K is locally pluriregular at a if and only if $h_{K_r, B(a, R)}^*(a) = -1$ for all small $0 < r < R$.

Lemma 12.1.6 *Let q be bounded and upper semicontinuous on K , and suppose that raw contact holds for the parameter $\delta > 0$ and the obstacle q on K , that is, $V_{\delta, q} = q$ on K . If K is locally pluriregular at a , then $F_{\delta, K, q}(a) = q(a)$ and K is locally (δ, q) -regular at a . These equalities also hold with δ replaced by any larger parameter.*

Proof Put $M_r = \sup_{K_r} q$. Raw contact, monotonicity of envelopes with respect to the compact set, and (12.3) for K_r give

$$q(a) \leq F_{\delta, K, q}(a) \leq F_{\delta, K_r, q}(a) \leq M_r + \delta V_{K_r}^*(a) = M_r.$$

Since q is upper semicontinuous and $a \in K_r$, we have $M_r \downarrow q(a)$ as $r \downarrow 0$, which gives $F_{\delta, K, q}(a) = q(a)$.

Every compact subset $E \subseteq K$ inherits raw contact: on E , the raw envelope for E is at least the raw envelope for K , which equals q , and at most the obstacle q . For fixed $s > 0$, apply the same bounds with $r < s$ and K_s in place of K , and let $r \downarrow 0$. This proves local (δ, q) -regularity. By **Theorem 12.1.3**, raw contact also holds for every larger parameter, and applying what has been proved to each of them gives the last assertion. $\square$

Theorem 12.1.6 *Let $a \in K$, $\tau > 0$ and $\Psi \in \mathcal{L}_\tau \cap C(\mathbb{C}^n)$, and put $q = \Psi|_K$. Suppose that, for some $R, c > 0$,*

$$\text{dd}^c \Psi \geq c \omega_0 \quad \text{on } B(a, R), \quad \omega_0 = \text{dd}^c \|z\|^2.$$

For $0 < r < R$ and $\delta \geq \tau$,

$$F_{\delta, K, q}(a) - \Psi(a) \geq cr^2(1 + h_{K_r, B(a, R)}^*(a)). \quad (12.17)$$

Regular contact at a , that is, $F_{\delta, K, q}(a) = q(a)$, holds for some $\delta \geq \tau$ if and only if K is locally pluriregular at a . In that case it holds for every $\delta \geq \tau$.

Proof Set $B = B(a, R)$ and $E = K_r$. For a competitor u for $h_{E, B}$, the function

$$H_u(z) = \Psi(z) - c\|z - a\|^2 + cr^2(u(z) + 1)$$

is plurisubharmonic on B , because the assumption on $\text{dd}^c \Psi$ makes $\Psi - c\|z - a\|^2$ plurisubharmonic there. Since $u \leq 0$, we have $H_u \leq \Psi$ where $\|z - a\| \geq r$. Define $W = \max(\Psi, H_u)$ on B and $W = \Psi$ outside B . The two definitions agree near ∂B , so W is plurisubharmonic on $\mathbb{C}^n$, and it belongs to $\mathcal{L}_\tau$ because it equals Ψ outside B . On E , the equality $u = -1$ gives $H_u \leq \Psi$, and on $K \setminus E$ the distance bound gives the same inequality. Thus $W = q$ on K , so W is a competitor for $F_{\delta, K, q}$ for each $\delta \geq \tau$. Since $W \geq H_u$ near a , taking the supremum over u , regularizing, and using the continuity of Ψ , we obtain (12.17).

The function Ψ itself is a competitor, so raw contact holds for every $\delta \geq \tau$. If regular contact holds for one such δ , the left-hand side of the estimate vanishes, so $h_{K_r, B(a, R)}^*(a) = -1$ for all $0 < r < R$. By Lemma 12.1.5, every K_r with $r < R$ is then non-pluripolar and satisfies $V_{K_r}^*(a) = 0$; for $r \geq R$ this follows by monotonicity. Conversely, local pluriregularity and Lemma 12.1.6 give regular contact at a for every $\delta \geq \tau$. $\square$

In this regular case, $V_K^*(a) \leq V_{K_r}^*(a) = 0$ by monotonicity, and the right derivative $D_\tau(a)$ with respect to the growth allowance, for the weight q , vanishes by Corollary 12.1.2, since regular contact persists.

Corollary 12.1.5 *Let $\tau > 0$, $\Psi \in \mathcal{L}_\tau \cap C^2(\mathbb{C}^n)$ and $a \in K$. If $F_{\tau, K, \Psi|_K}(a) = \Psi(a)$, but $F_{\delta, K, \Psi|_K}(a) > \Psi(a)$ for some $\delta > \tau$, then*

$$(\text{dd}^c \Psi)^n(a) = 0.$$

Proof The complex Hessian of Ψ is semipositive. If its top power did not vanish at a , it would be positive definite at a , and by continuity $\text{dd}^c \Psi \geq c\omega_0$ on a neighborhood of a for some $c > 0$. Theorem 12.1.6 would then give regular contact at a for every $\delta \geq \tau$, a contradiction. $\square$

12.1.1.4 A regularization defect along a complex disk

Raw contact with a constant obstacle can hold for every positive growth parameter while regularization raises the value of the envelope at a point of the compact set. In the following example, a complex disk through the point, transverse to the planar direction, prevents any local plurisubharmonic function from separating the point from the rest of the compact set, but it does not remove this defect.

In the complex plane, let D be the open unit disk and put

$$p_j = 2 + 2^{-j}, \quad r_j = \exp(-16 \cdot 2^j), \quad E = \overline{D} \cup \{2\} \cup \bigcup_{j \geq 1} \overline{D}(p_j, r_j).$$

Lemma 12.1.7 *The set E is compact, and every neighborhood of each of its points contains an open disk contained in E . The series*

$$h(\zeta) = \sum_{j \geq 1} 2^{-j} \log |\zeta - p_j| + 2 \log 2$$

defines a subharmonic function on $\mathbb{C}$ of logarithmic growth at most one; it satisfies $h(2) = 0$ and is at most $-16 + 2 \log 2$ on every small disk $\overline{D}(p_j, r_j)$. The function

$$v(\zeta) = \frac{8 \log^+ |\zeta| + h(\zeta) - 4 \log 2}{9}$$

is subharmonic of logarithmic growth at most one, is nonpositive on $E \setminus \{2\}$, and satisfies $v(2) = 4 \log 2/9$.

Proof Since $r_j < 2^{-j-3}$, the small disks are pairwise disjoint and disjoint from $\overline{D}$, and they accumulate only at 2. This proves compactness. Every neighborhood of 2 contains one of the small disks, and every other point of E lies in the closure of the interior of one of the disks.

To show that the series defines a subharmonic function, write $\chi(\zeta) = \log(1 + |\zeta|^2)$ on $\mathbb{C}$ and $\theta = \omega_{\text{FS}}/2$ on $\mathbb{P}^1$. By [Lemma 12.1.1](#), each

$$q_j = \log |\zeta - p_j| - \chi/2$$

extends to a θ -plurisubharmonic function on $\mathbb{P}^1$. The Cauchy–Schwarz inequality gives $q_j \leq \log 4$, while the value of q_j at infinity is zero. Thus $0 \leq \sup q_j \leq \log 4$, and [Theorem 1.4.1](#) bounds $\|q_j - \log 4\|_{L^1}$ uniformly. The partial sums

$$w_N = \sum_{j=1}^N 2^{-j} (q_j - \log 4)$$

decrease, remain θ -plurisubharmonic and have uniformly bounded L^1 norms. By [Corollary 1.4.1](#), their limit w belongs to $\text{PSH}(\mathbb{P}^1, \theta)$. Since $\sum_j 2^{-j} = 1$,

$$h = w + \chi/2 + \log 4 + 2 \log 2$$

on the affine chart. This proves subharmonicity and the growth bound, and $\sum_j j 2^{-j} = 2$ gives $h(2) = 0$.

On the j th small disk, all distances to the other centers are less than one, so the corresponding terms are negative, and

$$h \leq 2^{-j} \log r_j + 2 \log 2 = -16 + 2 \log 2.$$

On $\overline{D}$ all distances to the centers are less than four, hence $h \leq 4 \log 2$ and $v \leq 0$. On each small disk $|\zeta| < 4$, so $9v \leq 14 \log 2 - 16 < 0$. The growth bound for v and its value at 2 follow directly from the formula. $\square$

Now let $n \geq 2$ and $K = E \times \overline{D}^{n-1} \subset \mathbb{C}^n$. For a non-pluripolar compact set $L \subset \mathbb{C}^n$, write $V_{\delta, L}$ and $F_{\delta, L}$ for the raw envelope with growth allowance δ and zero obstacle on L , and for its regularization.

Proposition 12.1.8 *For every point of K and every neighborhood W of it, the set $K \cap W$ is non-pluripolar. For $\delta > 0$ and $a = (2, w)$ with $w \in \overline{D}^{n-1}$,*

$$V_{\delta,K}|_K = 0, \quad F_{\delta,K}(a) \geq \frac{4\delta}{9} \log 2 > 0. \quad (12.18)$$

For every $r > 0$, the same lower bound holds for $F_{\delta,K \cap \overline{B}(a,r)}(a)$. At $a_0 = (2, 0, \dots, 0)$, every plurisubharmonic function f defined near a_0 satisfies

$$f(a_0) \leq \limsup_{K \setminus \{a_0\} \ni z \rightarrow a_0} f(z). \quad (12.19)$$

Thus K is not plurithin at a_0 , although the regularized envelope does not touch the obstacle at a_0 for any positive growth parameter.

Proof By the preceding lemma, every neighborhood of a point of K contains a nonempty open subset of K , namely a product of open disks. This proves the first assertion, which applies in particular to each $K \cap \overline{B}(a, r)$, $r > 0$.

Put $b(\zeta) = \log |\zeta - 2| - \log 3$. Since $|\zeta - 2| \leq 3$ on E , we have $b \leq 0$ there, and $b(2) = -\infty$. For $\varepsilon > 0$, the plurisubharmonic function

$$u_\varepsilon(z) = \frac{v(z_1) + \varepsilon b(z_1)}{1 + \varepsilon}$$

belongs to $\mathcal{L}_1$ and satisfies $u_\varepsilon \leq 0$ at every point of K , including the points with $z_1 = 2$, where it equals $-\infty$. Thus $u_\varepsilon \leq F_{1,K}$. Letting $\varepsilon \downarrow 0$ gives $v(z_1) \leq F_{1,K}(z)$ off the hyperplane $\{z_1 = 2\}$, and [Lemma 1.3.3](#) extends this inequality everywhere. The value $v(2) = 4 \log 2/9$ gives the lower bound for $\delta = 1$. Since 0 is a competitor, $V_{\delta,K}|_K = 0$, and scaling of competitors gives $F_{\delta,K} = \delta F_{1,K}$. Replacing K by a smaller compact set only increases the envelope, which proves the local assertion.

Finally, let f be plurisubharmonic near a_0 . If $f(a_0) = -\infty$, (12.19) is automatic. Otherwise, restrict f to the complex line through a_0 in which only the second coordinate varies. Small circles in this line centered at a_0 lie in $K \setminus \{a_0\}$, and the submean inequality on these circles gives (12.19). $\square$

12.2 Bounded domination in a semipositive background

We return to the compact manifold X .

The domination principle for Hermitian backgrounds, [Theorem 10.2.2](#), extends to a smooth semipositive background θ provided every bounded θ -plurisubharmonic potential has positive mass. For bounded potentials u, v satisfying the measure inequality below, contact support bounds $\sup_X P_\theta(bu - (b-1)v)$ from below as the stretching parameter $b > 1$ increases. A fixed gap between u and v would then force the L^1 norms of these envelopes, normalized by their suprema, to diverge, contradicting compactness.

We call a smooth semipositive form θ *non-collapsing on bounded potentials* if

$$\int_X \text{MA}_\theta(w) > 0 \quad \text{for every } w \in \text{PSH}(X, \theta) \cap L^\infty(X).$$

Every Hermitian form has this property by [Corollary 10.2.1](#). Bigness also implies it, by the following envelope argument.

Proposition 12.2.1 *If a smooth real $(1, 1)$ -form θ is big, every bounded $u \in \text{PSH}(X, \theta)$ has strictly positive Monge–Ampère mass.*

Proof Choose $\rho \in \text{PSH}(X, \theta)$ and $a > 0$ with $\theta_\rho \geq a\omega$, normalize $\rho \leq 0$, and put

$$p = P_{a\omega}(u - \rho).$$

The obstacle is finite almost everywhere and bounded below, so [Lemma 1.19.2](#) shows that p is bounded. The obstacle is quasi-continuous off the pluripolar pole set of ρ . The contact theorem, [Theorem 12.1.2](#), applied in the Hermitian background $a\omega$, shows that $\text{MA}_{a\omega}(p)$ is carried by $D = \{p + \rho = u\}$, outside the pole set of ρ .

By [Lemma 1.3.3](#), $p + \rho \leq u$ everywhere, and

$$\theta + \text{dd}^c(p + \rho) = (a\omega + \text{dd}^c p) + (\theta_\rho - a\omega) \geq a\omega + \text{dd}^c p \geq 0.$$

On common finite truncation levels, positivity of the mixed products and ordered contact give

$$\mathbf{1}_D \text{MA}_{a\omega}(p) \leq \mathbf{1}_D \text{MA}_\theta(p + \rho) \leq \mathbf{1}_D \text{MA}_\theta(u).$$

Exhausting by these levels proves the same inequalities for the extended measures. Since p is bounded, its Monge–Ampère mass with respect to the Hermitian form $a\omega$ is positive by [Corollary 10.2.1](#). Integrating the inequalities proves the assertion. $\square$

Theorem 12.2.1 (Guedj–Lu) *Let $\theta \geq 0$ be non-collapsing on bounded potentials. Suppose that $u, v \in \text{PSH}(X, \theta) \cap L^\infty(X)$ and $0 \leq c < 1$. If*

$$\mathbf{1}_{\{u < v\}} \text{MA}_\theta(u) \leq c \mathbf{1}_{\{u < v\}} \text{MA}_\theta(v),$$

then $u \geq v$.

Proof If the conclusion failed, we could choose $a > 0$ such that $E = \{u < v - a\}$ is nonempty. This set has positive volume by [Lemma 1.3.4](#). Fix C with $|u|, |v| \leq C$.

For $b > 1$ define the bounded envelope

$$w_b = P_\theta(bu - (b - 1)v), \quad D_b = \{w_b = bu - (b - 1)v\}.$$

Since $\theta \geq 0$, constants below the obstacle are competitors. By the bounded contact theorem, [Theorem 12.1.1](#), the measure $\text{MA}_\theta(w_b)$ is concentrated on D_b . The potential $b^{-1}w_b + (1 - b^{-1})v$ lies below u quasi-everywhere, hence everywhere by [Lemma 1.3.3](#), and it equals u on D_b outside a pluripolar set. Ordered contact and positivity of the mixed terms give

$$\mathbf{1}_{D_b} [b^{-n} \text{MA}_\theta(w_b) + (1 - b^{-1})^n \text{MA}_\theta(v)] \leq \mathbf{1}_{D_b} \text{MA}_\theta(u).$$

Choose b so large that $(1 - b^{-1})^n > c$. Then the hypothesis forces $\text{MA}_\theta(w_b) = 0$ on $D_b \cap \{u < v\}$. Since θ is non-collapsing, w_b has positive total mass, so some of this mass is carried by $D_b \cap \{u \geq v\}$. At a point of this set outside the exceptional pluripolar set,

$$w_b = bu - (b - 1)v = u + (b - 1)(u - v) \geq -C.$$

Consequently $\sup_X w_b \geq -C$ for all large b .

On the other hand, on the fixed set E the obstacle bound gives $w_b \leq C - (b - 1)a$ quasi-everywhere. Hence

$$\int_X |w_b - \sup_X w_b| dV \geq ((b - 1)a - 2C) \text{vol}_{dV}(E)$$

for all sufficiently large b . This contradicts the uniform L^1 bound for normalized potentials in [Theorem 1.4.1](#). $\square$

The exponential comparison principle follows as in [Corollary 10.2.2](#). For unbounded potentials, the stretched envelopes must also be kept in the required singularity class; this is the role of the relative classes introduced below.

12.3 Upper and lower volumes

Let θ be any smooth real $(1, 1)$ -form. Taking the infimum and the supremum of the mass over a singularity type gives two invariants with values in $[0, +\infty]$. They can differ, because a bounded change of potential need not preserve the mass.

Definition 12.3.1 For $u \in \text{PSH}(X, \theta)$, define

$$\begin{aligned} \underline{\text{vol}}_\theta(u) &= \inf_{v \in \text{PSH}(X, \theta), v \sim u} \int_X \text{MA}_\theta(v), \\ \overline{\text{vol}}_\theta(u) &= \sup_{v \in \text{PSH}(X, \theta), v \sim u} \int_X \text{MA}_\theta(v). \end{aligned}$$

These are the *lower* and *upper volumes* of the singularity type of u in the background θ . When $\text{PSH}(X, \theta)$ is nonempty, we write $\underline{\text{vol}}(\theta)$ and $\text{vol}(\theta)$ for their values at the potential V_θ with minimal singularities.

For semipositive θ , the singularity type of the zero potential consists of the bounded potentials. Extending the lower mass of [Definition 6.5.1](#) to this background, we put

$$v_-(\theta) = \underline{\text{vol}}_\theta(0) = \inf_{v \in \text{PSH}(X, \theta) \cap L^\infty(X)} \int_X \text{MA}_\theta(v).$$

The condition $v_-(\theta) > 0$ is stronger than the non-collapsing property used in bounded domination: it requires a single positive lower bound for the masses of all bounded potentials. Singularity volumes under a bounded mass hypothesis are compared in [Chapter 29](#).

Both volumes are invariant under bounded changes of u , by definition. They are also invariant under the smooth change of decomposition $(\theta, u) \mapsto (\theta + \text{dd}^c f, u - f)$, for $f \in C^\infty(X, \mathbb{R})$: the map $v \mapsto v - f$ identifies the competitors, their currents and their measures. Scaling gives

$$\underline{\text{vol}}_{t\theta}(tu) = t^n \underline{\text{vol}}_\theta(u), \quad \overline{\text{vol}}_{t\theta}(tu) = t^n \overline{\text{vol}}_\theta(u) \quad (t > 0).$$

12.4 Relative envelope classes

Fix a reference potential $\varphi \in \text{PSH}(X, \theta)$. For $b \geq 1$, the stretched obstacle $bu - (b - 1)\varphi = \varphi + b(u - \varphi)$ magnifies the difference between u and φ by the factor b , and so becomes more singular where u lies below φ . Requiring a competitor below every finite stretch defines a relative class that is stable under convex combinations and finite rooftops.

For $u \in \text{PSH}(X, \theta)$ and $b \geq 1$, define the family of competitors

$$\mathcal{A}_b(u, \varphi) = \{h \in \text{PSH}(X, \theta) : b^{-1}h + (1 - b^{-1})\varphi \leq u\}.$$

For $b = 1$ the inequality means $h \leq u$. Away from the poles of u and φ , the inequality means $h \leq bu - (b - 1)\varphi$. The convex combination on the left is defined everywhere, so the definition does not require a value of $bu - (b - 1)\varphi$ at common poles. When $\mathcal{A}_b(u, \varphi)$ is nonempty, we write

$$Q_b(u, \varphi) = P_\theta(bu - (b - 1)\varphi)$$

for its upper envelope. Since the obstacle is finite almost everywhere, the competitors have a common upper bound by [Section 1.19](#), so $Q_b(u, \varphi)$ is then a θ -plurisubharmonic function; in particular, it is not identically $-\infty$. The upper-envelope theorem gives its defining inequality almost everywhere, and [Lemma 1.3.3](#) makes it pointwise; thus $Q_b(u, \varphi)$ is the largest member of $\mathcal{A}_b(u, \varphi)$.

Definition 12.4.1 The *relative envelope class* of φ is

$$\mathcal{E}_{\text{env}}(X, \theta, \varphi) = \{u \in \text{PSH}(X, \theta) : u \preceq \varphi, \mathcal{A}_b(u, \varphi) \neq \emptyset \text{ for every } b \geq 1\}.$$

When the background θ is fixed, we abbreviate $\mathcal{E}_\varphi = \mathcal{E}_{\text{env}}(X, \theta, \varphi)$.

Proposition 12.4.1 *The class $\mathcal{E}_{\text{env}}(X, \theta, \varphi)$ is convex, contains all potentials of the singularity type of φ , and is stable under bounded changes of its members. If u belongs to it, $v \in \text{PSH}(X, \theta)$, $u \leq v$ and $v \preceq \varphi$, then v belongs to it. In particular, it is stable under maxima of two members. Replacing φ by another member of $\text{PSH}(X, \theta)$*

of the same singularity type does not change the class. For every smooth real function f ,

$$u \in \mathcal{E}_{\text{env}}(X, \theta, \varphi) \iff u - f \in \mathcal{E}_{\text{env}}(X, \theta + \text{dd}^c f, \varphi - f).$$

Proof If $u \geq \varphi - C$, then $h = \varphi - bC$ belongs to $\mathcal{A}_b(u, \varphi)$ for each b ; hence every $u \sim \varphi$ belongs to the class. More generally, if $u' \geq u - C$ and $h \in \mathcal{A}_b(u, \varphi)$, then $h - bC \in \mathcal{A}_b(u', \varphi)$. Since the condition $u \preceq \varphi$ is also unchanged by bounded changes of u , the class is stable under such changes. A convex combination of two competitors is a competitor for the same convex combination of the two potentials, which proves convexity. Finally, a competitor for u is a competitor for any larger v , and the assumption $v \preceq \varphi$ gives the remaining condition.

If $\varphi' \in \text{PSH}(X, \theta)$ and $\varphi' \sim \varphi$, choose $C \geq 0$ with $|\varphi' - \varphi| \leq C$ off their common pole set. For $h \in \mathcal{A}_b(u, \varphi)$, the function $h - (b-1)C$ belongs to $\mathcal{A}_b(u, \varphi')$: the required inequality holds off the poles, and it extends everywhere by [Lemma 1.3.3](#). The reverse implication follows by interchanging the references, and $u \preceq \varphi$ is equivalent to $u \preceq \varphi'$.

For the last assertion, note that $h \mapsto h - f$ is a bijection from $\text{PSH}(X, \theta)$ onto $\text{PSH}(X, \theta + \text{dd}^c f)$. It preserves the order $\preceq$ and transforms each stretching inequality into

$$b^{-1}(h - f) + (1 - b^{-1})(\varphi - f) \leq u - f.$$

This identity also holds at poles, because f is smooth and finite. Thus the corresponding families of competitors are in bijection for every $b \geq 1$. $\square$

Lemma 12.4.1 *If $u \in \mathcal{E}_\varphi$ and $u \leq \varphi$, then $Q_b(u, \varphi) \in \mathcal{E}_\varphi$ for every $b \geq 1$. More generally, if $u, w \in \mathcal{E}_\varphi$ and $u \leq w$, then $Q_b(u, w) \in \mathcal{E}_\varphi$.*

Proof Fix $b, s \geq 1$ and put $h = Q_{bs}(u, \varphi)$. Its defining inequality gives, off the pole sets,

$$s^{-1}h + (1 - s^{-1})\varphi \leq bu - (b-1)\varphi.$$

The left-hand side is θ -plurisubharmonic, so it is at most $Q_b(u, \varphi)$. Hence $h \in \mathcal{A}_s(Q_b(u, \varphi), \varphi)$ for every s . Also $Q_b(u, \varphi) \leq u \leq \varphi$, so $Q_b(u, \varphi) \preceq \varphi$. The inequalities between convex combinations extend across the poles by [Lemma 1.3.3](#), which proves the first assertion.

For the second assertion, choose a constant C such that $u - C \leq \varphi$ and $w - C \leq \varphi$. Since $Q_b(u - C, w - C) = Q_b(u, w) - C$ and class membership is unchanged by translation, we may assume $u, w \leq \varphi$. Because $u \leq w \leq \varphi$, the obstacle for $Q_b(u, w)$ lies above that for $Q_b(u, \varphi)$ and below u . Thus

$$Q_b(u, \varphi) \leq Q_b(u, w) \leq u \leq \varphi.$$

Since $Q_b(u, \varphi) \in \mathcal{E}_\varphi$ by the first assertion, the stability under increase proved in [Proposition 12.4.1](#) gives the conclusion. $\square$

Proposition 12.4.2 *If $u_1, \dots, u_N \in \mathcal{E}_\varphi$, $N \geq 1$, then the rooftop envelope $P_\theta(\min_i u_i)$ is not identically $-\infty$ and belongs to $\mathcal{E}_\varphi$.*

Proof Adding a common constant to all u_i , we may assume $u_i \leq \varphi$. By [Lemma 12.4.1](#) and [Proposition 12.4.1](#),

$$h = \frac{1}{N} \sum_{i=1}^N Q_N(u_i, \varphi) \in \mathcal{E}_\varphi.$$

Each summand is at most φ . For every i , the defining inequality of $Q_N(u_i, \varphi)$ therefore gives

$$h \leq N^{-1} Q_N(u_i, \varphi) + (1 - N^{-1})\varphi \leq u_i.$$

These inequalities between convex combinations also hold at common poles. Thus h is a competitor for $p = P_\theta(\min_i u_i)$, so p is not identically $-\infty$, and $h \leq p \leq u_1 \preceq \varphi$. Stability under increase gives $p \in \mathcal{E}_\varphi$, and undoing the translation preserves this conclusion. $\square$

The finiteness of the family is essential: every $\varphi - j$ belongs to $\mathcal{E}_\varphi$, whereas $P_\theta(\inf_{j \geq 1} (\varphi - j)) \equiv -\infty$. The constructions of common envelopes for sequences in [Chapter 30](#) require additional estimates.

Proposition 12.4.3 *If $u \in \mathcal{E}_\varphi$, then for every smooth real function F ,*

$$P_{\theta,F}[u] = P_{\theta,F}[\varphi].$$

In particular, $P_\theta[u] = P_\theta[\varphi]$.

Proof The relation $u \preceq \varphi$ gives $P_{\theta,F}[u] \leq P_{\theta,F}[\varphi]$. For the reverse inequality, let $a \in (0, 1)$ and choose $h_a \in \mathcal{A}_{1/(1-a)}(u, \varphi)$, so that $a\varphi + (1-a)h_a \leq u$. Combining competitors below F gives

$$aP_{\theta,F}[\varphi] + (1-a)P_{\theta,F}[h_a] \leq P_{\theta,F}[u].$$

Indeed, if g_1 and g_2 are competitors for $P_{\theta,F}[\varphi]$ and $P_{\theta,F}[h_a]$, then $ag_1 + (1-a)g_2$ lies below F and is at least as singular as $a\varphi + (1-a)h_a \leq u$; taking the two upper envelopes preserves the inequality, by local regularization. Write $m = \min_X F$ and $M = \max_X F$. Translating competitors gives

$$P_\theta[h_a] + m \leq P_{\theta,F}[h_a] \leq P_\theta[h_a] + M.$$

Every $P_\theta[h_a]$ has supremum zero, since it lies above $h_a - \sup_X h_a$ and below zero. The uniform L^1 bound for normalized potentials in [Theorem 1.4.1](#) therefore bounds the L^1 norms of the $P_{\theta,F}[h_a]$ uniformly in a . Letting $a \uparrow 1$ in the first inequality gives $P_{\theta,F}[\varphi] \leq P_{\theta,F}[u]$ almost everywhere, and by [Lemma 1.3.3](#) the inequality holds everywhere. $\square$

12.5 Model references and positive mass

In this section θ is semipositive and big. Suppose that a potential $u \in \text{PSH}(X, \theta)$ has a competitor in a smaller background $a\theta$, $0 < a < 1$, that is, $P_{a\theta}(u) \not\equiv -\infty$. Then the big form $(1-a)\theta$ remains available: an envelope in this background has positive mass, and the contact property transfers this mass to u . To obtain such competitors for all members of a relative class, we use a reference φ satisfying

$$P_\theta[\varphi] = \varphi, \quad P_{\varepsilon\theta}(\varphi) \not\equiv -\infty \quad \text{for some } 0 < \varepsilon < 1. \quad (12.20)$$

We call such a φ a *model reference* and fix one such ε . Note that $\varphi = P_\theta[\varphi] \leq 0$. For $u \in \mathcal{E}_\varphi$, the envelope of $u - \varphi$ belongs to the relative envelope class $\mathcal{E}_0 = \mathcal{E}_{\text{env}}(X, \theta, 0)$ of the zero potential, and stretching realizes it in an arbitrarily small background. Under a bounded mass hypothesis, [Chapter 29](#) uses instead the condition (29.5), in which a positive lower volume replaces the condition on the smaller background; the two conditions are compared there.

Lemma 12.5.1 *Let φ be a model reference. If $u \in \mathcal{E}_\varphi$ and $u \leq \varphi$, then*

$$w = P_\theta(u - \varphi) \in \mathcal{E}_0, \quad w \leq 0, \quad w + \varphi \leq u.$$

Proof Since $\varphi \leq 0$, the potential u lies below the obstacle $u - \varphi$ away from the pole set of φ , so it is a competitor. Hence the envelope w is not identically $-\infty$. It is at most zero, since $u - \varphi \leq 0$, and it satisfies $w + \varphi \leq u$ off the poles, hence everywhere by [Lemma 1.3.3](#). For $b \geq 1$, let $h_b = Q_b(u, \varphi)$. Then, off the poles,

$$h_b \leq bu - (b-1)\varphi \leq b(u - \varphi).$$

Since $\theta \geq 0$, the function $b^{-1}h_b$ is θ -plurisubharmonic, and so it is a competitor for w . Hence $h_b \leq bw$, so $\mathcal{A}_b(w, 0)$ is nonempty for every b . Since also $w \leq 0$, this means exactly that $w \in \mathcal{E}_0$. $\square$

Lemma 12.5.2 *Let $0 < a < 1$ and $u \in \text{PSH}(X, \theta)$. If $q = P_{a\theta}(u)$ is not identically $-\infty$, then*

$$\int_X \text{MA}_\theta(u) \geq (1-a)^n v_-(\theta),$$

and the mass on the left is strictly positive, even when $v_-(\theta) = 0$.

Proof The obstacle $u - q$ is nonnegative away from the poles, so by [Lemma 1.19.2](#) the envelope $p = P_{(1-a)\theta}(u - q)$ is bounded. By the contact theorem, its measure is carried by $D = \{p + q = u\}$, and $p + q \leq u$ everywhere. Since $p + q$ is θ -plurisubharmonic, positivity of mixed products and ordered contact imply

$$\text{MA}_{(1-a)\theta}(p) \leq \mathbf{1}_D \text{MA}_\theta(p + q) \leq \mathbf{1}_D \text{MA}_\theta(u),$$

where all assertions are first restricted to the complement of the poles. Writing $p = (1-a)\tilde{p}$ with $\tilde{p} \in \text{PSH}(X, \theta) \cap L^\infty(X)$ and integrating, we obtain the lower

bound from the definition of $v_-(\theta)$. Finally, the bounded potential p has strictly positive mass by [Proposition 12.2.1](#), since $(1 - a)\theta$ is big. $\square$

Theorem 12.5.1 *Let φ be a model reference, with ε as in (12.20). For every $u \in \mathcal{E}_\varphi$ and every $0 < \delta < 1 - \varepsilon$, the envelope $P_{(\varepsilon+\delta)\theta}(u)$ is not identically $-\infty$. Consequently,*

$$\int_X \text{MA}_\theta(u) \geq (1 - \varepsilon)^n v_-(\theta), \quad \int_X \text{MA}_\theta(u) > 0.$$

The mass may be infinite.

Proof After adding a constant to u , we may assume $u \leq \varphi$. Let $w \in \mathcal{E}_0$ be as in [Lemma 12.5.1](#). Since $w \in \mathcal{E}_0$, the envelope $P_\theta(w/\delta)$ is not identically $-\infty$, and $\delta P_\theta(w/\delta) \leq w$. The potential

$$P_{\varepsilon\theta}(\varphi) + \delta P_\theta(w/\delta) \leq \varphi + w \leq u$$

belongs to $\text{PSH}(X, (\varepsilon + \delta)\theta)$, so it is a competitor for $P_{(\varepsilon+\delta)\theta}(u)$. Applying [Lemma 12.5.2](#) with $a = \varepsilon + \delta$ and letting $\delta \downarrow 0$ gives the uniform estimate. The positivity follows from the same lemma with any one such δ . $\square$

12.6 Infinite mass inside the envelope class

We now take the Hermitian background $\theta = \omega$ and the reference $\varphi = 0$. If ω does not have the bounded mass property, that is, if the upper mass $v_+(\omega)$ of [Definition 6.5.1](#) is infinite, then the series constructed in [Theorem 6.6.1](#) has infinite mass. It splits into a smooth finite sum and a tail whose curvature is bounded below by an arbitrarily small multiple of $-\omega$. Multiplying a sufficiently late tail by the stretching factor gives a competitor for that stretch, so the series lies in the relative envelope class of zero.

Proposition 12.6.1 *If $v_+(\omega) = +\infty$, the potential U in [Theorem 6.6.1](#) can be chosen so that, in addition,*

$$U \in \mathcal{E}_{\text{env}}(X, \omega, 0), \quad P_\omega[U] = 0.$$

The same conclusions hold for εU , $0 < \varepsilon \leq 1$. Each of these potentials has infinite extended mass and trivial multiplier ideals at every positive weight.

Proof Use the smooth nonpositive ω -plurisubharmonic functions u_j , $j \geq 1$, of [Theorem 6.6.1](#) and their convergent series $U = \sum_{j \geq 1} 2^{-j} u_j$. For each integer $N \geq 1$, write

$$U = A_N + V_N, \quad A_N = \sum_{j \leq N} 2^{-j} u_j, \quad V_N = \sum_{j > N} 2^{-j} u_j, \quad \delta_N = 2^{-N}.$$

The head A_N is smooth, and since the finite partial sums of the tail decrease, $V_N \in \text{PSH}(X, \delta_N \omega)$; the tail is not identically $-\infty$, because $U = A_N + V_N$ is not.

Fix $b > 1$ and choose N so large that $b\delta_N \leq 1$. Then

$$h_b = bV_N + \min_X (bA_N)$$

is ω -plurisubharmonic, because $\text{dd}^c h_b \geq -b\delta_N \omega \geq -\omega$. Moreover, $h_b \leq bU$. Thus $h_b \in \mathcal{A}_b(U, 0)$ for every b , and since $U \leq 0$, this proves $U \in \mathcal{E}_{\text{env}}(X, \omega, 0)$. For εU , use the tails εV_N , and choose N with $b\varepsilon\delta_N \leq 1$. By [Proposition 12.4.3](#), the singularity envelope of each of these potentials is $P_\omega[0] = 0$. Their infinite mass and trivial multiplier ideals are given by [Corollary 6.6.1](#). $\square$

The bound on the mass in [Proposition 12.1.4](#) concerns the envelope fixed point itself. This example shows that potentials with the same singularity envelope as a fixed point, even with trivial multiplier ideals at every positive weight, need not have finite mass.

Corollary 12.6.1 *The following conditions on a Hermitian metric ω are equivalent:*

- (1) $v_+(\omega) < +\infty$;
- (2) every member of $\mathcal{E}_{\text{env}}(X, \omega, 0)$ has finite extended mass;
- (3) every $u \in \text{PSH}(X, \omega)$ with $P_\omega[u] = 0$ has finite extended mass.

Proof If $v_+(\omega) < +\infty$, all ω -plurisubharmonic functions have finite extended mass by [Proposition 6.5.2](#). If $v_+(\omega) = +\infty$, [Proposition 12.6.1](#) contradicts each of the other two conditions. $\square$

Chapter 13

Equations with prescribed singularities

Throughout this chapter we fix a Hermitian metric ω on X and a smooth positive probability volume form dV . Unless another measure is named, L^p norms, volumes and the phrase “almost everywhere” refer to dV , while capacity and convergence in capacity refer to Cap_ω from [Section 1.8](#). The background θ is a smooth real $(1, 1)$ -form whose positivity is specified in each section. For a smooth real $(1, 1)$ -form α and $u \in \text{PSH}(X, \alpha)$ we write $\alpha_u = \alpha + \text{dd}^c u$, and we call $\{u = -\infty\}$ the *pole set* of u ; it is pluripolar and has zero volume. We write $\text{MA}_\theta(u)$ for the extended non-pluripolar Monge–Ampère measure $\text{MA}_\theta^{\text{ext}}(u)$ of [Theorem 6.1.1](#). It equals $(\theta + \text{dd}^c u)^n$ when u is bounded, charges no pluripolar set, and may have infinite total mass; we keep the superscript where this possibility matters. Finally, $s_+ = \max(s, 0)$ for real s .

We use the following notation from earlier chapters. As in [Definition 1.12.1](#), $u \preceq v$ means that $u \leq v + C$ for some constant C , and $u \sim v$ means that $u \preceq v$ and $v \preceq u$; the equivalence classes of $\sim$ are the ordinary singularity types. For an obstacle f , $P_\theta(f)$ is the largest θ -plurisubharmonic function lying below f quasi-everywhere, $P_\theta(u, v) = P_\theta(\min(u, v))$ is the rooftop envelope, and $V_\theta = P_\theta(0)$; a potential has minimal singularities if it is equivalent to V_θ ([Section 1.19](#)). The ordinary envelope $P_\theta[u]$ and the envelope fixed points, those u with $P_\theta[u] = u$, are defined in [Definition 1.19.1](#). Recall that θ is big if some $\rho \in \text{PSH}(X, \theta)$ satisfies $\theta_\rho \geq \delta\omega$ with $\delta > 0$. We call such a ρ a *strict barrier*; by [Theorem 1.15.2](#) it can be chosen with analytic singularities.

We seek potentials u in the ordinary singularity type of a given reference $\varphi \in \text{PSH}(X, \theta)$ solving

$$\text{MA}_\theta(u) = e^{\lambda u} \mu \quad (\lambda > 0) \quad \text{or} \quad \text{MA}_\theta(u) = c\mu,$$

where μ is a given measure, typically $f dV$ with $f \in L^p$ and $p > 1$, and the constant $c > 0$ is part of the unknown. When φ is unbounded, the comparison principles for bounded potentials no longer apply, and a limit of approximate solutions may leave the prescribed type. For a semipositive big background, both difficulties are overcome by a smaller background. If $P_{\delta\theta}(\varphi) \not\equiv -\infty$ for some $0 < \delta < 1$, then the part $\delta\theta$ of the background can carry the singularity of φ , while bounded envelopes in the

remaining big background $(1 - \delta)\theta$ have Monge–Ampère measures of positive mass. This gives a domination principle for singular potentials (Theorem 13.1.1), and hence uniqueness. Existence starts from bounded equations with L^p densities, solved with a subsolution built from a strict barrier. A compactness criterion with a common lower barrier identifies limits of Monge–Ampère measures, and an addition theorem for weighted measures in a fixed type removes a possible deficit of mass in a limit. Together with a uniform estimate relative to the reference (Theorem 13.11.2), these results solve both equations in the type of an envelope fixed point that admits such a smaller-background envelope (Theorem 13.11.1). At exponent zero, comparison determines the constant c but, in general, not the potential.

If θ is big but not semipositive, V_θ may be unbounded and the smaller-background construction is not available. A strict analytic barrier ρ takes over its role. For two potentials bounded below by ρ minus a constant, a small perturbation by ρ forces a negative infimum of their difference to be attained away from the poles of ρ , where a local comparison applies. Resolving the singularities of analytic approximants of V_θ reduces the equations to semipositive big backgrounds. Stability above the barrier then produces solutions with minimal singularities which are locally Hölder continuous off the poles of ρ (Theorems 13.15.1, 13.15.2 and 13.16.1). They are smooth off these poles when the density is smooth and strictly positive on the whole complement (Theorem 13.17.1).

The same barrier controls smooth equations as a semipositive background degenerates (Theorem 13.18.1). For small resolutions of threefold nodes with a closed background, the potentials converge smoothly away from the exceptional curves, and comparing the limiting and approximating metrics reduces to controlling the diameters of neighborhoods of these curves. In the projective example of Theorem 11.6.1, where the normalized potential is not unique, symmetry selects the zero-exponent limit, while local examples show that a positive density on a small open set does not by itself give regularity. Resolved logarithmic poles and minimal types on blowups give explicit equations whose data are determined by the residual form and the Jacobian of the modification.

The last part of the chapter concerns a Hermitian background h and general right-hand sides. Solvability of $\text{MA}_h(u) = c\mu$ for every nonzero finite non-pluripolar measure μ is equivalent to a positive lower bound for the masses of bounded h -plurisubharmonic functions. For an individual nonnegative density $f \in L^1$, bounded truncations and Gauduchon tests determine the largest coefficient a for which $\text{MA}_h(u) \geq af \, dV$ has a solution. Passing from this threshold to an exact equation at exponent zero requires control of the potentials as well as of their measures. At a positive exponent, exponential decay controls the mass on deep sublevels (Theorem 13.29.1); this control is lost as the exponent tends to zero.

13.1 Domination with a smaller background

Throughout this section θ is semipositive and big. Let $0 < \delta < 1$. When a singular potential lies above a $\delta\theta$ -plurisubharmonic function, the gap between them can be measured by an envelope in the remaining background $(1 - \delta)\theta$. This background is again semipositive and big, so its bounded potentials have Monge–Ampère measures of positive mass by [Proposition 12.2.1](#), and bounded domination applies to them. It bounds the envelope from below. A family of stretched envelopes then converts a strict measure inequality into a pointwise inequality, as in the bounded case of [Theorem 12.2.1](#).

We say that $u \in \text{PSH}(X, \theta)$ admits a smaller-background envelope if $P_{\delta\theta}(u) \not\equiv -\infty$ for some $0 < \delta < 1$. This property depends only on the ordinary singularity type of u : if $u' \geq u - C$, then $P_{\delta\theta}(u) - C$ is a competitor for $P_{\delta\theta}(u')$.

Lemma 13.1.1 *Suppose $u, v \in \text{PSH}(X, \theta)$, $v \preceq u$, and $\text{MA}_{\theta}^{\text{ext}}(u)(\{u < v\}) = 0$. If $0 < \delta < 1$ and $v_{\delta} = P_{\delta\theta}(v) \not\equiv -\infty$, then $u \geq v_{\delta}$.*

Proof Choose C with $v - C \leq u$. Since $v_{\delta} \leq v$, the obstacle $u - v_{\delta}$ is bounded below by $-C$ off the pole sets, and it is finite almost everywhere. Hence the envelope

$$p = P_{(1-\delta)\theta}(u - v_{\delta})$$

is bounded by [Lemma 1.19.2](#), and by contact support ([Theorem 12.1.2](#)) its measure is carried by $D = \{p + v_{\delta} = u\}$. Moreover $p + v_{\delta} \leq u$ everywhere, and

$$\theta + \text{dd}^c(p + v_{\delta}) = ((1 - \delta)\theta + \text{dd}^c p) + (\delta\theta + \text{dd}^c v_{\delta})$$

is a sum of two positive currents. Positivity of mixed products and ordered contact therefore give

$$\mathbf{1}_D \text{MA}_{(1-\delta)\theta}(p) \leq \mathbf{1}_D \text{MA}_{\theta}^{\text{ext}}(u);$$

this inequality is first proved on common finite truncation levels and then extended by exhaustion. Off the pole sets, every point of $D \cap \{p < 0\}$ satisfies $u = p + v_{\delta} < v_{\delta} \leq v$. The hypothesis therefore gives $\text{MA}_{(1-\delta)\theta}(p)(\{p < 0\}) = 0$. Since $(1 - \delta)\theta$ is semipositive and big, bounded domination ([Theorem 12.2.1](#), with [Proposition 12.2.1](#)), applied to p and the constant 0 with coefficient zero, yields $p \geq 0$. Hence $u \geq p + v_{\delta} \geq v_{\delta}$. $\square$

Theorem 13.1.1 *Let $u \in \text{PSH}(X, \theta)$ satisfy $P_{\delta\theta}(u) \not\equiv -\infty$ for some $0 < \delta < 1$. Suppose $v \in \text{PSH}(X, \theta)$, $v \preceq u$, and $0 \leq c < 1$. If*

$$\mathbf{1}_{\{u < v\}} \text{MA}_{\theta}^{\text{ext}}(u) \leq c \mathbf{1}_{\{u < v\}} \text{MA}_{\theta}^{\text{ext}}(v),$$

then $u \geq v$.

Proof Since $\max(u, v) = v$ on the plurifine open set $\{u < v\}$, plurifine locality shows that replacing v by $\max(u, v)$ preserves the hypothesis; it does not change the

conclusion. We may therefore assume $u \leq v$, and since $v \preceq u$ there is $C \geq 0$ with $u \leq v \leq u + C$. For $b > 1$ consider the stretched envelopes

$$p_b = P_\theta(bu - (b-1)v), \quad D_b = \{p_b = bu - (b-1)v\}.$$

The function $u - (b-1)C$ is a competitor, so $p_b \not\equiv -\infty$; and since $bu - (b-1)v \leq u$, we have $u - (b-1)C \leq p_b \leq u$. By contact support, the measure of p_b is concentrated on D_b . The potential $b^{-1}p_b + (1-b^{-1})v$ lies below u and agrees with it on D_b , so ordered contact and positivity of mixed products give

$$\mathbf{1}_{D_b} [b^{-n} \text{MA}_\theta^{\text{ext}}(p_b) + (1-b^{-1})^n \text{MA}_\theta^{\text{ext}}(v)] \leq \mathbf{1}_{D_b} \text{MA}_\theta^{\text{ext}}(u).$$

Choose b so large that $(1-b^{-1})^n > c$. On $D_b \cap \{u < v\}$ the hypothesis then forces $\text{MA}_\theta^{\text{ext}}(p_b)$ to vanish. Since the masses may be infinite, we justify this subtraction as follows. On each set where $u, v, p_b > -k$, every measure involved is finite, being bounded by the mass of the corresponding bounded truncation. We subtract the finite terms on each such set and then take the union over k , so no infinite masses are ever subtracted.

It follows that the measure of p_b is carried by $D_b \cap \{u = v\} \subset \{p_b = u\}$. We apply [Lemma 13.1.1](#) to the pair (p_b, u) : their singularities are equivalent, $\text{MA}_\theta^{\text{ext}}(p_b)(\{p_b < u\}) = 0$, and $P_{\delta\theta}(u) \not\equiv -\infty$. We obtain

$$p_b \geq P_{\delta\theta}(u)$$

for all sufficiently large b . Suppose now that $u \geq v$ fails. By [Lemma 1.3.3](#), the set $\{u < v\}$ has positive volume. Since both potentials are finite almost everywhere, some set $E = \{u < v - a\}$ with $a > 0$ has positive volume and both functions are finite on E . On E the obstacle inequality gives

$$P_{\delta\theta}(u) \leq p_b \leq v - ba$$

quasi-everywhere. Letting b tend to infinity through the integers shows that the quasi-plurisubharmonic function $P_{\delta\theta}(u) \not\equiv -\infty$ equals $-\infty$ on a set of positive volume, a contradiction. Thus $u \geq v$ off the pole sets, and [Lemma 1.3.3](#) gives the inequality everywhere. $\square$

Corollary 13.1.1 *Let $u, v \in \text{PSH}(X, \theta)$ satisfy $v \preceq u$, and suppose that u admits a smaller-background envelope. If $\lambda > 0$ and*

$$e^{-\lambda u} \text{MA}_\theta^{\text{ext}}(u) \leq e^{-\lambda v} \text{MA}_\theta^{\text{ext}}(v)$$

off the pole sets, then $u \geq v$. In particular, for every $\lambda > 0$ and every positive measure μ , the equation $\text{MA}_\theta(u) = e^{\lambda u} \mu$ has at most one solution in an ordinary singularity type admitting a smaller-background envelope.

Proof Fix $t > 0$. On $\{u < v - t\}$ the assumed inequality gives $\text{MA}_\theta^{\text{ext}}(u) \leq e^{-\lambda t} \text{MA}_\theta^{\text{ext}}(v - t)$. The theorem, applied to u and $v - t$ with $c = e^{-\lambda t}$, gives $u \geq v - t$; now let $t \downarrow 0$. For two solutions of the same equation in the stated type, apply this

result in both directions. The weighted measures are compared off the common pole sets, which these measures do not charge, so no value of an infinite weight is needed. $\square$

13.2 Bounded equations in a semipositive big background

In this section θ is again semipositive and big, and we solve the exponential and the normalized equations with L^p densities by bounded potentials. The basic tool is a bounded subsolution. A strict barrier, corrected by the solution of a Hermitian equation, is composed with a bounded convex function; the result is a bounded θ -plurisubharmonic function whose Monge–Ampère measure dominates a prescribed density. The derivative of the convex function decays polynomially near the poles of the barrier, and we compensate for this decay by multiplying the auxiliary density by the reciprocal weight.

Fix a strict barrier $\rho \in \text{PSH}(X, \theta)$ and $0 < a \leq 1$ such that

$$\theta + \text{dd}^c \rho \geq a\omega, \quad \rho \leq -1.$$

No property of ρ other than these two inequalities will be used.

Lemma 13.2.1 *Fix $p > 1$ and $L > 0$. There is $b > 0$ such that, for every $f \geq 0$ with $\|f\|_{L^p(\text{d}V)} \leq L$, one can find $s \in \text{PSH}(X, \theta)$ satisfying*

$$-1 \leq s \leq 0, \quad \text{MA}_\theta(s) \geq b f \, \text{d}V.$$

The constant b depends only on the fixed geometry and on ρ, a, p, L .

Proof Choose $1 < q < p$. Since a fixed quasi-plurisubharmonic function belongs to every finite L^r space, Hölder's inequality gives a uniform L^q bound for

$$g = (-\rho)^{2n} f.$$

By [Theorem 10.1.1](#) there are $c > 0$ and a continuous ω -plurisubharmonic v , normalized by $\sup_X v = -1$, such that

$$\omega_v^n = c(1 + g) \, \text{d}V.$$

The construction in that theorem gives a uniform upper bound for c , because in its Gauduchon trace estimate the root integral of $1 + g$ is bounded below by the root integral of 1. The lower-density estimate of [Theorem 10.3.1](#) gives $c\|1 + g\|_q \geq c_q > 0$, so c is also bounded below. The potential estimate of the same theorem then gives $-C \leq v \leq -1$ with a uniform C .

Put $h = \rho + av \leq -1$. Then $\theta_h \geq a\omega_v$. On $(-\infty, -1]$ define

$$\chi(t) = -t^{-1} - 1, \quad \chi'(t) = t^{-2} \in (0, 1], \quad \chi''(t) = -2t^{-3} > 0,$$

and set $s = \chi(h)$, with value -1 at the poles of h . To justify both the positivity of $\theta + dd^c s$ and the computation of its Monge–Ampère measure, we first work with the bounded functions $h_k = \max(h, -k)$, $k \geq 1$. The chain rule for bounded potentials and $\theta \geq 0$ give

$$\theta + dd^c \chi(h_k) = (1 - \chi'(h_k))\theta + \chi'(h_k)\theta_{h_k} + \chi''(h_k) dh_k \wedge d^c h_k \geq 0.$$

These bounded potentials decrease to s , so $s \in \text{PSH}(X, \theta)$ and $-1 \leq s \leq 0$. On $\{h > -k\}$, locality and positivity of mixed products give

$$\text{MA}_\theta(s) \geq a^n |h|^{-2n} \omega_v^n \geq a^n c |h|^{-2n} (-\rho)^{2n} f dV.$$

Letting $k \rightarrow \infty$, we obtain this inequality on the set where h is finite; its complement is pluripolar and has zero volume. Since $|h| \leq (-\rho) + aC \leq (1 + aC)(-\rho)$, the assertion follows with any common lower bound for $a^n c (1 + aC)^{-2n}$. $\square$

The lemma gives a subsolution for each density in an L^p -bounded family. It does not give a lower bound for the masses of all bounded θ -plurisubharmonic functions.

13.2.1 The exponential equation

We approximate θ from above by the Hermitian forms $\theta + \varepsilon \omega$. The bounded subsolution provides a common lower barrier for the corresponding solutions, and exponential comparison shows that they decrease as ε decreases. Their limit solves the equation in the original background.

Theorem 13.2.1 *Let $0 \leq f \in L^p(dV)$, $p > 1$, be nonzero, and let $\lambda > 0$. There is a unique bounded $v \in \text{PSH}(X, \theta)$ such that*

$$\text{MA}_\theta(v) = e^{\lambda v} f dV.$$

For fixed λ , these solutions are uniformly bounded when $\|f\|_p$ is bounded above and $\int_X f^{1/n} dV$ is bounded away from zero.

Proof For $0 < \varepsilon \leq 1$, set $\theta_\varepsilon = \theta + \varepsilon \omega$. By the Hermitian existence theorem [Theorem 10.1.2](#), there is a continuous solution v_ε of

$$\text{MA}_{\theta_\varepsilon}(v_\varepsilon) = e^{\lambda v_\varepsilon} f dV.$$

Take s, b from [Lemma 13.2.1](#), and put $w = s + \lambda^{-1} \log b$. Positivity of bounded products gives

$$\text{MA}_{\theta_\varepsilon}(w) \geq \text{MA}_\theta(s) \geq b f dV \geq e^{\lambda w} f dV,$$

and bounded exponential comparison ([Corollary 10.2.2](#)) yields $w \leq v_\varepsilon$. If $0 < \varepsilon' < \varepsilon$, then $v_{\varepsilon'}$ is also θ_{ε} -plurisubharmonic and

$$\text{MA}_{\theta_\varepsilon}(v_{\varepsilon'}) \geq e^{\lambda v_{\varepsilon'}} f dV,$$

so the same comparison gives $v_{\varepsilon'} \leq v_{\varepsilon}$. Hence v_{ε} decreases to a bounded θ -plurisubharmonic function v with $w \leq v \leq v_1$.

To pass to the limit in the equation, we use the fixed Hermitian background $\Omega = \theta + \omega$ and the expansion

$$(\theta_{\varepsilon} + \text{dd}^c v_{\varepsilon})^n = \sum_{k=0}^n \binom{n}{k} (\Omega + \text{dd}^c v_{\varepsilon})^k \wedge (-(1 - \varepsilon)\omega)^{n-k}.$$

Continuity of bounded products along monotone sequences applies to every term, and the smooth coefficients converge. Dominated convergence applies to the right-hand sides. This proves the equation. Uniqueness follows from bounded domination in the semipositive big background ([Theorem 12.2.1](#) and [Proposition 12.2.1](#)) by the usual exponential comparison argument.

For the uniform assertion, note first that the lower barrier w is uniform by [Lemma 13.2.1](#). The upper barrier v_1 solves an equation in the fixed Hermitian background Ω . The proof of [Lemma 10.4.1](#) bounds its supremum using only an upper bound for the density norm and a positive lower bound for the root integral: these two bounds control, respectively, the Hölder term and the denominator in (10.8), and they survive the smooth approximation used there. Thus v_1 , and hence v , has a uniform upper bound. $\square$

Local continuity of this bounded solution will follow from [Theorem 13.5.1](#).

13.2.2 The normalized equation

For the normalized equation the approximating potentials need not be monotone. Upper envelopes and lower envelopes of their tails provide monotone sequences on either side of an L^1 cluster limit. Comparison identifies the two limits, and hence the equation, while the constant is controlled by the Gauduchon trace and the bounded subsolution.

Theorem 13.2.2 *For every nonzero $0 \leq f \in L^p(dV)$, $p > 1$, there are a bounded $\varphi \in \text{PSH}(X, \theta)$ and a uniquely determined $c > 0$ such that*

$$\text{MA}_\theta(\varphi) = c f dV, \quad \sup_X \varphi = 0.$$

The construction gives uniform bounds for $\|\varphi\|_\infty$, c and c^{-1} when $\|f\|_p$ is bounded above and $\int_X f^{1/n} dV$ is bounded away from zero.

Only the constant c is asserted to be unique; the normalized potential need not be unique, as [Theorem 11.6.1](#) shows already for a Hermitian background.

Proof *Step 1: approximating equations and their constants.* For integers $j \geq 1$, put $\omega_j = \theta + 2^{-j}\omega$, and choose continuous normalized solutions

$$\text{MA}_{\omega_j}(\varphi_j) = c_j f dV, \quad \sup_X \varphi_j = 0.$$

We first bound c_j . Fix a Gauduchon metric γ_0 ; when $n = 1$ any Hermitian form will do, and the calculation below reduces to Stokes' theorem. The smooth approximation in the proof of [Theorem 10.1.1](#), together with the Gauduchon trace, gives a common upper bound: the numerator $\int_X \omega_j \wedge \gamma_0^{n-1}$ is bounded above by $\int_X (\theta + \omega) \wedge \gamma_0^{n-1}$, and the root integral of f is positive and fixed. Here the estimate is applied to the smooth approximating equations before passing to their continuous limits.

For a lower bound, take s, b from [Lemma 13.2.1](#). If $c_j < b$, then

$$\text{MA}_{\omega_j}(\varphi_j) \leq (c_j/b) \text{MA}_{\omega_j}(s + A)$$

for every constant A , and strict domination in the Hermitian background ω_j ([Theorem 10.2.2](#)) would give $\varphi_j \geq s + A$ for every A , which is absurd. Thus $c_j \geq b$. In fact the constants decrease with j : if $k > j$, positivity gives $\text{MA}_{\omega_j}(\varphi_k) \geq c_k f dV$, and the same argument excludes $c_j < c_k$. Hence $c_j \downarrow c > 0$.

Step 2: a uniform bound for the potentials. For the Hermitian form $\Omega = \theta + \omega$, all φ_j are normalized Ω -plurisubharmonic functions. Using uniform exponential integrability ([Lemma 1.5.1](#)) and Hölder's inequality, choose $\gamma > 0$ small and $1 < q < p$ such that

$$g_j = e^{-\gamma\varphi_j} f$$

is bounded in L^q . Since $\varphi_j \leq 0$, we have $g_j \geq f$. [Theorem 13.2.1](#), applied with the exponent q , therefore gives uniformly bounded $w_j \in \text{PSH}(X, \theta)$ with

$$\text{MA}_\theta(w_j) = e^{\gamma w_j} g_j dV.$$

Choose $C_0 \geq \max\{1, \sup_j c_j\}$ and set $z_j = w_j - \gamma^{-1} \log C_0$. Then

$$\text{MA}_{\omega_j}(z_j) \geq e^{\gamma z_j} c_j g_j dV, \quad \text{MA}_{\omega_j}(\varphi_j) = e^{\gamma \varphi_j} c_j g_j dV,$$

and exponential comparison gives $z_j \leq \varphi_j \leq 0$. Thus all φ_j take values in a common bounded interval.

Step 3: the upper envelopes. Extract a subsequence converging in L^1 and almost everywhere to the canonical θ -plurisubharmonic representative φ . We keep the indices j ; the coefficients of ω in ω_j still decrease to zero. Define

$$\Phi_j^+ = \left(\sup_{\ell \geq j} \varphi_\ell \right)^*, \quad h_j = \inf_{\ell \geq j} \varphi_\ell, \quad p_j = P_\theta(h_j).$$

All these functions take values in a common bounded interval. The upper envelopes are ω_j -plurisubharmonic and decrease to φ , since the regularized upper envelope agrees almost everywhere with the L^1 limit; this also follows from the local Hartogs lemma applied to the bounded tails.

For $\ell \geq j$, positivity gives $\text{MA}_{\omega_j}(\varphi_\ell) \geq c_\ell f \, dV \geq c f \, dV$. By ordered contact (Lemma 1.7.1), finite maxima of these functions satisfy the same lower bound. Continuity of bounded products along increasing sequences, followed by the decreasing limit in j and the expansion in the smooth background, gives

$$\text{MA}_{\omega_j}(\Phi_j^+) \geq c f \, dV, \quad \text{MA}_\theta(\varphi) \geq c f \, dV. \quad (13.1)$$

Step 4: the lower envelopes. For the reverse inequality we use lower envelopes, which carry a useful exponential weight. For $N \geq j$ put

$$p_{j,N} = P_\theta \left(\min_{j \leq \ell \leq N} \varphi_\ell \right).$$

The obstacle is continuous and bounded, so the measure of $p_{j,N}$ is carried by its contact set. Partition this set into disjoint Borel pieces according to the first index ℓ at which $p_{j,N} = \varphi_\ell$. On such a piece, positivity and ordered contact in the background ω_ℓ give

$$\text{MA}_\theta(p_{j,N}) \leq \text{MA}_{\omega_\ell}(p_{j,N}) \leq c_\ell f \, dV.$$

Moreover $p_{j,N} = \varphi_\ell \geq h_j$ there, and $c_\ell \leq c_j$. Summing over the pieces therefore yields the global inequality

$$\text{MA}_\theta(p_{j,N}) \leq e^{p_{j,N} - h_j} c_j f \, dV.$$

As $N \rightarrow \infty$, the envelopes decrease to p_j . Indeed, their limit lies below each tail obstacle quasi-everywhere and is thus a competitor for $P_\theta(h_j)$, while the reverse inequality is immediate. Continuity of bounded products along monotone sequences and dominated convergence give

$$\text{MA}_\theta(p_j) \leq e^{p_j - h_j} c_j f \, dV.$$

The functions p_j increase. Let $\varphi' = (\lim_j p_j)^*$. Since $h_j \rightarrow \varphi$ almost everywhere, we have $\varphi' \leq \varphi$ for the canonical representatives. Passing to the increasing limit and using (13.1), we obtain

$$\text{MA}_\theta(\varphi') \leq e^{\varphi' - \varphi} c f \, dV \leq e^{\varphi' - \varphi} \text{MA}_\theta(\varphi).$$

Bounded exponential comparison forces $\varphi' \geq \varphi$. Thus $\varphi' = \varphi$, and the last inequality, together with (13.1), proves the equation. If necessary, subtracting $\sup_X \varphi$ gives the required normalization.

Step 5: uniformity and uniqueness of c . All bounds used above depend only on the two stated density bounds and the fixed data, which proves the uniform assertion for the constructed solution. Finally, two different positive constants for the same f would contradict strict domination after an arbitrary translation of one of the bounded solutions, exactly as in the lower bound for c_j . This proves the uniqueness of c . $\square$

For $\lambda > 0$, let v_λ be the bounded solution of $\text{MA}_\theta(v_\lambda) = e^{\lambda v_\lambda} f \, dV$, and let (φ, c) be a normalized solution given by Theorem 13.2.2. The two exponential barriers used in Proposition 10.5.1 give

$$\|\lambda v_\lambda - \log c\|_\infty \leq \lambda \text{osc}_X \varphi$$

also in this semipositive background.

13.3 A quantitative stability estimate

If a θ -plurisubharmonic function exceeds a bounded solution only by a small amount in L^1 , the excess is also uniformly small. To prove this, we restrict the density of the solution to a strict superlevel set of the difference and construct a subsolution for the restricted density. Domination bounds the height of the superlevel set in terms of the norm of the restricted density, and Hölder's inequality converts its volume into a power of the L^1 error.

Throughout this section θ is semipositive and big, and $p > 1$ is fixed.

Theorem 13.3.1 Fix $L, C_0 > 0$. Let $u \in \text{PSH}(X, \theta)$ satisfy

$$-C_0 \leq u \leq 0, \quad \text{MA}_\theta(u) = f \, dV, \quad 0 \leq f \in L^p(dV), \quad \|f\|_p \leq L.$$

For every

$$0 < \eta < \frac{p-1}{np+p-1}$$

there is a constant C , depending only on the fixed data and η , such that every $v \in \text{PSH}(X, \theta)$ with $v \leq 0$ satisfies

$$\sup_X (v - u)_+ \leq C \left(\int_X (v - u)_+ \, dV \right)^\eta.$$

The comparison potential v need not be bounded.

Proof Replacing v by $\max(v, u)$ leaves both sides unchanged, so we may assume $-C_0 \leq u \leq v \leq 0$. Put $I = \int_X (v - u) \, dV$. If $I = 0$, the two canonical potentials agree everywhere and there is nothing to prove, so we assume $I > 0$.

Choose $q \in (1, p)$, to be specified at the end. For $\delta > 0$ put

$$E_\delta = \{u < v - \delta\}, \quad g_\delta = \mathbf{1}_{E_\delta} f, \quad m_\delta = \|g_\delta\|_q.$$

If $m_\delta > 0$, apply [Lemma 13.2.1](#) to g_δ/m_δ . It gives $h \in \text{PSH}(X, \theta)$ and $b > 0$ such that

$$-1 \leq h \leq 0, \quad \text{MA}_\theta(h) \geq b g_\delta / m_\delta \, dV.$$

The constant b does not depend on δ, f, u, v , since the auxiliary density has L^q norm one.

First suppose $0 < m_\delta < b/2$, and take

$$t = (2m_\delta/b)^{1/n} \in (0, 1), \quad w = (1-t)v + th - \delta - C_0 t.$$

Because $h - v \leq C_0$, we have $w \leq v - \delta$, and hence $\{u < w\} \subset E_\delta$. Positivity of bounded mixed products gives

$$\text{MA}_\theta(w) \geq t^n \text{MA}_\theta(h) \geq 2g_\delta \, dV.$$

On $\{u < w\}$ the last measure equals $2\text{MA}_\theta(u)$. Bounded strict domination in the semipositive big background ([Theorem 12.2.1](#)) therefore implies $u \geq w$. Consequently

$$v - u \leq v - w = \delta + C_0 t + t(v - h) \leq \delta + (C_0 + 1)t.$$

If $m_\delta = 0$, the measure of u vanishes on E_δ , and the same domination theorem with coefficient zero, applied to u and $v - \delta$, gives $v - u \leq \delta$. If $m_\delta \geq b/2$, the bound $v - u \leq C_0$ gives the following inequality after an increase of its constant. Thus in every case

$$\sup_X (v - u) \leq \delta + C_1 m_\delta^{1/n}. \quad (13.2)$$

Hölder's inequality and Chebyshev's inequality give

$$m_\delta \leq \|f\|_p \, dV(E_\delta)^{1/q-1/p} \leq L(I/\delta)^{(p-q)/(pq)}.$$

Set $a = (p - q)/(npq) > 0$. For $0 < I \leq 1$, choose $\delta = I^{a/(1+a)}$. Substituting in (13.2) yields

$$\sup_X (v - u) \leq C_2 I^{\eta_q}, \quad \eta_q = \frac{p - q}{npq + p - q}.$$

As $q \downarrow 1$, the exponent η_q tends to $(p - 1)/(np + p - 1)$. For the prescribed η we choose $q > 1$ so close to 1 that $\eta_q > \eta$; then $I^{\eta_q} \leq I^\eta$ on $(0, 1]$. When $I > 1$, the bound $v - u \leq C_0$ gives the same conclusion after increasing C . This proves the theorem. $\square$

Corollary 13.3.1 *Fix $C_0 > 0$. Let $u_j, u \in \text{PSH}(X, \theta)$ satisfy $-C_0 \leq u_j, u \leq 0$ and*

$$\text{MA}_\theta(u_j) = f_j \, dV, \quad \text{MA}_\theta(u) = f \, dV, \quad \sup_j \|f_j\|_p + \|f\|_p < +\infty.$$

If $u_j \rightarrow u$ in L^1 , then $u_j \rightarrow u$ uniformly. More precisely, for every exponent η as in the theorem,

$$\|u_j - u\|_\infty \leq C \|u_j - u\|_{L^1(dV)}^\eta.$$

Proof Apply the theorem first with solution u and comparison potential u_j , and then with solution u_j and comparison potential u . The constants are uniform because of the common range and the common density bound. The larger of the two suprema is the uniform norm, and each integral of a positive part is at most the full L^1 difference. $\square$

The corollary assumes that the limit u already solves an equation with an L^p density. In an existence proof, this must be established before the corollary can be applied.

13.4 Hölder continuity from bounded stability

Bounded stability also gives a Hölder modulus. We apply it to Demailly's Chern-connection regularization of a solution: the L^1 error of the regularization controls its pointwise error, and a gradient estimate for the smooth averages then gives the modulus. We use the averaging operators R_t and the transforms $\Phi_{c,\delta}$ of Lemma 1.21.1, with the constants A, K given there, together with the estimates of Lemma 1.21.2. Interpolating between the smoothing error and the gradient bound yields the exponent below.

Theorem 13.4.1 *Let $p > 1$ and let $u \in \text{PSH}(X, \omega) \cap L^\infty(X)$ solve*

$$\text{MA}_\omega(u) = f \, dV, \quad 0 \leq f \in L^p(dV).$$

Then u is Hölder continuous with every exponent

$$0 < \beta < \frac{2(p-1)}{np+3(p-1)}.$$

The Hölder constants are uniform for a fixed bound $-C_0 \leq u \leq 0$ and a fixed bound for $\|f\|_p$. In particular, the continuous solutions constructed in [Theorem 10.1.1](#) have this regularity.

Proof After adding a constant we may assume $-C_0 \leq u \leq 0$. Choose

$$0 < \eta < \frac{p-1}{np+p-1}, \quad \alpha = 2\eta < 1.$$

For small $\delta > 0$ set

$$c = \delta^\alpha, \quad e = Ac + 2K\delta, \quad r = -C_0 - 1, \quad v_\delta = \frac{\Phi_{c,\delta} + er}{1+e}.$$

The curvature estimate of [Lemma 1.21.1](#) gives $v_\delta \in \text{PSH}(X, \omega)$. Evaluating the infimum defining $\Phi_{c,\delta}$ at $t = \delta$ gives $\Phi_{c,\delta} \leq R_\delta u \leq 0$. On the other hand,

$$\Phi_{c,\delta} \geq u - K(\delta^2 + \delta),$$

since $R_t u + Kt^2 \geq u$, $Kt \geq 0$ and $-c \log(t/\delta) \geq 0$ for $0 < t \leq \delta$. For small δ this lower bound is at least r , and therefore

$$v_\delta \leq \Phi_{c,\delta} \leq R_\delta u \leq 0.$$

The Hermitian form ω is semipositive and big, so [Theorem 13.3.1](#) applies in the background ω . Together with the L^1 estimate of [Lemma 1.21.2](#), it gives

$$\sup_X (v_\delta - u)_+ \leq C \left(\int_X (v_\delta - u)_+ \, dV \right)^\eta \leq C \|R_\delta u - u\|_1^\eta \leq C \delta^\alpha.$$

Since $e \leq C\delta^\alpha$ and $u - r \leq C_0 + 1$, it follows that

$$\Phi_{c,\delta} - u = (1+e)(v_\delta - u) + e(u - r) \leq C\delta^\alpha. \quad (13.3)$$

We now bound the minimizing radius from below. Fix z and a radius $t = t(z) \in (0, \delta]$ at which the infimum is attained. The lower estimate at this radius and [\(13.3\)](#) give

$$-c \log(t/\delta) \leq \Phi_{c,\delta}(z) - u(z) + K(\delta^2 + \delta) \leq C\delta^\alpha = Cc.$$

Thus $t(z) \geq a\delta$ with the constant $a = e^{-C} > 0$, which is independent of z and δ . Since $R_s u + Ks^2$ is increasing in s ,

$$\begin{aligned}
R_{a\delta}u + K(a\delta)^2 &\leq R_t u + Kt^2 \\
&= \Phi_{c,\delta} + K\delta^2 + K\delta - Kt + c \log(t/\delta) \\
&\leq \Phi_{c,\delta} + K\delta^2 + K\delta.
\end{aligned}$$

Combining this with (13.3) and the lower bound $R_s u - u \geq -Ks^2$, and setting $s = a\delta$, we obtain

$$\|R_s u - u\|_\infty \leq Cs^\alpha$$

for every sufficiently small $s > 0$.

Finally, let x, y be points at a small distance d . The gradient estimate $\|\nabla R_s u\|_\infty \leq C/s$ gives

$$|u(x) - u(y)| \leq 2Cs^\alpha + Cd/s.$$

With $s = d^{1/(1+\alpha)}$, both terms are bounded by a constant times $d^{\alpha/(1+\alpha)}$, and larger distances are controlled by the bound on the oscillation. This proves Hölder continuity with exponent $\alpha/(1+\alpha)$. Letting η approach its upper endpoint gives every β in the theorem; smaller exponents follow on compact X by changing the constant. $\square$

13.5 Local continuity in a semipositive big background

We return to a semipositive big background θ . Where θ degenerates, regularization loses some positivity, and this curvature error can be repaired by adding a small multiple of a strict barrier. Bounded stability then shows that a bounded solution is continuous wherever the barrier is locally bounded.

Fix $\rho \in \text{PSH}(X, \theta)$ with $\theta + \text{dd}^c \rho \geq \kappa\omega$ for some $\kappa > 0$. For bounded $u \in \text{PSH}(X, \theta)$ we use the averages $R_t u$, the transforms $\Phi_{c,\delta}$ and the curvature modulus $\epsilon(\delta)$, with the constants A, K , from [Section 1.21.1](#) and [Lemma 1.21.3](#).

Theorem 13.5.1 *Let $p > 1$ and let $u \in \text{PSH}(X, \theta) \cap L^\infty(X)$ satisfy*

$$\text{MA}_\theta(u) = f \, dV, \quad 0 \leq f \in L^p(dV).$$

Then u is continuous on every open set $U \subseteq X$ on which ρ is locally bounded.

Proof After adding constants we may assume $-C_0 \leq u \leq 0$ and $\rho \leq -C_0 - 1$. Choose

$$0 < \eta < \frac{p-1}{np+p-1}, \quad \alpha = 2\eta < 1,$$

and set, for small $\delta > 0$,

$$c = \delta^\alpha + \epsilon(\delta), \quad e = Ac + \epsilon(\delta), \quad s = e/\kappa, \quad v_\delta = \frac{\Phi_{c,\delta} + s\rho}{1+s}.$$

Since $s\kappa = e$, the curvature bounds for $\Phi_{c,\delta}$ and ρ give $v_\delta \in \text{PSH}(X, \theta)$. Moreover

$$\rho \leq -C_0 - 1 \leq \Phi_{c,\delta} \leq R_\delta u \leq 0$$

for small δ : the lower bound follows from $\Phi_{c,\delta} \geq u - K(\delta^2 + \delta)$, exactly as in the proof of [Theorem 13.4.1](#). Hence $v_\delta \leq \Phi_{c,\delta} \leq R_\delta u \leq 0$.

[Theorem 13.3.1](#) allows an unbounded comparison potential, so it applies to v_δ . Together with the L^1 smoothing estimate, it gives

$$\sup_X (v_\delta - u)_+ \leq C \left(\int_X (v_\delta - u)_+ dV \right)^\eta \leq C\delta^\alpha.$$

Fix M and consider the points where $\rho \geq -M$. Since $s \leq Cc$ and $c \rightarrow 0$, the identity

$$\Phi_{c,\delta} - u = (1 + s)(v_\delta - u) + s(u - \rho)$$

gives $\Phi_{c,\delta} - u \leq C_M c$ there.

At a radius t where the infimum defining $\Phi_{c,\delta}$ is attained, the same lower estimate yields

$$-c \log(t/\delta) \leq \Phi_{c,\delta} - u + K(\delta^2 + \delta) \leq C_M c.$$

Thus $t \geq a_M \delta$ with $a_M > 0$ independent of the point and of δ . Since $R_t u + Kt^2$ is increasing in t , we obtain

$$R_{a_M \delta} u + K(a_M \delta)^2 \leq R_t u + Kt^2 \leq \Phi_{c,\delta} + K\delta^2 + K\delta.$$

This upper bound and the lower bound $R_s u \geq u - Ks^2$ imply

$$\sup_{\{\rho \geq -M\}} |R_{a_M \delta} u - u| \leq C_M (\delta^\alpha + \epsilon(\delta)) \rightarrow 0.$$

On every compact subset of U , the function ρ is bounded below. The smooth functions $R_{a_M \delta} u$ therefore converge uniformly to u on each such compact set, which proves that u is continuous on U . $\square$

The proof also gives a modulus of continuity on each compact subset of U , obtained by combining the uniform smoothing error with the gradient bound C/t . A Hölder exponent would require a power bound for the modulus $\epsilon(\delta)$. For potentials that are locally bounded off the poles of a strict analytic barrier, [Lemma 1.21.5](#) refines the classical expansion and gives a curvature error linear in δ . Combined with stability above a strict barrier, this yields local Hölder continuity even for solutions with minimal singularities ([Theorem 13.16.1](#)). Neither argument gives continuity across the pole set of the barrier.

13.6 Homogeneous replacement on a coordinate ball

To show that the Monge–Ampère measure of an envelope vanishes off the contact set, we shall replace the envelope on small balls by a solution of the homogeneous equation with the same boundary values. We first recall the smooth Dirichlet problem with a smooth positive density; the replacement is obtained by letting a constant

density tend to zero, and continuous boundary values are then handled by uniform approximation.

In this section we work on the ball $B = B_R = \{|z| < R\} \subset \mathbb{C}^n$, put $\beta = \text{dd}^c |z|^2$, and let θ be any smooth real $(1, 1)$ -form defined near $\overline{B}$. Distances and the Laplacian Δ are Euclidean.

Lemma 13.6.1 *Let $\varphi \in C^\infty(\partial B)$, and let F be a smooth strictly positive function on $\overline{B}$. There is a unique smooth function v on $\overline{B}$ such that*

$$\theta + \text{dd}^c v > 0, \quad (\theta + \text{dd}^c v)^n = F\beta^n, \quad v|_{\partial B} = \varphi.$$

Proof Extend φ to a smooth function $\tilde{\varphi}$ on $\overline{B}$. For sufficiently large A , the function $\underline{v} = \tilde{\varphi} + A(|z|^2 - R^2)$ is a smooth strict subsolution with the prescribed boundary values: $\theta + \text{dd}^c \underline{v}$ is positive and its determinant is at least $(\max_{\overline{B}} F)\beta^n$. For $n \geq 2$, the classical smooth Dirichlet theorem of Guan–Li therefore applies on the ball, with the arbitrary smooth background $\chi = \theta$ and the smooth positive right-hand side F . Their operator is $(i/2)\partial\bar{\partial}$, so our potential is π times theirs. No closedness condition is needed here; such conditions enter only in their separate theorems on compact manifolds. For $n = 1$ the lemma is the Dirichlet problem for the Poisson equation. For uniqueness, integrate the derivative of $\log \det$ along the segment between the two positive matrices: the difference of the logarithms of the two determinants becomes a uniformly elliptic linear operator with smooth coefficients applied to the difference of the solutions, and the maximum principle applies. $\square$

The same argument gives smooth comparison on subdomains D of the ball. Let a, b be smooth functions on $\overline{D}$ with $\theta + \text{dd}^c a > 0$ and $\theta + \text{dd}^c b > 0$. If $(\theta + \text{dd}^c a)^n \geq (\theta + \text{dd}^c b)^n$ in D and $a \leq b$ on ∂D , then $a \leq b$ in D . Indeed, integrating the derivative of the logarithm of the determinant along the segment between the two positive matrices gives a linear elliptic inequality for $a - b$, and the maximum principle proves the assertion. The boundary of D need not be smooth for this argument.

Theorem 13.6.1 *For every $\varphi \in C(\partial B)$ there exists a continuous θ -plurisubharmonic function H_φ on $\overline{B}$ such that*

$$(\theta + \text{dd}^c H_\varphi)^n = 0 \quad \text{on } B, \quad H_\varphi|_{\partial B} = \varphi.$$

It dominates every continuous θ -plurisubharmonic function p on $\overline{B}$ with $p|_{\partial B} \leq \varphi$. For $\varphi, \psi \in C(\partial B)$, the construction satisfies

$$\|H_\varphi - H_\psi\|_{C(\overline{B})} \leq \|\varphi - \psi\|_{C(\partial B)}.$$

For smooth boundary data the constructed function is Lipschitz on $\overline{B}$.

Proof *Step 1: boundary barriers.* We first take φ smooth and $0 < \varepsilon \leq 1$, and let v_ε be the solution of **Lemma 13.6.1** with the constant density $F \equiv \varepsilon$. The strict subsolution $\underline{v}$ constructed there for $F \equiv 1$ lies below every v_ε , by smooth comparison. Choose a

smooth function q with $q = \varphi$ on the boundary and $\Delta q = -C$, where C is so large that $\theta + \text{dd}^c v_\varepsilon \geq 0$ implies $\Delta v_\varepsilon \geq -C$. The maximum principle for the Laplacian gives $v_\varepsilon \leq q$. Both barriers are smooth and equal $\tilde{\varphi}$ on the boundary. Consequently

$$|v_\varepsilon(z) - \tilde{\varphi}(z)| \leq C_1 \text{dist}(z, \partial B), \quad (13.4)$$

with C_1 independent of ε .

Step 2: a Lipschitz bound independent of ε . Let $h \in \mathbb{C}^n$ be small, and set $D_h = \{z \in B : z + h \in B\}$. Since θ is smooth, there is $C_2 > 0$, independent of the translation h , such that

$$\theta(z) - \theta(z + h) + C_2|h|\beta \geq 0.$$

For a constant $C_3 > 0$ to be fixed, define on D_h

$$w(z) = v_\varepsilon(z + h) + C_2|h|(|z|^2 - R^2) - C_3|h|.$$

Then $\theta + \text{dd}^c w \geq \theta(z + h) + \text{dd}^c v_\varepsilon(z + h) > 0$, and the determinant of $\theta + \text{dd}^c w$ is at least $\varepsilon\beta^n$, because the Euclidean volume form is translation invariant. On ∂D_h , one of the points z and $z + h$ lies on ∂B , and the other has distance at most $|h|$ from ∂B . Estimate (13.4) and the Lipschitz bound for $\tilde{\varphi}$ therefore give $w \leq v_\varepsilon$ on ∂D_h if C_3 is chosen sufficiently large, and smooth comparison extends this inequality to all of D_h . Together with the same argument for $-h$, this gives

$$|v_\varepsilon(z + h) - v_\varepsilon(z)| \leq C_4|h|,$$

with constants independent of ε . The same bound for arbitrary pairs of points follows by subdividing the segment joining them inside the convex ball, and it extends to $\overline{B}$ because each v_ε is continuous there.

Step 3: the limit $\varepsilon \rightarrow 0$. Smooth comparison also shows that v_ε increases as ε decreases. By the barriers and the common Lipschitz bound, the limit H_φ is Lipschitz and the convergence is uniform on $\overline{B}$. The inequality $\theta + \text{dd}^c v_\varepsilon > 0$ of currents passes to the limit, and continuity of local bounded products under uniform convergence gives $(\theta + \text{dd}^c H_\varphi)^n = 0$. For smooth boundary values φ, ψ , denote the solutions of Lemma 13.6.1 with $F \equiv \varepsilon$ by $v_{\varepsilon, \varphi}$ and $v_{\varepsilon, \psi}$. Smooth comparison gives $\|v_{\varepsilon, \varphi} - v_{\varepsilon, \psi}\|_\infty \leq \|\varphi - \psi\|_\infty$, and passing to the limit proves the contraction for smooth data.

Step 4: continuous boundary values. For continuous φ , choose smooth $\varphi_j \rightarrow \varphi$ uniformly on ∂B . By the contraction, H_{φ_j} is uniformly Cauchy. Its limit H_φ is continuous and θ -plurisubharmonic, has the prescribed boundary values, and satisfies the homogeneous equation, again by continuity of bounded products under uniform convergence. Passing to the limit also proves the contraction for all continuous boundary data.

Step 5: domination. It remains to prove the domination property, which does not follow from a comparison of total masses. First take φ smooth and p as in the statement. For $\delta > 0$ put $p_\delta = p + \delta(|z|^2 - R^2)$, so that $\theta + \text{dd}^c p_\delta \geq \delta\beta$. By

Lemma 1.3.9, every C^2 function a touching p_δ from above at an interior point z_0 satisfies

$$\theta(z_0) + \text{dd}^c a(z_0) \geq \delta\beta.$$

Suppose that $p_\delta - v_\varepsilon$ had a positive maximum. Since this difference is nonpositive on the boundary, the maximum would be attained at an interior point, where v_ε plus the maximum touches p_δ from above. The determinant of $\theta + \text{dd}^c v_\varepsilon$ at that point would then be at least $\delta^n \beta^n$, contradicting the equation for v_ε when $\varepsilon < \delta^n$. Hence $p_\delta \leq v_\varepsilon$ for small ε . Letting first ε and then δ decrease to zero, we obtain $p \leq H_\varphi$.

Finally, for continuous φ , take the smooth approximants φ_j above and set $a_j = \|\varphi_j - \varphi\|_\infty$. The boundary values of $p - a_j$ are at most φ_j , so the result for smooth data gives $p - a_j \leq H_{\varphi_j}$. Uniform convergence proves $p \leq H_\varphi$. $\square$

By the domination property, H_φ is the largest continuous θ -plurisubharmonic function on $\overline{B}$ whose boundary values are at most φ . This is the property needed for replacing an envelope locally.

13.7 Contact support in a big background

Throughout this section, θ is an arbitrary smooth big background, not necessarily semipositive. For a continuous obstacle, regularization shows that the envelope is continuous off the poles of a strict analytic barrier. On a small ball where the envelope stays below the obstacle, a homogeneous replacement then shows that the envelope already solves the homogeneous equation, so its Monge–Ampère measure vanishes away from the contact set.

By **Theorem 1.15.2**, applied to a strict barrier with a sufficiently small curvature error, we may fix $\rho \in \text{PSH}(X, \theta)$ with analytic singularities and a smooth remainder after resolution such that

$$\theta + \text{dd}^c \rho \geq \kappa\omega, \quad \kappa > 0.$$

Its pole set $Z = \{\rho = -\infty\}$ is an analytic, hence pluripolar, subset of X .

Theorem 13.7.1 *Let $h \in C(X)$. Then $p = P_\theta(h)$ is a θ -plurisubharmonic function, continuous on $X \setminus Z$, whose Monge–Ampère measure satisfies*

$$\mathbf{1}_{\{p < h\}} \text{MA}_\theta(p) = 0.$$

Here $\text{MA}_\theta(p)$ is allowed to have infinite total mass.

Proof Subtract a constant from ρ so that $\rho + 2 \leq h$. Then $\rho + 2$ is a competitor, and since the obstacle is continuous, the envelope lies below it everywhere; thus

$$\rho + 2 \leq p \leq h.$$

In particular, p is locally bounded off Z . We first prove that p is continuous there; this part does not use the contact assertion.

Apply [Lemma 1.21.5](#) to $p - \sup_X p$ and add back the constant. The transforms $\Phi_{c,\delta}$ of that lemma are defined on X and, with fixed constants $A, K, C > 0$ and $\epsilon(\delta) = C\delta$, satisfy

$$\theta + dd^c \Phi_{c,\delta} \geq -(Ac + \epsilon(\delta))\omega. \quad (13.5)$$

Off Z the infimum defining $\Phi_{c,\delta}$ is attained at a positive radius, and

$$p - K(\delta^2 + \delta) \leq \Phi_{c,\delta} \leq R_\delta p \leq R_\delta h.$$

For small δ the first inequality gives $\Phi_{c,\delta} \geq \rho + 1$, hence $\rho \leq \Phi_{c,\delta}$ on X .

Set

$$m(\delta) = \sup_{0 < t \leq \delta} \|R_t h - h\|_\infty, \quad c = m(\delta) + \epsilon(\delta) + \delta, \quad s = \frac{Ac + \epsilon(\delta)}{K}.$$

The averaging kernels are positive, have integral one and are supported in balls of radius comparable to t , so uniform continuity of h gives $m(\delta) \rightarrow 0$. Define

$$v_\delta = \frac{\Phi_{c,\delta} + s\rho}{1 + s}.$$

By the choice of s , the strict barrier and (13.5) show that v_δ is θ -plurisubharmonic. Since $\rho \leq \Phi_{c,\delta}$,

$$v_\delta \leq \Phi_{c,\delta} \leq R_\delta h \leq h + m(\delta).$$

Thus $v_\delta - m(\delta)$ is a competitor for the envelope, and $v_\delta \leq p + m(\delta)$.

Let $L \Subset X \setminus Z$ be compact. On L the difference $p - \rho$ is bounded above. Since $s \leq Cc$, the identity

$$\Phi_{c,\delta} - p = (1 + s)(v_\delta - p) + s(p - \rho)$$

therefore gives $\Phi_{c,\delta} - p \leq C_L c$ on L . At a radius t where the infimum is attained,

$$-c \log(t/\delta) \leq \Phi_{c,\delta} - p + K(\delta^2 + \delta) \leq C_L c.$$

Since $c \geq \delta$, this yields $t \geq a_L \delta$ with a fixed $a_L > 0$. Because $R_t p + Kt^2$ is increasing in t , it follows that

$$p - K(a_L \delta)^2 \leq R_{a_L \delta} p \leq \Phi_{c,\delta} + K\delta^2 + K\delta.$$

Consequently $R_{a_L \delta} p \rightarrow p$ uniformly on L . These averages are smooth for positive radius, even though p is unbounded on X . Applying this to compact neighborhoods of the points of $X \setminus Z$ proves that p is continuous on $X \setminus Z$.

We turn to the contact assertion. By the continuity just proved, the set $\{p < h\} \setminus Z$ is open. Let x be one of its points, and choose a small coordinate ball B_r centered at x whose closure lies in this set. Let H be the homogeneous replacement of

Theorem 13.6.1 with boundary values $p|_{\partial B_r}$. Its domination property gives $H \geq p$ on the ball.

We claim that $H \leq h$ on B_r if r is small enough. Indeed, in the chosen Euclidean coordinates z , with Laplacian Δ , the inequality $\theta + dd^c H \geq 0$ implies a fixed bound $\Delta H \geq -C$. Comparison with the function $\sup_{\partial B_r} p + C'(r^2 - |z - x|^2)$, with C' fixed large enough, gives

$$H \leq \sup_{\partial B_r} p + C'r^2.$$

As $r \rightarrow 0$, the right-hand side tends to $p(x)$, whereas $\inf_{B_r} h \rightarrow h(x) > p(x)$. This proves the claim for sufficiently small r .

Now replace p by H on the ball. The resulting function is θ -plurisubharmonic. To see this, fix $a > 0$ and take $\max\{p, H - a\}$ inside the ball and p outside. Since H and p are continuous with equal boundary values, $H - a < p$ on a collar of ∂B_r , so this is an ordinary local maximum construction. Letting $a \downarrow 0$ gives the function equal to H on B_r and to p outside, with locally uniform convergence near the boundary of the ball. This function is bounded above by h on all of X , so the definition of the envelope forces it to be at most p . Thus $p = H$ on B_r , and $\text{MA}_\theta(p)$ vanishes there.

These balls cover $\{p < h\} \setminus Z$. There the extended measure agrees with the local bounded product, and it does not charge the pluripolar set Z . This proves the contact assertion on X ; no bound on the total mass of $\text{MA}_\theta(p)$ was needed. $\square$

13.7.1 Quasi-continuous obstacles

We now extend the contact property to discontinuous obstacles. Continuous approximations of an obstacle need not preserve every competitor of its envelope pointwise. For lower semicontinuous obstacles, the approximation of [Lemma 1.19.3](#) repairs this, and quasi-continuity then allows us to pass to limits of weighted measures. An unbounded obstacle is truncated at finite levels; in an arbitrary smooth background this produces signed products, whose limits are controlled by [Lemma 1.8.4](#) before we restrict to the region where the product is positive. The strict analytic barrier ρ and its pole set Z are those fixed above.

Proposition 13.7.1 *If f is bounded and lower semicontinuous, then $p = P_\theta(f)$ is locally bounded on $X \setminus Z$, and*

$$\mathbf{1}_{\{p < f\}} \text{MA}_\theta(p) = 0.$$

Proof Using the infimum construction in the proof of [Proposition 12.1.2](#), take continuous $f_j \uparrow f$ with common bounds $m \leq f_j \leq M$, and shift ρ below m . The envelopes $p_j = P_\theta(f_j)$ increase and satisfy

$$\rho \leq p_j \leq M.$$

Their regularized limit $q = (\lim_j p_j)^*$ is therefore θ -plurisubharmonic. Outside a pluripolar set it equals the pointwise limit, which is at most f ; hence $q \leq p = P_\theta(f)$.

We prove the reverse inequality without using a domination theorem. Let u be any competitor for $P_\theta(f)$, and let $u_t \leq f$ be the potentials given by [Lemma 1.19.3](#), which satisfy this inequality everywhere. For fixed $t, \eta > 0$, the sets

$$\{u_t < f_j + \eta\}, \quad j \geq 1,$$

are open, increase with j , and cover X . By compactness, $u_t \leq f_j + \eta$ everywhere for all large j . Thus $u_t - \eta$ is a competitor for p_j , and $q \geq u_t - \eta$. Letting first $\eta \downarrow 0$ and then $t \downarrow 0$, we obtain $q \geq u$ almost everywhere, hence everywhere by [Lemma 1.3.3](#). Taking the supremum over all competitors u gives $q \geq p$, so $q = p$.

For fixed k , the set $U_k = \{p < f_k\}$ is open. If $j \geq k$, then $p_j \leq p < f_k \leq f_j$ on U_k , so [Theorem 13.7.1](#) gives $\text{MA}_\theta(p_j) = 0$ there. On every relatively compact open subset of $X \setminus Z$ the functions p_j have common bounds. After a common smooth correction and a finite expansion, the local Bedford–Taylor continuity along increasing sequences shows that their measures converge to $\text{MA}_\theta(p)$ there. Since the measure of an open set is at most the lower limit of the measures of the approximating sequence, $\text{MA}_\theta(p)$ vanishes on $U_k \setminus Z$. The union of these sets is $\{p < f\} \setminus Z$, and the extended measure does not charge the pluripolar set Z . $\square$

Proposition 13.7.2 *The conclusion of [Proposition 13.7.1](#) holds for every bounded quasi-continuous obstacle f .*

Proof By [Lemma 1.8.2](#), there are bounded lower semicontinuous f_j with common bounds and $f_j \downarrow f$ quasi-everywhere. The envelopes $p_j = P_\theta(f_j)$ decrease to $p = P_\theta(f)$. Indeed, the common lower barrier shows that the limit is not identically $-\infty$; the limit lies below f quasi-everywhere and is thus a competitor for $P_\theta(f)$, while monotonicity gives the other inequality. All these functions have common local bounds off Z .

For fixed k , put $H_k = \min\{1, (f - p_k)_+\}$ on $X \setminus Z$, a bounded quasi-continuous function there. If $j \geq k$, then on $\{H_k > 0\}$ we have $p_j \leq p_k < f \leq f_j$ outside a pluripolar set, so [Proposition 13.7.1](#) gives $H_k \text{MA}_\theta(p_j) = 0$ off Z .

Let g be continuous with compact support in $X \setminus Z$. The continuity of bounded products against quasi-continuous weights from [Section 1.6](#) applies to the fixed quasi-continuous coefficient gH_k . Consequently $H_k \text{MA}_\theta(p) = 0$ off Z . As $k \rightarrow \infty$, the sets $\{H_k > 0\}$ exhaust $\{p < f\} \setminus Z$, and Z is not charged because it is pluripolar. $\square$

For an unbounded obstacle, we truncate and use the convergence of signed products in [Lemma 1.8.4](#).

Theorem 13.7.2 *Let θ be smooth and big. Let f be a quasi-continuous obstacle, finite almost everywhere, such that $p = P_\theta(f) \not\equiv -\infty$. Then $p \leq f$ quasi-everywhere and*

$$\mathbf{1}_{\{p < f\}} \text{MA}_\theta(p) = 0.$$

As before, the measure $\text{MA}_\theta(p)$ may have infinite total mass.

Proof As in the proof of [Theorem 12.1.2](#), the local envelope theorem and a countable Choquet family give $p \leq f$ quasi-everywhere. Set $f_j = \max(f, -j)$ and $p_j = P_\theta(f_j)$. Then p is a competitor for every f_j . Since $f_j \leq f_1$ and f_1 is finite almost everywhere, the finite-sublevel argument in [Section 1.19](#) gives a common upper bound for all competitors. Thus the envelopes p_j are θ -plurisubharmonic and uniformly bounded above. Choose M strictly larger than this bound.

The obstacle $g_j = \min(f_j, M)$ is bounded and quasi-continuous. Since $p_j < M$ and $p_j \leq f_j$ quasi-everywhere, p_j is a competitor for $P_\theta(g_j)$; the reverse inequality follows from $g_j \leq f_j$. Thus $p_j = P_\theta(g_j)$, and [Proposition 13.7.2](#) gives contact support for p_j with respect to g_j . Because $p_j < M$, no contact occurs at the artificial upper cutoff, so

$$\mathbf{1}_{\{p_j < f_j\}} \text{MA}_\theta(p_j) = 0. \quad (13.6)$$

Each p_j is locally bounded off Z , with a lower barrier of the form $\rho - C_j$. The sequence decreases to p : its limit is not identically $-\infty$ because it dominates p , and it lies below f quasi-everywhere, so it is itself a competitor for $P_\theta(f)$.

Fix a Hermitian form $\Omega \geq \theta$. For integers $C, k \geq 1$, consider the bounded Ω -plurisubharmonic functions

$$v_{j,C} = \max(p_j, -C), \quad v_C = \max(p, -C),$$

and set

$$H_{k,C} = \min\{1, (f - p_k)_+\} \min\{1, (p + C)_+\} \quad \text{on } X \setminus Z,$$

extended by zero on Z . This function is bounded and quasi-continuous. Indeed, off Z the function p_k is a finite quasi-plurisubharmonic function, truncation by bounded continuous functions preserves quasi-continuity, and the pluripolar set Z can be removed by an open set of arbitrarily small capacity. At a pole of p the second factor vanishes.

For $j \geq k$, on $\{H_{k,C} > 0\}$ we have, outside pluripolar sets,

$$p_j \geq p > -C, \quad p_j \leq p_k < f \leq f_j.$$

By plurifine locality, the signed measure $v_{j,C} = (\theta + \text{dd}^c v_{j,C})^n$ therefore agrees there with $\text{MA}_\theta(p_j)$, and [\(13.6\)](#) gives

$$H_{k,C} v_{j,C} = 0.$$

For fixed C , the potentials $v_{j,C}$ have common global bounds and decrease to v_C , so [Lemma 1.8.4](#) yields

$$\int_X H_{k,C}(\theta + \text{dd}^c v_C)^n = 0.$$

On the set where $H_{k,C}$ is positive we have $p > -C$, so the restricted product in [Theorem 6.1.1](#) identifies $H_{k,C}(\theta + \text{dd}^c v_C)^n$ with the positive measure $H_{k,C} \text{MA}_\theta(p)$; on the complement the coefficient is zero. Hence $\text{MA}_\theta(p)$ vanishes on $\{H_{k,C} > 0\}$.

Finally, if $p(x)$ is finite and $p(x) < f(x)$, then $p_k(x) < f(x)$ for large k and $p(x) > -C$ for large C . The countable union of the sets $\{H_{k,C} > 0\}$ therefore covers $\{p < f\}$ outside $Z \cup \{p = -\infty\}$. Both excluded sets are pluripolar, and the theorem follows. $\square$

13.8 Compactness with a common lower barrier

We return to a semipositive big background θ . Convergence of potentials in L^1 does not by itself imply convergence of their Monge–Ampère measures. We give a criterion for convergence in capacity when the potentials stay within a bounded distance of a reference admitting a smaller-background envelope. This common lower barrier ensures that all finite and infinite rooftop envelopes of the sequence are θ -plurisubharmonic. A small error integral of each potential against its own Monge–Ampère measure bounds the corresponding error of the rooftops by a summable tail. Weighted lower semicontinuity passes this bound to the limit, and singular domination identifies the limit of the lower envelopes with the L^1 limit. Squeezing the sequence between lower and upper envelopes then gives convergence in capacity, and a domination of the measures also controls their mass on deep sublevels.

Theorem 13.8.1 *Let $\theta \geq 0$ be big. Suppose $\varphi \in \text{PSH}(X, \theta)$ satisfies $P_{\delta\theta}(\varphi) \neq -\infty$ for some $0 < \delta < 1$. Let $u_j \in \text{PSH}(X, \theta)$ satisfy, for a fixed C ,*

$$\varphi - C \leq u_j \leq \varphi + C, \quad u_j \longrightarrow u \text{ in } L^1(X).$$

If

$$I_j := \int_X |e^{u_j} - e^u| \text{MA}_\theta^{\text{ext}}(u_j) \longrightarrow 0, \quad (13.7)$$

then $u_j \rightarrow u$ in capacity.

Proof The canonical representative of the limit also lies between $\varphi - C$ and $\varphi + C$. It suffices to show that every subsequence has a further subsequence converging in capacity. We may therefore assume that $I_j \leq 2^{-j}$ and that $u_j \rightarrow u$ almost everywhere. For $N \geq j$ define

$$p_{j,N} = P_\theta(\min\{u_j, \dots, u_N\}), \quad p_j = P_\theta\left(\inf_{\ell \geq j} u_\ell\right).$$

All these envelopes lie between $\varphi - C$ and $\varphi + C$. The contact theorem and ordered contact give an inequality for the finite rooftops. Partition the contact set of $p_{j,N}$ according to the first index ℓ for which $p_{j,N} = u_\ell$. On the corresponding piece, the measure of $p_{j,N}$ is bounded by that of u_ℓ , and $e^{p_{j,N}} = e^{u_\ell}$. Therefore

$$\int_X |e^{p_{j,N}} - e^u| \text{MA}_\theta^{\text{ext}}(p_{j,N}) \leq \sum_{\ell=j}^N I_\ell \leq 2^{1-j}.$$

Only positive measures enter this argument, so it applies also when their total masses are infinite.

As $N \rightarrow \infty$, $p_{j,N}$ decreases to p_j ; the limit is the envelope of the infimum because every competitor lies below every finite rooftop. The sequence p_j increases, and its canonical limit p is θ -plurisubharmonic. By [Lemma 1.8.6](#), both monotone limits hold in capacity. Applying [Lemma 6.3.1](#) to the bounded nonnegative weights $|e^{p_{j,N}} - e^u|$, first in N and then in j , we obtain

$$\int_X |e^p - e^u| \text{MA}_\theta^{\text{ext}}(p) = 0.$$

The inequalities $p_j \leq u_\ell$ for all $\ell \geq j$ imply $p \leq u$, first almost everywhere and then for the canonical representatives. Also $p \sim u \sim \varphi$. Off the pole sets, $e^p < e^u$ exactly on $\{p < u\}$, so $\text{MA}_\theta^{\text{ext}}(p)(\{p < u\}) = 0$. Since $P_{\delta\theta}(\varphi) - C$ is a competitor for $P_{\delta\theta}(p)$, the latter is not identically $-\infty$. [Theorem 13.1.1](#), applied with coefficient zero, gives $p \geq u$, and hence $p = u$.

Finally, by Hartogs' lemma and the almost-everywhere convergence, $U_j = (\sup_{\ell \geq j} u_\ell)^*$ decreases to u . The inequalities $p_j \leq u_j \leq U_j$, together with the convergence in capacity of both monotone sequences, prove the claim. $\square$

Proposition 13.8.1 *In [Theorem 13.8.1](#), the two bounds on u_j may be replaced by*

$$\varphi - C \leq u_j \leq C,$$

provided that the L^1 limit satisfies $u \preceq \varphi$. In particular, the approximants may be bounded while φ is unbounded.

Proof The L^1 limit satisfies $u \geq \varphi - C$, so the additional hypothesis gives $u \sim \varphi$. We repeat the construction of the finite rooftops in the theorem. Every $p_{j,N}$ is still θ -plurisubharmonic and lies between $\varphi - C$ and C , which is enough for contact support and for the boundedness of the exponential weights. The resulting inequality is again

$$\int_X |e^{p_{j,N}} - e^u| \text{MA}_\theta^{\text{ext}}(p_{j,N}) \leq 2^{1-j}.$$

The limits p_j exist because of the common lower bound, and $p_j \leq u$ follows from $p_j \leq u_\ell$ for every $\ell \geq j$ and almost-everywhere convergence. Thus $\varphi - C \leq p_j \leq u$, so all p_j and their increasing limit p have the same ordinary singularity type as φ . Monotone convergence in capacity and weighted lower semicontinuity give

$\text{MA}_\theta^{\text{ext}}(p)(\{p < u\}) = 0$, and singular domination applies to (p, u) exactly as before, so $p = u$. The upper envelopes of the tails decrease to u , and the same squeezing argument gives convergence in capacity. Neither the finite rooftops nor the individual approximants needed to have the singularity type of φ . $\square$

Corollary 13.8.1 *In the setting of Theorem 13.8.1, with the bounds $\varphi - C \leq u_j \leq \varphi + C$, suppose either*

- (1) $\text{MA}_\theta^{\text{ext}}(u_j) \leq \nu$ for a fixed finite non-pluripolar measure ν ; or
- (2) $\text{MA}_\theta^{\text{ext}}(u_j) \leq A\omega_{w_j}^n$, where A is fixed and $w_j \in \text{PSH}(X, \omega)$ are uniformly bounded and converge in capacity to a bounded w .

Then $u_j \rightarrow u$ in capacity, all the measures $\text{MA}_\theta^{\text{ext}}(u_j)$ and $\text{MA}_\theta^{\text{ext}}(u)$ have finite mass, and

$$\text{MA}_\theta^{\text{ext}}(u_j) \rightarrow \text{MA}_\theta^{\text{ext}}(u).$$

Proof In the first case, Lemma 1.23.1, applied to the exponentials e^{u_j} , proves (13.7). In the second case we use Lemma 1.23.3 instead, since these exponentials are bounded and have a common lower bound for their curvature. In both cases the criterion gives convergence in capacity.

The masses are uniformly bounded by those of the dominating measures. For the deep sublevels we use $u_j \geq \varphi - C$, which gives $\{u_j < -T\} \subset \{\varphi < C - T\}$. In the first case the masses of these sublevels are at most $\nu(\{\varphi < C - T\})$, which tends to zero as $T \rightarrow \infty$ because ν does not charge the pole set of φ . In the second case Lemma 1.8.3 bounds them by $C' \text{Cap}_\omega(\{\varphi < C - T\})$, which also tends to zero. The tail criterion Theorem 7.4.1, in the general-background form of Theorem 7.6.1, now gives finiteness of the limiting measure and weak convergence. $\square$

The reference φ in these results need not be an envelope fixed point; the smaller-background condition suffices. Envelope fixed points enter when the two barriers must be derived from an a priori estimate, as in Theorem 13.11.2. When no common lower barrier is available, one has to be constructed in a relative envelope class; this problem is treated in Section 30.6.

13.9 A bounded subsolution theorem

The bounded exponential equation remains solvable for right-hand sides that are singular with respect to smooth volume, provided they have a bounded density with respect to the Monge–Ampère measure of a bounded potential. We regularize this potential to obtain equations with bounded densities with respect to smooth volume; their solutions are controlled by a moving dominating measure. When the density is allowed to vanish, the normalizations are bounded by the mixed density inequality of Lemma 1.7.3 and the trace estimate for a fixed reference in Lemma 1.8.7.

Theorem 13.9.1 *Let θ be semipositive and big. Suppose*

$$\mu = f \operatorname{MA}_\theta(\psi), \quad \psi \in \operatorname{PSH}(X, \theta) \cap L^\infty(X), \quad 0 \leq f \in L^\infty(\operatorname{MA}_\theta(\psi)),$$

and $\mu(X) > 0$. For every $\lambda > 0$ there is a unique bounded $u \in \operatorname{PSH}(X, \theta)$ satisfying

$$\operatorname{MA}_\theta(u) = e^{\lambda u} \mu.$$

Proof Write $\nu = \operatorname{MA}_\theta(\psi)$, a finite non-pluripolar measure.

Step 1: smooth strictly positive density. First suppose f is smooth and strictly positive. Choose a Hermitian form $\Omega \geq \theta$ and, by [Theorem 1.11.1](#), smooth Ω -plurisubharmonic functions $\psi_j \downarrow \psi$. The envelopes

$$q_j = P_\theta(\psi_j)$$

lie between ψ and ψ_j , so they are uniformly bounded and decrease to ψ . Contact support and ordered contact in the background Ω give

$$\operatorname{MA}_\theta(q_j) \leq \mathbf{1}_{\{q_j = \psi_j\}} \Omega_{\psi_j}^n.$$

In particular, each $\operatorname{MA}_\theta(q_j)$ has a bounded density with respect to smooth volume. Moreover $\operatorname{MA}_\theta(q_j)(X) > 0$ by [Proposition 12.2.1](#). [Theorem 13.2.1](#) therefore gives bounded $u_j \in \operatorname{PSH}(X, \theta)$ with

$$\operatorname{MA}_\theta(u_j) = e^{\lambda u_j} f \operatorname{MA}_\theta(q_j).$$

Since f is bounded above and away from zero, we can choose C such that $e^{\lambda(q_j - C)} f \leq 1 \leq e^{\lambda(q_j + C)} f$ for all j . Then $q_j - C$ and $q_j + C$ are a subsolution and a supersolution, and bounded exponential comparison gives $q_j - C \leq u_j \leq q_j + C$.

Extract an L^1 limit u , which is again bounded. The moving domination

$$\operatorname{MA}_\theta(u_j) \leq C' \Omega_{\psi_j}^n$$

and [Corollary 13.8.1](#), applied with the reference zero, give convergence in capacity. Continuity of bounded products under convergence in capacity, with the quasi-continuous weights $e^{\lambda u_j} f$, then gives

$$\operatorname{MA}_\theta(u) = e^{\lambda u} f \nu.$$

Step 2: bounded measurable density. Choose smooth positive functions f_j with a common upper bound $L > 0$ such that $f_j \rightarrow f$ in $L^1(\nu)$. Such an approximation exists: by regularity of the finite measure ν , f can be approximated by continuous functions on large compact sets, and continuous functions by smooth ones uniformly; truncating to a fixed bounded interval and adding a positive constant tending to zero preserves the bounds and the convergence. Step 1 gives bounded u_j with

$$\operatorname{MA}_\theta(u_j) = e^{\lambda u_j} f_j \nu.$$

For a fixed C we have $e^{\lambda(\psi-C)} f_j \leq 1$ for all j , so $\psi - C$ is a subsolution and $u_j \geq \psi - C$. The upper bound requires a separate argument, because $\inf_X f_j$ may tend to zero.

The construction in Step 1 also gives the mixed inequality

$$\theta_{u_j} \wedge \theta_\psi^{n-1} \geq e^{\lambda u_j/n} f_j^{1/n} \nu. \quad (13.8)$$

To prove it without a mixed inequality for arbitrary singular measures, we use the approximants $u_{j,k}$ and q_k of Step 1, for which

$$\text{MA}_\theta(u_{j,k}) = e^{\lambda u_{j,k}} f_j \text{MA}_\theta(q_k),$$

and both Monge–Ampère measures have densities with respect to smooth volume. **Lemma 1.7.3** applies to the pair $(u_{j,k}, q_k)$. For fixed j , both sequences are uniformly bounded and converge in capacity to (u_j, ψ) , so continuity of bounded products against quasi-continuous weights passes the mixed inequality to the limit and yields (13.8).

Put $M_j = \sup_X u_j$, $v_j = u_j - M_j$ and $c_j = e^{\lambda M_j}$. Suppose the M_j were unbounded above. After extraction, $M_j \rightarrow +\infty$ and $v_j \rightarrow v$ in $L^1(X)$, where $v \in \text{PSH}(X, \theta)$ is normalized. By **Lemma 1.23.1**, $e^{\lambda v_j/n} \rightarrow e^{\lambda v/n}$ in $L^1(\nu)$. Together with the inequalities

$$|f_j^{1/n} - f^{1/n}|^n \leq |f_j - f|, \quad 0 \leq f_j \leq L,$$

this gives

$$\int_X e^{\lambda v_j/n} f_j^{1/n} d\nu \longrightarrow \int_X e^{\lambda v/n} f^{1/n} d\nu > 0;$$

the last integral is positive because $\mu(X) > 0$ and ν does not charge the pole set of v . Integrating (13.8) and applying **Lemma 1.8.7**, we find some $a > 0$ such that, along the extraction,

$$ac_j^{1/n} \leq \int_X \theta_{v_j} \wedge \theta_\psi^{n-1} \leq C_\psi,$$

contradicting $M_j \rightarrow +\infty$. Thus the u_j are uniformly bounded above as well as below.

Extract an L^1 limit u . Now $\text{MA}_\theta(u_j) \leq C''\nu$, so **Corollary 13.8.1** gives convergence in capacity and weak convergence of the Monge–Ampère measures. The right-hand sides converge in total variation, by the convergence of exponentials against the fixed measure ν and the estimate

$$\int_X |e^{\lambda u_j} f_j - e^{\lambda u} f| d\nu \leq C \|f_j - f\|_{L^1(\nu)} + \|f\|_\infty \int_X |e^{\lambda u_j} - e^{\lambda u}| d\nu.$$

Consequently $\text{MA}_\theta(u) = e^{\lambda u} \mu$. Uniqueness follows from bounded exponential comparison. $\square$

13.10 Adding weighted Monge–Ampère measures

Let u and v be potentials of the same ordinary singularity type. We show that the sum of their weighted measures $e^{-\lambda u} \text{MA}_\theta(u) + e^{-\lambda v} \text{MA}_\theta(v)$ is again of the form $e^{-\lambda a} \text{MA}_\theta(a)$ for a potential a of that type. Truncating u and v gives bounded equations, solved by the bounded subsolution theorem, whose solutions have a common lower barrier. Their exponential error tends to zero even though the approximating masses may grow, so the lower-barrier criterion identifies the limit. This addition step will remove a deficit of mass in the existence proof of [Section 13.11](#).

Theorem 13.10.1 *Let $\theta \geq 0$ be big, and suppose $\varphi \in \text{PSH}(X, \theta)$ satisfies $P_{\delta\theta}(\varphi) \neq -\infty$ for some $0 < \delta < 1$. Let $u, v \in \text{PSH}(X, \theta)$ satisfy $u, v \sim \varphi$, and let $\lambda > 0$. If*

$$\mu = e^{-\lambda u} \text{MA}_\theta^{\text{ext}}(u) + e^{-\lambda v} \text{MA}_\theta^{\text{ext}}(v)$$

is a finite measure, then there exists $a \in \text{PSH}(X, \theta)$, with $a \sim \varphi$, such that

$$\text{MA}_\theta^{\text{ext}}(a) = e^{\lambda a} \mu.$$

Here the weights are evaluated off the pole sets. The solution a is unique in the ordinary singularity type of φ .

Proof Step 1: truncated equations and barriers. Choose $S \geq \max(\sup_X u, \sup_X v)$. A common translation reduces the theorem to the case $u, v \leq 0$: translating u and v by $-S$ multiplies μ by $e^{\lambda S}$, and the resulting solution is then translated back by S .

For integers $j \geq 1$, set $u_j = \max(u, -j)$, $v_j = \max(v, -j)$ and

$$\mu_j = e^{-\lambda u_j} \text{MA}_\theta(u_j) + e^{-\lambda v_j} \text{MA}_\theta(v_j).$$

For $s_j = (u_j + v_j)/2$, positivity of mixed products gives

$$\mu_j \leq 2^n e^{\lambda j} \text{MA}_\theta(s_j).$$

Thus μ_j has a bounded density with respect to the Monge–Ampère measure of the bounded potential s_j , and $\mu_j \neq 0$ by [Proposition 12.2.1](#). The bounded subsolution theorem [Theorem 13.9.1](#) therefore gives bounded $a_j \in \text{PSH}(X, \theta)$ with $\text{MA}_\theta(a_j) = e^{\lambda a_j} \mu_j$, and bounded exponential comparison yields

$$a_j \leq \min(u_j, v_j) \leq 0.$$

Choose C with $|u - v| \leq C$ off the common pole set; then $|u_j - v_j| \leq C$. Put

$$D = C/2 + n\lambda^{-1} \log 2, \quad b_j = s_j - D.$$

Because $|u_j - v_j| \leq C$, positivity of mixed products gives

$$e^{-\lambda b_j} \text{MA}_\theta(b_j) \geq 2^{-n} e^{\lambda D - \lambda s_j} (\text{MA}_\theta(u_j) + \text{MA}_\theta(v_j)) \geq \mu_j.$$

Hence $a_j \geq b_j \geq w$, where

$$w = (u + v)/2 - D \sim \varphi$$

is a fixed θ -plurisubharmonic function. Extract a subsequence with $a_j \rightarrow a$ in $L^1(X)$. The upper barriers decrease to $\min(u, v)$, so $w \leq a \leq \min(u, v)$ and $a \sim \varphi$.

Step 2: convergence in capacity. Write $E_j = \{\min(u, v) > -j\}$. By locality, $\mu_j = \mu$ on E_j ; since $a_j \leq 0$, it follows that

$$\int_{E_j} |e^{a_j} - e^a| \text{MA}_\theta(a_j) \leq \int_X |e^{a_j} - e^a| d\mu \rightarrow 0$$

by [Lemma 1.23.1](#). On $X \setminus E_j$ we have $a_j \leq -j$ and $a \leq -j$, whence $|e^{a_j} - e^a| \leq e^{-j}$. Moreover

$$\text{MA}_\theta(a_j) = e^{\lambda(a_j - u_j)} \text{MA}_\theta(u_j) + e^{\lambda(a_j - v_j)} \text{MA}_\theta(v_j) \leq \text{MA}_\theta(u_j) + \text{MA}_\theta(v_j).$$

Choose a Hermitian form $\Omega \geq \theta$. Since $\text{MA}_\theta(u_j) \leq \text{MA}_\Omega(u_j)$ and $-j \leq u_j \leq 0$, and similarly for v_j , the range estimate of [Proposition 7.1.1](#), with $r_n = \max(n - 2, 0)$, gives

$$\int_{X \setminus E_j} |e^{a_j} - e^a| \text{MA}_\theta(a_j) \leq C' e^{-j} (1 + j)^{r_n} \rightarrow 0.$$

The lower-barrier criterion [Proposition 13.8.1](#) now gives $a_j \rightarrow a$ in capacity. Note that only a polynomial bound for the masses of the approximating measures was needed.

Step 3: the limiting equation. We identify the equation on sets where w is bounded below, without first proving weak convergence of the measures $\text{MA}_\theta(a_j)$. For $T > 0$, let g_T be the continuous cutoff from the proof of [Lemma 6.3.1](#), and put $\zeta_T = g_T(w)$. Where $\zeta_T > 0$, we have $w > -2T$, hence every a_j and a is above $-2T$. If $j > 2T$ and $x \notin E_j$, the inequalities $w(x) \leq a_j(x) \leq -j$ force $\zeta_T(x) = 0$. Consequently, for all $j > 2T$,

$$\zeta_T \text{MA}_\theta(a_j) = \zeta_T e^{\lambda a_j} \mu.$$

We test this identity against a continuous function. On the left we may replace a_j by $\max(a_j, -2T)$ and use continuity of bounded products under convergence in capacity, with the fixed bounded quasi-continuous weight ζ_T . On the right, the exponentials converge against the fixed measure μ , which gives convergence in total variation. Therefore

$$\zeta_T \text{MA}_\theta^{\text{ext}}(a) = \zeta_T e^{\lambda a} \mu.$$

As $T \rightarrow \infty$, the cutoffs increase to one off the pole set of w , which no measure involved charges. This proves the equation and, in particular, shows that $\text{MA}_\theta^{\text{ext}}(a)$ has finite mass. Uniqueness follows from [Corollary 13.1.1](#). $\square$

13.11 Equations in a prescribed ordinary type

We return to a semipositive big background θ and now require the solution to have the ordinary singularity type of a fixed reference φ . Throughout this section, $\varphi \in \text{PSH}(X, \theta)$ is an envelope fixed point admitting a smaller-background envelope; that is, (12.20) holds:

$$P_\theta[\varphi] = \varphi, \quad P_{\varepsilon\theta}(\varphi) \not\equiv -\infty \quad \text{for some } 0 < \varepsilon < 1.$$

We fix such an ε . Note that $\varphi \leq 0$, since every competitor for $P_\theta[\varphi]$ is nonpositive. For a normalized solution u , the fixed-point property gives the upper bound $u \leq \varphi$, while the smaller-background envelope $P_{\varepsilon\theta}(\varphi)$ yields a uniform lower bound $u \geq \varphi - C$. A supersolution and the addition theorem then prove existence in this type.

Theorem 13.11.1 *Let θ and φ be as above, and let $\mu = f \, dV$, where $0 \leq f \in L^p(dV)$, $p > 1$, and $\mu(X) > 0$. Then:*

- (1) *For every $\lambda > 0$ there is a unique $u \in \text{PSH}(X, \theta)$ with $u \sim \varphi$ such that*

$$\text{MA}_\theta(u) = e^{\lambda u} \mu.$$

- (2) *There are $u \in \text{PSH}(X, \theta)$ with $u \sim \varphi$ and a uniquely determined constant $c > 0$ such that*

$$\text{MA}_\theta(u) = c\mu.$$

The potential in part (2) need not be unique up to an additive constant, even for a Hermitian background and the reference $\varphi = 0$; see the counterexample in Theorem 11.6.1.

The proof uses two estimates in the prescribed type. The first is a lower bound for the norm of a Monge–Ampère density.

Lemma 13.11.1 *Fix $q > 1$. There is $b_q > 0$ such that every $u \in \text{PSH}(X, \theta)$ with $u \sim \varphi$ and*

$$\text{MA}_\theta^{\text{ext}}(u) = F \, dV, \quad 0 \leq F \in L^q(dV),$$

satisfies $\|F\|_q \geq b_q$. For fixed θ and ε , the constant b_q is independent of φ .

Proof Since $u \sim \varphi$, the smaller-background envelope $P_{\varepsilon\theta}(u)$ is not identically $-\infty$. If $F = 0$, then Theorem 13.1.1, applied to u and $u + 1$ with coefficient zero, would give $u \geq u + 1$; hence $N = \|F\|_q > 0$.

Apply Lemma 13.2.1 in the semipositive big background $(1 - \varepsilon)\theta$ to F/N , whose L^q norm is one. It gives a bounded s with $-1 \leq s \leq 0$ and a constant $b_q > 0$, depending only on this fixed background and on q , such that

$$\text{MA}_{(1-\varepsilon)\theta}(s) \geq (b_q/N)F \, dV.$$

Put $h = P_{\varepsilon\theta}(\varphi) + s$. This is a θ -plurisubharmonic function with $h \preceq u$. Since θ_h is the sum of the positive currents $\varepsilon\theta + \text{dd}^c P_{\varepsilon\theta}(\varphi)$ and $(1 - \varepsilon)\theta + \text{dd}^c s$, the same

density bound holds for $\text{MA}_\theta^{\text{ext}}(h)$. To justify this, we truncate $P_{\varepsilon\theta}(\varphi)$ at finite levels, use positivity of bounded mixed products, and exhaust the set where $P_{\varepsilon\theta}(\varphi)$ is finite; its pole set has zero volume.

If $N < b_q$, we would have

$$\text{MA}_\theta^{\text{ext}}(u) \leq (N/b_q)\text{MA}_\theta^{\text{ext}}(h+t) \quad \text{for every } t \in \mathbb{R}.$$

Since $N/b_q < 1$, **Theorem 13.1.1** would then imply $u \geq h+t$ for every t , which is impossible at a point where both potentials are finite. Thus $N \geq b_q$. The construction of s used no property of φ , which proves the last assertion. $\square$

The lemma bounds the L^q norm of the density from below; it gives no positive lower bound for the total mass $\int_X F \, dV$.

The second estimate bounds a normalized solution from below by φ minus a uniform constant. It is what keeps limits of solutions in the ordinary singularity type of φ .

Theorem 13.11.2 *Let θ and φ be as above. Suppose $u \in \text{PSH}(X, \theta)$, $u \sim \varphi$, $\sup_X u = 0$, and*

$$\text{MA}_\theta(u) \leq f \, dV, \quad 0 \leq f \in L^p(dV), \quad p > 1.$$

There is a constant C , depending only on the fixed geometry, φ , p , and an upper bound for $\|f\|_{L^p}$, such that

$$\varphi - C \leq u \leq \varphi.$$

Proof The upper bound follows directly from the fixed-point property: since $u \leq 0$ and $u \preceq \varphi$, the function u is a competitor for $P_\theta[\varphi] = \varphi$.

For the lower bound we construct a subsolution ψ of the type of φ whose measure dominates a multiple of $e^{-\gamma u} \text{MA}_\theta(u)$, and then apply singular domination. Put $\varphi_\varepsilon = P_{\varepsilon\theta}(\varphi)$, so that $\varphi_\varepsilon \leq \varphi \leq 0$. Uniform exponential integrability (**Lemma 1.5.1**) for the normalized potentials u and exponential integrability for the fixed function φ_ε allow us to choose $\gamma > 0$ and $1 < q < p$ such that

$$g = e^{-\gamma(\varphi_\varepsilon + u)} f$$

has a uniform L^q bound. Explicitly, we first choose $q < p$ and apply Hölder's inequality with exponents p/q and $p/(p-q)$; then we choose γ so small that the exponential factor is controlled by the Cauchy–Schwarz inequality and the two exponential integrability estimates.

Theorem 13.2.2, applied in the semipositive big background $(1-\varepsilon)\theta$ to the density $1+g$, gives a bounded v with $\sup_X v = 0$ and a constant $c > 0$ such that

$$((1-\varepsilon)\theta + \text{dd}^c v)^n = c(1+g) \, dV.$$

Both $\|v\|_\infty$ and c^{-1} are uniformly bounded. Adding the constant one to g makes the root integral of the density at least one, so no lower bound for the integral of f is needed.

Put $h = \varphi_\varepsilon + v \leq \varphi$, which is θ -plurisubharmonic, and define

$$\chi(t) = \frac{1}{1-t} \quad (t \leq 0), \quad \psi = \varphi + \chi(h - \varphi),$$

where the formula for ψ is evaluated off the pole sets. Then $0 \leq \chi \leq 1$, $0 < \chi' \leq 1$, and $\chi'' > 0$. For bounded potentials with $h \leq \varphi$, [Lemma 1.7.6](#), applied with $G(x, y) = x + \chi(y - x)$, gives

$$\theta + \text{dd}^c G(\varphi, h) \geq (1 - \chi'(h - \varphi))\theta_\varphi + \chi'(h - \varphi)\theta_h \geq 0.$$

For unbounded potentials we apply this bounded assertion to $\varphi_k = \max(\varphi, -k)$ and $h_k = \max(h, -k) \leq \varphi_k$. Since G is nondecreasing in both variables, $G(\varphi_k, h_k)$ decreases as k increases. Its limit is θ -plurisubharmonic and lies between φ and $\varphi + 1$; hence it is not identically $-\infty$, and it equals ψ . Locality on common finite levels and positivity of bounded products give

$$\text{MA}_\theta^{\text{ext}}(\psi) \geq (\varphi - h + 1)^{-2n} \text{MA}_\theta^{\text{ext}}(h) \geq c(\varphi - h + 1)^{-2n} e^{-\gamma\varphi_\varepsilon} e^{-\gamma u} f \, dV,$$

where the second inequality uses $\text{MA}_\theta^{\text{ext}}(h) \geq ((1 - \varepsilon)\theta + \text{dd}^c v)^n \geq c g \, dV$. These inequalities are first obtained off the pole sets; since pole sets have zero volume, they extend by exhaustion to all Borel sets.

Write $T = -\varphi_\varepsilon \geq 0$. If $C_1 \geq 1 + \|v\|_\infty$, then $\varphi - h + 1 \leq T + C_1$. Since

$$A := \inf_{T \geq 0} \frac{e^{\gamma T}}{(T + C_1)^{2n}} > 0,$$

we obtain, with a uniform $d > 0$,

$$\text{MA}_\theta^{\text{ext}}(\psi) \geq d e^{-\gamma u} \text{MA}_\theta^{\text{ext}}(u).$$

Choose $K = 2 + \gamma^{-1} |\log d|$. On $\{u < \psi - K\}$ we have $u < 1 - K$, because $\psi \leq \varphi + 1 \leq 1$; hence

$$\text{MA}_\theta^{\text{ext}}(u) \leq d^{-1} e^{\gamma(1-K)} \text{MA}_\theta^{\text{ext}}(\psi - K) \leq e^{-\gamma} \text{MA}_\theta^{\text{ext}}(\psi - K).$$

The potentials u and $\psi - K$ have the same ordinary singularity type. Moreover, $u \geq \varphi - C_u$ for some constant C_u , so $P_{\varepsilon\theta}(u) \geq \varphi_\varepsilon - C_u$ is not identically $-\infty$. [Theorem 13.1.1](#) therefore yields $u \geq \psi - K \geq \varphi - K$. All constants used to choose K are uniform over the family in the theorem; the possibly nonuniform constant C_u serves only to show that the smaller-background envelope of u is not identically $-\infty$, and it enters no estimate. $\square$

The existence proof starts from a supersolution in the prescribed type. It is obtained from a bounded solution by a rooftop envelope with φ .

Lemma 13.11.2 *For nonzero $0 \leq f \in L^p(dV)$, $p > 1$, and $\lambda > 0$, there exists $w \in \text{PSH}(X, \theta)$ with $w \sim \varphi$ such that*

$$\text{MA}_\theta^{\text{ext}}(w) \leq e^{\lambda w} f \, dV.$$

Proof Let v be the bounded solution of $\text{MA}_\theta(v) = e^{\lambda v} f \, dV$ given by [Theorem 13.2.1](#), and write $M = \sup_X v$ and $a = v - M \leq 0$. The rooftop envelope $p = P_\theta(a, \varphi)$ satisfies $\varphi - \|a\|_\infty \leq p \leq \varphi$, so $p \sim \varphi$. By the rooftop inequality of [Proposition 12.1.3](#),

$$\text{MA}_\theta^{\text{ext}}(p) \leq \mathbf{1}_{\{p=a \leq \varphi\}} \text{MA}_\theta(a) + \mathbf{1}_{\{p=\varphi < a\}} \text{MA}_\theta^{\text{ext}}(\varphi).$$

The second term vanishes: by [Proposition 12.1.4](#), the measure of φ is carried by $\{\varphi = 0\}$, whereas $\varphi < a \leq 0$ on the set in question. On the first contact set, $a = p$ and $\text{MA}_\theta(a) = e^{\lambda(a+M)} f \, dV$. Thus $\text{MA}_\theta^{\text{ext}}(p) \leq e^{\lambda(p+M)} f \, dV$, and $w = p + M$ has the required properties. $\square$

13.11.1 Existence for a positive exponent

We prove part (1) of [Theorem 13.11.1](#) by maximizing a weighted mass. Among the potentials $z \sim \varphi$ whose weighted measure $e^{-\lambda z} \text{MA}_\theta(z)$ lies below $\mu = f \, dV$, we find one of maximal weighted mass; [Theorem 13.11.2](#) provides the compactness needed for this. If its weighted measure were strictly smaller than μ , the addition theorem would produce a potential of larger weighted mass.

Proof (of [Theorem 13.11.1](#), part (1)) *Step 1: a maximizing sequence.* Fix $\lambda > 0$. By [Lemma 13.11.2](#), there is $w \sim \varphi$ such that

$$v_0 := e^{-\lambda w} \text{MA}_\theta^{\text{ext}}(w) \leq \mu = f \, dV.$$

Consider all potentials $z \sim \varphi$ for which

$$v_0 \leq v_z := e^{-\lambda z} \text{MA}_\theta^{\text{ext}}(z) \leq \mu,$$

and let B be the supremum of their weighted masses $v_z(X)$. This family is nonempty, since it contains w , and $B \leq \mu(X) < +\infty$. Choose u_j in the family with $v_{u_j}(X) \rightarrow B$. Since $v_0 \leq v_{u_j}$, [Corollary 13.1.1](#) gives $u_j \leq w$.

Step 2: uniform bounds. We need a lower bound for the suprema of the u_j . Put $\varphi_\varepsilon = P_{\varepsilon\theta}(\varphi) \leq 0$, and let ψ be the bounded solution of

$$((1 - \varepsilon)\theta + \text{dd}^c \psi)^n = e^{\lambda \psi} f \, dV$$

given by [Theorem 13.2.1](#). For $h = \psi + \varphi_\varepsilon$, positivity of the splitting $\theta_h = (\varepsilon\theta + \text{dd}^c \varphi_\varepsilon) + ((1 - \varepsilon)\theta + \text{dd}^c \psi)$ gives

$$e^{-\lambda h} \text{MA}_\theta^{\text{ext}}(h) \geq e^{-\lambda \varphi_\varepsilon} f \, dV \geq \mu \geq v_{u_j}.$$

Here $h \preceq u_j$, because $h \preceq \varphi$ and $u_j \sim \varphi$, and each u_j admits a smaller-background envelope because $u_j \sim \varphi$. [Corollary 13.1.1](#) therefore gives $u_j \geq h$. Consequently

$$\sup_X h \leq M_j := \sup_X u_j \leq \sup_X w,$$

and the lower bound is finite.

We now apply [Theorem 13.11.2](#) to $v_j = u_j - M_j$. Their measures satisfy

$$\mathrm{MA}_\theta^{\mathrm{ext}}(v_j) = \mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \leq e^{\lambda \sup_X w} f \, dV,$$

so $\varphi - C \leq v_j \leq \varphi$. Together with the bounds for M_j , this shows that all u_j lie within a fixed bounded distance of φ .

Step 3: the limit. Extract an L^1 limit u . By [Corollary 13.8.1](#), applied with the dominating measure $e^{\lambda \sup_X w} \mu$, the convergence holds in capacity, $u \sim \varphi$, and

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) \rightarrow \mathrm{MA}_\theta^{\mathrm{ext}}(u).$$

After a further extraction we may also assume $v_{u_j} \rightarrow v$. Since $v_0 \leq v_{u_j} \leq \mu$, the limit satisfies the same inequalities. We claim that

$$e^{\lambda u_j} v_{u_j} \rightarrow e^{\lambda u} v.$$

Indeed, $e^{\lambda u_j} \rightarrow e^{\lambda u}$ in $L^1(\mu)$ by [Lemma 1.23.1](#), and all the measures v_{u_j} are at most μ ; this controls the error caused by changing the weight. The fixed bounded weight $e^{\lambda u}$ can be approximated in $L^1(\mu)$ by continuous functions, and since both v_{u_j} and v are dominated by μ , this approximation is uniform in the integrals. The weak convergence $v_{u_j} \rightarrow v$ then gives the claim, and the same argument applies after multiplication by any continuous test function.

Since $e^{\lambda u_j} v_{u_j} = \mathrm{MA}_\theta^{\mathrm{ext}}(u_j)$, it follows that

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = e^{\lambda u} v, \quad e^{-\lambda u} \mathrm{MA}_\theta^{\mathrm{ext}}(u) = v, \quad v(X) = B.$$

The second identity holds off the pole set of u , which has zero μ -measure. Hence u belongs to the family and attains the supremum B . Write $v = g \, dV$, with $0 \leq g \leq f$.

Step 4: no deficit. Suppose that $g \neq f$ in $L^1(dV)$. Applying [Lemma 13.11.2](#) to $f - g$, we find $v \sim \varphi$ with

$$v_v := e^{-\lambda v} \mathrm{MA}_\theta^{\mathrm{ext}}(v) \leq (f - g) \, dV.$$

This measure is nonzero. In fact, no potential v admitting a smaller-background envelope has zero Monge–Ampère measure, since [Theorem 13.1.1](#), applied with coefficient zero to v and $v + 1$, would give $v \geq v + 1$. Thus $v_v(X) > 0$.

The sum $v + v_v$ is finite, so [Theorem 13.10.1](#) gives $a \sim \varphi$ with

$$e^{-\lambda a} \mathrm{MA}_\theta^{\mathrm{ext}}(a) = v + v_v.$$

This measure still lies between v_0 and μ , but its mass is $B + v_v(X) > B$, a contradiction. Therefore $g = f$, and u solves the required equation. Uniqueness in the prescribed ordinary type follows from [Corollary 13.1.1](#). $\square$

13.11.2 The normalized equation

For the normalized equation we let the positive exponent tend to zero. Bounded comparison controls the normalizing constants from above, while the lower density estimate of [Lemma 13.11.1](#) keeps them away from zero. The common barriers then give convergence of the Monge–Ampère measures and keep the limit in the prescribed type.

Proof (of [Theorem 13.11.1](#), part (2)) For each $j \geq 1$, part (1) gives $u_j \sim \varphi$ with

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u_j) = e^{u_j/j} f \, dV.$$

Write $M_j = \sup_X u_j$, $v_j = u_j - M_j$ and $c_j = e^{M_j/j}$. Let h be a bounded normalized solution of $\mathrm{MA}_\theta(h) = \alpha f \, dV$, with $\alpha > 0$, given by [Theorem 13.2.2](#).

For $H_j = h + \|h\|_\infty + j \log \alpha$ we have

$$e^{-H_j/j} \mathrm{MA}_\theta(H_j) = e^{-(h+\|h\|_\infty)/j} f \, dV \leq f \, dV = e^{-u_j/j} \mathrm{MA}_\theta^{\mathrm{ext}}(u_j).$$

The bounded function H_j admits a smaller-background envelope, and $u_j \preceq H_j$, so [Corollary 13.1.1](#) gives $u_j \leq H_j$. In particular,

$$0 < c_j \leq \alpha \exp(2\|h\|_\infty/j).$$

The lower density bound of [Lemma 13.11.1](#), applied to v_j with $q = p$, gives

$$b_p \leq \|c_j e^{v_j/j} f\|_p \leq c_j \|f\|_p,$$

so the c_j are also bounded away from zero.

Since $\sup_X v_j = 0$ and $\mathrm{MA}_\theta^{\mathrm{ext}}(v_j) = c_j e^{v_j/j} f \, dV \leq C f \, dV$, [Theorem 13.11.2](#) gives $\varphi - C' \leq v_j \leq \varphi$. Extract a subsequence with $v_j \rightarrow v$ in $L^1(X)$ and $c_j \rightarrow c > 0$. By [Corollary 13.8.1](#), the convergence holds in capacity, $v \sim \varphi$, and the Monge–Ampère measures converge weakly. Meanwhile, [Lemma 1.23.2](#) gives

$$\int_X |e^{v_j/j} - 1| f \, dV \rightarrow 0.$$

Thus the right-hand sides converge in total variation to $c f \, dV$, and $\mathrm{MA}_\theta^{\mathrm{ext}}(v) = c f \, dV$.

For the uniqueness of the constant, suppose that $a, b \sim \varphi$ solve the normalized equation with constants $c_a < c_b$. For every real t ,

$$\mathrm{MA}_\theta^{\mathrm{ext}}(a) = \frac{c_a}{c_b} \mathrm{MA}_\theta^{\mathrm{ext}}(b + t),$$

so [Theorem 13.1.1](#) gives $a \geq b + t$. This is impossible as $t \rightarrow +\infty$, at any point where both potentials are finite. Interchanging the roles of the two constants proves that c is unique. $\square$

13.12 Comparison above a strict singular barrier

From now on, θ is an arbitrary smooth big real $(1, 1)$ -form. Then V_θ may be unbounded, and the smaller-background construction used above is no longer available. Its role is taken by a strict analytic barrier. When two potentials bounded below by the barrier are compared, adding a small multiple of the barrier forces a negative infimum of their difference to be attained away from its pole set, and there a local comparison principle rules it out.

Since θ is big, [Theorem 1.15.2](#) provides $\rho \in \text{PSH}(X, \theta)$ with analytic singularities and a smooth remainder after resolution such that $\theta_\rho \geq \kappa\omega$ for some $\kappa > 0$. Replacing ω by a small positive multiple and subtracting a constant from ρ , we fix such a ρ with $\rho \leq 0$ and $\theta_\rho \geq \omega$. Put $Z = \{\rho = -\infty\}$ and $\Omega = X \setminus Z$. From now on until the end of [Section 13.17](#), these data remain fixed, and Ω always denotes this open set rather than an auxiliary Hermitian form. A potential bounded below by $\rho - C$ is locally bounded on Ω , and there its extended Monge–Ampère measure agrees with the local bounded product.

Lemma 13.12.1 *Let $B \Subset \Omega$ be a coordinate ball, and let u, v be bounded θ -plurisubharmonic functions on B . Assume*

$$\liminf_{x \rightarrow \partial B} (u - v)(x) \geq 0, \quad \mathbf{1}_{\{u < v\}} \text{MA}_\theta(u) \leq \mathbf{1}_{\{u < v\}} \text{MA}_\theta(v).$$

Then $u \geq v$ on B .

Proof Fix $\varepsilon > 0$ and set $v_\varepsilon = \max(u, v - \varepsilon)$, which equals u near the boundary. We claim that

$$\text{MA}_\theta(u) \leq \text{MA}_\theta(v_\varepsilon)$$

throughout B . On $\{u > v - \varepsilon\}$ this follows from locality, since $v_\varepsilon = u$ there. On $\{u \leq v - \varepsilon\}$ it follows from ordered contact and from the assumed inequality, which applies because this set is contained in $\{u < v\}$.

Let q be the plurisubharmonic envelope on B of the obstacle $u - v_\varepsilon$, in the sense of [\(1.5\)](#). This obstacle is bounded, quasi-continuous and zero near the boundary. Hence it lies between Ah and zero for a sufficiently large A , where $h < 0$ is a smooth strictly plurisubharmonic defining function for the ball. Thus q tends to zero at the boundary, and [\(1.5\)](#) shows that $(\text{dd}^c q)^n$ is carried by $D = \{q = u - v_\varepsilon\}$.

Since $q \leq u - v_\varepsilon$ quasi-everywhere, the canonical representatives satisfy $q + v_\varepsilon \leq u$. Ordered contact, followed by the measure inequality above, yields

$$\mathbf{1}_D \text{MA}_\theta(q + v_\varepsilon) \leq \mathbf{1}_D \text{MA}_\theta(u) \leq \mathbf{1}_D \text{MA}_\theta(v_\varepsilon).$$

The positive expansion of $(\theta_{v_\varepsilon} + \text{dd}^c q)^n$ contains both $\text{MA}_\theta(v_\varepsilon)$ and $(\text{dd}^c q)^n$. Thus $\mathbf{1}_D(\text{dd}^c q)^n = 0$, and since $(\text{dd}^c q)^n$ is carried by D , we get $(\text{dd}^c q)^n = 0$. The classical Bedford–Taylor comparison principle for bounded plurisubharmonic functions with zero boundary values implies $q = 0$. Consequently $u \geq v_\varepsilon$, first quasi-everywhere and then everywhere. Finally let $\varepsilon \downarrow 0$. $\square$

Theorem 13.12.1 Suppose $u, v \in \text{PSH}(X, \theta)$ satisfy, for constants $C_0, C_1 \geq 0$,

$$\min(u, v) \geq \rho - C_0, \quad v \leq u + C_1.$$

If, for some $0 \leq c < 1$,

$$\mathbf{1}_{\{u < v\}} \text{MA}_\theta(u) \leq c \mathbf{1}_{\{u < v\}} \text{MA}_\theta(v),$$

then $u \geq v$.

The measures in the theorem need not have finite total mass.

Proof We first modify the barrier. Let $r = a\rho - A$, where $a > 1$ is sufficiently close to one and A is sufficiently large. Since

$$\theta + \text{dd}^c(a\rho) = a\theta_\rho + (1-a)\theta,$$

we can arrange $\theta_r \geq \omega/2$ and $r - v \leq -1$, and moreover $u - r \rightarrow +\infty$ at Z , because $u - r \geq (a-1)(-\rho) + A - C_0$. When Z is empty, the last property is not needed.

Choose $0 < \delta < 1$ with $(1-\delta)^n > c$, and put $v_\delta = (1-\delta)v + \delta r$. Then

$$u - v_\delta \geq \delta(u - r) - (1-\delta)C_1.$$

Suppose that the infimum m of $u - v_\delta$ on Ω were negative. Since $u - v_\delta \rightarrow +\infty$ at Z , a sequence x_j along which $u - v_\delta$ tends to m has a subsequence converging to a point $x_0 \in \Omega$. Choose a coordinate ball $B \Subset \Omega$ centered at x_0 , identify it with $\{|z| < 1\}$, and take

$$\eta(z) = b(1 - |z|^2), \quad 0 < b < 1, \quad \omega/2 + \text{dd}^c \eta \geq 0.$$

The function $w = v_\delta + \delta\eta + m$ is θ -plurisubharmonic on B , and $\liminf_{\partial B} (u - w) \geq 0$ because η vanishes on ∂B . Also

$$w - v = \delta(r - v + \eta) + m < 0.$$

Thus $\{u < w\} \subset \{u < v\}$, and positivity of mixed products gives on this set

$$\text{MA}_\theta(u) \leq c \text{MA}_\theta(v) \leq (1-\delta)^n \text{MA}_\theta(v) \leq \text{MA}_\theta(w).$$

By [Lemma 13.12.1](#), $u \geq w$ on B . Evaluating at x_j gives $u(x_j) - v_\delta(x_j) \geq m + \delta\eta(x_j)$, which contradicts $\eta(x_0) > 0$ in the limit. Hence $u \geq v_\delta$ on Ω . Letting $\delta \downarrow 0$ along values with $(1-\delta)^n > c$, we obtain $u \geq v$ on Ω , and [Lemma 1.3.3](#) extends this inequality to X . $\square$

Corollary 13.12.1 *Let $u, v \in \text{PSH}(X, \theta)$ satisfy $u, v \geq \rho - C$ for some $C \geq 0$ and $u \sim v$.*

- (1) *If $\text{MA}_\theta(u) \leq c \text{MA}_\theta(v)$ for some $c \geq 0$, then $c \geq 1$.*
- (2) *If $\text{MA}_\theta(u) \leq e^{\lambda(u-v)} \text{MA}_\theta(v)$ for some $\lambda > 0$, then $u \geq v$.*

In particular, let μ be a positive measure. Among potentials bounded below by ρ minus a constant, each ordinary singularity type contains at most one solution of $\text{MA}_\theta(u) = e^{\lambda u} \mu$, and the constant $c > 0$ in $\text{MA}_\theta(u) = c\mu$ is uniquely determined within each type.

Proof If $c < 1$, apply the theorem to u and $v + A$ for every constant $A > 0$; the constants in its hypotheses may depend on A . The resulting inequality $u \geq v + A$ for all A is impossible. For the second assertion, fix $a > 0$ and restrict the measure inequality to $\{u < v - a\}$. There the factor is at most $e^{-\lambda a} < 1$, so the theorem gives $u \geq v - a$; now let $a \downarrow 0$. For two solutions of the exponential equation, apply the second assertion in both orders; for two solutions of the normalized equation, apply the first. $\square$

13.13 Subsolutions and the Gauduchon trace

The strict barrier also yields subsolutions within a bounded distance of any reference between ρ and zero. The curvature estimate comes from composing a convex function with the difference between the reference and a barrier-based subsolution, which produces a convex combination of positive currents. Pairing the equation with a Gauduchon metric then bounds the normalizing constants through a linear trace.

Lemma 13.13.1 *Fix $p > 1$ and $L > 0$. There is $m > 0$ such that, whenever*

$$\rho \leq \eta \leq 0, \quad \eta \in \text{PSH}(X, \theta), \quad g \geq 0, \quad \|g\|_{L^p(dV)} \leq L,$$

there exists $v \in \text{PSH}(X, \theta)$ with

$$\eta \leq v \leq \eta + 1, \quad \text{MA}_\theta(v) \geq mg \, dV.$$

The constant m depends only on the fixed geometry and on ρ, p, L .

Proof Choose $1 < q < p$. By Hölder's inequality and the finiteness of all polynomial moments of the fixed quasi-plurisubharmonic function ρ , the functions $h = g(2 - \rho)^{2n}$ have uniformly bounded L^q norms. **Lemma 13.2.1**, applied in the Hermitian background ω , gives $s \in \text{PSH}(X, \omega)$ with $-1 \leq s \leq 0$ and

$$\omega_s^n \geq mh \, dV$$

for a fixed $m > 0$. Put $u_1 = \rho + s$. Then $\theta_{u_1} \geq \omega_s$ and $u_1 \leq \rho \leq \eta$. On Ω define

$$t = 1 + \eta - u_1, \quad v = \eta + t^{-1},$$

so that $1 \leq t \leq 2 - \rho$. **Lemma 1.7.6**, applied on relatively compact subsets of Ω with $a = \eta$, $h = u_1$ and $\chi(x) = (1 - x)^{-1}$, gives

$$\theta_v = (1 - t^{-2})\theta_\eta + t^{-2}\theta_{u_1} + 2t^{-3}d(\eta - u_1) \wedge d^c(\eta - u_1) \geq t^{-2}\theta_{u_1}.$$

Since $\eta \leq v \leq \eta + 1$, **Lemma 1.3.7** extends v across Z , and the bounds extend by **Lemma 1.3.3**. On Ω , positivity of the local products gives

$$\text{MA}_\theta(v) \geq t^{-2n}\theta_{u_1}^n \geq (2 - \rho)^{-2n}\omega_s^n \geq mg \, dV.$$

Neither side charges Z , so the inequality holds on X . $\square$

Proposition 13.13.1 *Let γ be a Gauduchon metric on X , write $\gamma^n = G \, dV$, and put*

$$T_\gamma = \int_X \theta \wedge \gamma^{n-1}.$$

Then $T_\gamma > 0$. If $u \in \text{PSH}(X, \theta)$ satisfies $u \geq \rho - C$ and $\text{MA}_\theta(u) \geq F \, dV$ with $F \geq 0$, then

$$\int_X F^{1/n} G^{1-1/n} \, dV \leq T_\gamma. \quad (13.9)$$

Consequently, let $0 \leq f \in L^p(dV)$, $p > 1$, be nonzero, and let $\lambda > 0$. Every solution of $\text{MA}_\theta(u) = e^{\lambda u} f \, dV$ that is bounded below by ρ minus a constant satisfies $\sup_X u \leq C'$, where C' depends only on θ , γ , f and λ . Moreover, if $v_j \in \text{PSH}(X, \theta)$, $j \geq 1$, and constants $C_j \geq 0$ and $c_j > 0$ satisfy

$$\sup_X v_j = 0, \quad \text{MA}_\theta(v_j) = c_j e^{v_j/j} f \, dV, \quad v_j \geq \rho - C_j,$$

then the constants c_j are uniformly bounded above.

Proof The current $\theta_u \wedge \gamma^{n-1}$ is linear in θ_u , so it is a globally defined positive current, even at Z . Since $dd^c \gamma^{n-1} = 0$, Stokes' theorem in the sense of currents gives

$$\int_X \theta_u \wedge \gamma^{n-1} = \int_X \theta \wedge \gamma^{n-1}.$$

Applied to ρ , this identity proves $T_\gamma \geq \int_X \omega \wedge \gamma^{n-1} > 0$.

On Ω , **Lemma 1.7.3**, applied to θ_u and γ , gives

$$\theta_u \wedge \gamma^{n-1} \geq F^{1/n} G^{1-1/n} \, dV.$$

Exhausting Ω and using positivity of the global trace measure, we obtain (13.9), since the complement Z has zero volume.

For the exponential equation, write $a = \sup_X u$ and $w = u - a$. The estimate becomes

$$e^{\lambda a/n} \int_X e^{\lambda w/n} f^{1/n} G^{1-1/n} dV \leq T_\gamma.$$

The integral has a positive lower bound over all normalized $w \in \text{PSH}(X, \theta)$. Otherwise, normalized compactness would give a sequence of such w with integrals tending to zero and converging almost everywhere to a θ -plurisubharmonic function; since $w \leq 0$ and $f^{1/n} G^{1-1/n}$ is integrable, dominated convergence would give a strictly positive limit integral, a contradiction. This bounds a from above.

For the last assertion, the same estimate contains the factors $c_j^{1/n}$ and $e^{v_j/(jn)}$. If the integrals $\int_X e^{v_j/(jn)} f^{1/n} G^{1-1/n} dV$ tended to zero along a subsequence with $j \rightarrow \infty$, normalized compactness and almost-everywhere convergence would give $v_j/j \rightarrow 0$ almost everywhere along a further subsequence. Dominated convergence would then give the positive limit $\int_X f^{1/n} G^{1-1/n} dV$. This contradiction bounds c_j for all large j , and each of the finitely many remaining constants is finite. Neither argument uses the total Monge–Ampère mass. $\square$

13.14 Stability above a strict barrier

The subsolutions of [Lemma 13.13.1](#) stay within a bounded distance of a given reference. With them, the proof of [Theorem 13.3.1](#) extends to unbounded potentials lying above ρ , and the resulting estimate is uniform over all references between ρ and zero. For a fixed reference, it upgrades L^1 compactness of solutions to uniform convergence of their differences on Ω .

Theorem 13.14.1 *Fix $C_0, L > 0$, $p > 1$, and*

$$0 < \gamma < \frac{p-1}{np+p-1}.$$

Let $\eta \in \text{PSH}(X, \theta)$ satisfy $\rho \leq \eta \leq 0$, and suppose that $u \in \text{PSH}(X, \theta)$ satisfies

$$\eta - C_0 \leq u \leq \eta, \quad \text{MA}_\theta(u) = f dV, \quad 0 \leq f \in L^p(dV), \quad \|f\|_p \leq L.$$

There is a constant C , depending only on the fixed geometry and on ρ, C_0, L, p, γ , such that every $v \in \text{PSH}(X, \theta)$ with $v \leq \eta$ satisfies

$$\sup_\Omega (v - u)_+ \leq C \left(\int_\Omega (v - u)_+ dV \right)^\gamma. \quad (13.10)$$

In particular, the constant does not depend on the reference η , and the comparison potential v need not have the ordinary singularity type of η . The difference $v - u$ is evaluated on Ω , where u and η are locally bounded; since Z has zero volume,

the integral is the same as over X . Since Z is pluripolar, the resulting inequality $v \leq u + C \left(\int_{\Omega} (v - u)_+ dV \right)^\gamma$ on Ω extends to the canonical representatives on all of X .

Proof Replacing v by $\max(v, u)$, we may assume $\eta - C_0 \leq u \leq v \leq \eta$, so that $0 \leq v - u \leq C_0$ on Ω .

Fix $q \in (1, p)$ and $\delta > 0$, and put

$$E_\delta = \{u < v - \delta\} \cap \Omega, \quad g_\delta = \mathbf{1}_{E_\delta} f, \quad m_\delta = \|g_\delta\|_q.$$

When $m_\delta > 0$, [Lemma 13.13.1](#), followed by subtracting one from its potential, gives $h \in \text{PSH}(X, \theta)$ and a fixed $b > 0$ such that

$$\eta - 1 \leq h \leq \eta, \quad \text{MA}_\theta(h) \geq b g_\delta / m_\delta dV.$$

The constant b is uniform in η , because the auxiliary density has L^q norm one and the strict barrier is fixed.

If $0 < m_\delta < b/2$, set

$$t = (2m_\delta/b)^{1/n}, \quad w = (1-t)v + th - \delta - C_0 t.$$

Since $h - v \leq C_0$, we have $w \leq v - \delta$, so the set $\{u < w\} \cap \Omega$ is contained in E_δ . On this set the local expansion into positive mixed products gives $\text{MA}_\theta(w) \geq t^n \text{MA}_\theta(h) \geq 2\text{MA}_\theta(u)$. Both potentials are bounded below by ρ minus a constant, and $w \leq u + C_0$, so [Theorem 13.12.1](#) applies and gives $u \geq w$. It follows that

$$v - u \leq \delta + C_0 t + t(v - h) \leq \delta + (C_0 + 1)t.$$

If $m_\delta = 0$, we apply the same domination theorem with coefficient zero to u and $v - \delta$. If $m_\delta \geq b/2$, we use $v - u \leq C_0$. In all cases,

$$\sup_{\Omega} (v - u) \leq \delta + C_1 m_\delta^{1/n}.$$

Write $I = \int_{\Omega} (v - u) dV$. If $I = 0$, the canonical potentials agree. Otherwise Hölder's and Chebyshev's inequalities give

$$m_\delta \leq L(I/\delta)^{(p-q)/(pq)}.$$

For $0 < I \leq 1$, the choice $\delta = I^{(p-q)/(npq+p-q)}$ yields the exponent $\gamma_q = (p - q)/(npq + p - q)$. We choose $q > 1$ so close to one that $\gamma_q > \gamma$. The case $I > 1$ follows from the bound $v - u \leq C_0$. This proves [\(13.10\)](#). $\square$

Corollary 13.14.1 Fix $\eta \in \text{PSH}(X, \theta)$ with $\rho \leq \eta \leq 0$, constants $C_0, L > 0$, and $p > 1$. Consider the family of potentials $u \in \text{PSH}(X, \theta)$ satisfying

$$\eta - C_0 \leq u \leq \eta, \quad \text{MA}_\theta(u) = f_u \, dV, \quad 0 \leq f_u \in L^p(dV), \quad \|f_u\|_p \leq L.$$

This family is compact for uniform convergence of differences on Ω . If u_j belong to the family and $u_j \rightarrow u$ in L^1 , then u belongs to the family and

$$\sup_{\Omega} |u_j - u| \leq C \|u_j - u\|_{L^1(dV)}^\gamma \longrightarrow 0$$

for every exponent γ as in [Theorem 13.14.1](#). Moreover, f_{u_j} converges weakly to f_u in L^p .

Proof Applying the theorem in both orders to u_j and u_k , with the common reference η , we see that an L^1 -Cauchy sequence in the family is uniformly Cauchy in differences on Ω . Its uniform limit on Ω is locally θ -plurisubharmonic and agrees almost everywhere, hence everywhere for the canonical representatives, with the L^1 limit u . The bounds $\eta - C_0 \leq u \leq \eta$ hold on all of X . Letting $k \rightarrow \infty$ in the pairwise estimate proves the quantitative bound, before any equation for u is used.

The densities form a bounded set in the reflexive space L^p . Let f be the weak limit of a subsequence $f_{u_{j_k}}$. Since the potentials are locally bounded and converge locally uniformly on Ω , Bedford–Taylor continuity, which holds also for the smooth nonclosed background, gives $\text{MA}_\theta(u) = f \, dV$ on Ω . Neither measure charges the analytic set Z , so this equality holds on X . Positivity and weak lower semicontinuity of the norm give $f \geq 0$ and $\|f\|_p \leq L$. Thus every weak cluster point equals the density f_u of $\text{MA}_\theta(u)$, which proves weak convergence of the whole sequence. Finally, the common bounds by η and $\eta - C_0$ give L^1 compactness of the family, by the compactness of quasi-plurisubharmonic functions, and the preceding argument upgrades each convergent subsequence to uniform convergence of differences on Ω . $\square$

For solutions with minimal singularities, normalized by $\sup_X u = 0$, we take $\eta = V_\theta$. Then $\rho \leq V_\theta \leq 0$, and every normalized comparison potential $v \in \text{PSH}(X, \theta)$ satisfies $v \leq V_\theta$, as the theorem requires.

13.15 Minimal singularities in an arbitrary big background

We now solve the equations in the ordinary singularity type of V_θ . Demailly’s regularization approximates V_θ by strict potentials with analytic singularities. On a resolution of these singularities, the corresponding equations become equations in a semipositive big background, which we have already solved. The solutions satisfy bounds relative to the approximating singularities that are uniform in the approximation, and upper and lower envelopes then produce a solution with minimal singularities. For the normalized equation, the normalized exponential solutions lie

in a common interval below V_θ , so the compactness theorem of the preceding section applies directly.

Since $\rho \leq 0$ is θ -plurisubharmonic, it is a competitor for V_θ , and hence $\rho \leq V_\theta \leq 0$. We use the analytic regularization of [Theorem 1.15.2](#) in its resolved form.

Lemma 13.15.1 *Let $\psi \in \text{PSH}(X, \theta)$ satisfy $\theta_\psi \geq a\omega$ for some $a > 0$, and suppose that ψ has a smooth remainder after resolution, as in [Theorem 1.15.2](#). For every nonzero $0 \leq f \in L^p(dV)$, $p > 1$, and every $\lambda > 0$, there exists $u \in \text{PSH}(X, \theta)$ with $u \sim \psi$ such that*

$$\text{MA}_\theta(u) = e^{\lambda u} f dV.$$

Proof Let $\pi : Y \rightarrow X$ be a modification resolving the singularities of ψ . The pulled-back current has the form

$$\pi^*\theta + \text{dd}^c \pi^*\psi = \beta + [D],$$

where D is an effective real divisor, $[D]$ is its current of integration, and β is a smooth real $(1, 1)$ -form on Y . Off D we have $\beta \geq a\pi^*\omega$, and by continuity this inequality holds everywhere. In particular, β is semipositive.

We check that β is big. For a blowup with smooth center and exceptional divisor E , choose a metric on $\mathcal{O}(-E)$ whose curvature is positive in the directions tangent to the projective fibers. Along E , the pullback of a Hermitian metric is positive in the complementary directions. Consequently, its sum with a sufficiently small positive multiple of this curvature form is a Hermitian metric: positivity holds first along E , then on a neighborhood of E , and finally on the compact complement, where the pullback is already positive. Iterating over the blowups, we obtain an effective real exceptional divisor F , with logarithmic potential ζ , and a smooth Hermitian form κ such that

$$\pi^*\omega + \text{dd}^c \zeta = \kappa + [F].$$

At each step of the iteration, we pull back the smooth positive form obtained so far, apply the construction for one blowup, and add the pullback of the previous divisor to the new positive multiple of E . Hence $\beta + \text{add}^c \zeta \geq a\kappa$, so β is big. This argument only involves Hermitian metrics and never requires a closed positive form on Y .

Fix a smooth positive volume form dV_Y on Y , and write $\pi^*dV = J dV_Y$. The function J is smooth, nonnegative and bounded, and it is positive off the exceptional locus. Define

$$H = e^{\lambda \pi^*\psi} (f \circ \pi) J.$$

This function is nonzero and belongs to $L^p(dV_Y)$. Indeed, ψ is bounded above, and the change of variables formula gives

$$\int_Y |(f \circ \pi) J|^p dV_Y \leq \|J\|_\infty^{p-1} \int_X |f|^p dV;$$

the analytic exceptional sets do not affect these integrals. [Theorem 13.2.1](#), applied on Y in the semipositive big background β , gives a bounded $s \in \text{PSH}(Y, \beta)$ with

$$\mathrm{MA}_\beta(s) = e^{\lambda s} H \, dV_Y.$$

The function $\pi^*\psi + s$ is $\pi^*\theta$ -plurisubharmonic, because the corresponding current is $\beta_s + [D] \geq 0$, where $\beta_s = \beta + \mathrm{dd}^c s$. By [Theorem A.2.1](#) it descends to some $u \in \mathrm{PSH}(X, \theta)$, and $u \sim \psi$ because s is bounded. Off the exceptional set and the pole set of ψ , the change of variables formula gives the required equation. Neither the extended measure on the left nor the measure $e^{\lambda u} f \, dV$ on the right charges these analytic sets, so the equation holds on all of X . $\square$

Theorem 13.15.1 *Let θ be any smooth big real $(1, 1)$ -form and let $0 \leq f \in L^p(dV)$, $p > 1$, be nonzero. For every $\lambda > 0$ there is a unique $u \in \mathrm{PSH}(X, \theta)$ such that*

$$u \sim V_\theta, \quad \mathrm{MA}_\theta(u) = e^{\lambda u} f \, dV.$$

Proof *Step 1: approximating singularity types.* Apply [Theorem 1.15.2](#) to V_θ . Set $\delta_j = 2^{-j}$ and pass to a subsequence whose curvature errors are at most δ_j . Denote its potentials by $\tilde{\psi}_j$; thus $\tilde{\psi}_j \downarrow V_\theta$ and $\theta_{\tilde{\psi}_j} \geq -\delta_j \omega$. Set

$$a_j = (1 - \delta_j) \sup_X \tilde{\psi}_j \geq 0, \quad \psi_j = (1 - \delta_j) \tilde{\psi}_j + \delta_j \rho - a_j.$$

By Hartogs' lemma, $\sup_X \tilde{\psi}_j \rightarrow \sup_X V_\theta = 0$, so $a_j \rightarrow 0$. A common resolution of the singularities of $\tilde{\psi}_j$ and ρ shows that ψ_j has a smooth remainder after resolution. Moreover,

$$\theta_{\psi_j} \geq \delta_j^2 \omega, \quad (1 - \delta_j) V_\theta + \delta_j \rho - a_j \leq \psi_j \leq V_\theta. \quad (13.11)$$

The upper inequality holds because ψ_j is θ -plurisubharmonic and nonpositive. Subtracting a_j explicitly keeps the normalization separate from the fixed barrier ρ .

Step 2: uniform bounds. By [Lemma 13.15.1](#) there are $u_j \sim \psi_j$ satisfying

$$\mathrm{MA}_\theta(u_j) = e^{\lambda u_j} f \, dV.$$

Each u_j is bounded below by ρ minus a constant depending on j , so [Proposition 13.13.1](#) gives a uniform upper bound for $\sup_X u_j$.

There is also a uniform lower bound. We apply [Lemma 13.13.1](#) with the barrier ρ replaced by $\rho - 1 - \sup_j a_j$ and with the reference $\psi_j - 1$, which lies between this barrier and zero. The lemma gives v_j with $\psi_j - 1 \leq v_j \leq \psi_j \leq 0$ and $\mathrm{MA}_\theta(v_j) \geq m f \, dV$, where $m > 0$ is independent of j . Put $w_j = v_j + \lambda^{-1} \log m$. Then

$$\mathrm{MA}_\theta(w_j) \geq e^{\lambda w_j} f \, dV, \quad u_j \sim w_j \sim \psi_j,$$

and the exponential order in [Corollary 13.12.1](#) gives $u_j \geq w_j$. Thus, for a uniform constant C ,

$$\psi_j - C \leq u_j \leq V_\theta + C. \quad (13.12)$$

After extraction, u_j converges in L^1 and almost everywhere to a θ -plurisubharmonic function u , and the preceding bounds give $V_\theta - C \leq u \leq V_\theta + C$.

Step 3: the equation for the limit. We identify the equation using envelopes. Put $A_j = \sup_{k \geq j} a_k$ and, for $N \geq j$, define

$$p_{j,N} = P_\theta(\min\{u_j, \dots, u_N\}), \quad t_{j,N} = \max_{j \leq k \leq N} u_k.$$

Both functions lie above the θ -plurisubharmonic function

$$b_j = (1 - \delta_j)V_\theta + \delta_j\rho - C - A_j,$$

which is a competitor for every $p_{j,N}$; in particular, no envelope is identically $-\infty$. All these functions are locally bounded on Ω , uniformly in j and N . Contact support ([Theorem 13.7.2](#)), together with a partition of the contact set according to the first index of contact, gives

$$\mathrm{MA}_\theta(p_{j,N}) \leq e^{\lambda p_{j,N}} f \, dV.$$

No factor N appears here: on each piece the envelope equals a single u_k , and ordered contact bounds its measure by the measure of that u_k . Similarly, locality and ordered contact for a finite maximum give

$$\mathrm{MA}_\theta(t_{j,N}) \geq e^{\lambda t_{j,N}} f \, dV.$$

Now let $N \rightarrow \infty$, and set $p_j = \lim_N p_{j,N}$ and $t_j = (\lim_N t_{j,N})^*$. Continuity of local bounded products along monotone sequences passes both inequalities to these limits. Next, p_j increases to a regularized limit p , while t_j decreases to u by Hartogs' lemma. The bound by b_j gives $p \sim V_\theta$, and $p \leq u$. A second application of the monotone continuity gives

$$\mathrm{MA}_\theta(p) \leq e^{\lambda p} f \, dV, \quad \mathrm{MA}_\theta(u) \geq e^{\lambda u} f \, dV.$$

These inequalities hold on Ω , and they extend across Z because no measure involved charges Z . Thus $\mathrm{MA}_\theta(p) \leq e^{\lambda(p-u)} \mathrm{MA}_\theta(u)$, and the exponential order in [Corollary 13.12.1](#) gives $p \geq u$. Hence $p = u$, and the equation follows. Applying the same order in both directions proves uniqueness. Note that the Monge–Ampère operator was only ever applied along monotone sequences that are locally bounded on Ω . $\square$

Lemma 13.15.2 *Under the hypotheses of [Theorem 13.15.1](#), let u_λ be the solution given there, and put*

$$v_\lambda = u_\lambda - \sup_X u_\lambda, \quad c_\lambda = e^{\lambda \sup_X u_\lambda}.$$

There are constants $B, C, m > 0$, independent of $0 < \lambda \leq 1$, such that

$$V_\theta - B \leq v_\lambda \leq V_\theta, \quad m \leq c_\lambda \leq C. \quad (13.13)$$

Proof The normalized potential satisfies

$$\mathrm{MA}_\theta(v_\lambda) = c_\lambda e^{\lambda v_\lambda} f \, dV.$$

Fix a Gauduchon metric γ and write $\gamma^n = G \, dV$. Since $v_\lambda \leq 0$ and $0 < \lambda \leq 1$, (13.9) gives

$$c_\lambda^{1/n} \int_X e^{v_\lambda/n} f^{1/n} G^{1-1/n} \, dV \leq \int_X \theta \wedge \gamma^{n-1}.$$

The integrals on the left have a positive lower bound independent of λ . Otherwise, the compactness of normalized quasi-plurisubharmonic functions would give an almost everywhere convergent sequence of the normalized v_λ whose integrals tend to zero, with a θ -plurisubharmonic limit; since f is nonzero, dominated convergence would give a positive limit integral. Thus $c_\lambda \leq C$.

To control the singularity type, we use uniform exponential integrability (Lemma 1.5.1) and Hölder's inequality to choose $\varepsilon > 0$ and $1 < q < p$ such that $\|e^{-\varepsilon v_\lambda} f\|_q$ is uniformly bounded. Lemma 13.13.1, applied with the reference $V_\theta - 1$ and the barrier $\rho - 1$, gives $\eta_\lambda \in \text{PSH}(X, \theta)$ with

$$V_\theta - 1 \leq \eta_\lambda \leq V_\theta, \quad \text{MA}_\theta(\eta_\lambda) \geq m e^{-\varepsilon v_\lambda} f \, dV \geq m f \, dV$$

for a fixed $m > 0$. The scalar order in Corollary 13.12.1, together with $\text{MA}_\theta(v_\lambda) \leq c_\lambda f \, dV$, gives $c_\lambda \geq m$. Set $D = \varepsilon^{-1} \max\{0, \log(C/m)\}$ and $w_\lambda = \eta_\lambda - D$. Then

$$e^{\varepsilon(w_\lambda - v_\lambda)} \text{MA}_\theta(v_\lambda) \leq m e^{-\varepsilon v_\lambda} f \, dV \leq \text{MA}_\theta(w_\lambda),$$

since $\lambda v_\lambda \leq 0$ and $\eta_\lambda \leq 0$. The exponential order in Corollary 13.12.1 gives $v_\lambda \geq w_\lambda$, which proves the uniform bounds with $B = 1 + D$. $\square$

Theorem 13.15.2 *Under the assumptions of Theorem 13.15.1, there are $v \in \text{PSH}(X, \theta)$, a constant $C > 0$ and a uniquely determined $c > 0$ such that*

$$\sup_X v = 0, \quad V_\theta - C \leq v \leq V_\theta, \quad \text{MA}_\theta(v) = c f \, dV.$$

As in the semipositive case, only the constant c is asserted to be unique, not the normalized potential.

Proof Apply Lemma 13.15.2 with $\lambda = 1/j$, and write $v_j = v_{1/j}$ and $c_j = c_{1/j}$. Extract a subsequence with $v_j \rightarrow v$ in L^1 and almost everywhere, and with $c_j \rightarrow c \in [m, C]$. The limit is normalized, θ -plurisubharmonic, and has minimal singularities. The densities $c_j e^{v_j/j} f$ have a common L^p bound. Hence Corollary 13.14.1, applied with the reference V_θ , upgrades the convergence to uniform convergence of differences on Ω and identifies the weak L^p limit of these densities with the density of $\text{MA}_\theta(v)$.

At almost every point, v_j converges to a finite value, so $v_j/j \rightarrow 0$. Since $v_j \leq 0$ and $c_j \leq C$, dominated convergence gives $c_j e^{v_j/j} f \rightarrow c f$ in L^p . Therefore $\text{MA}_\theta(v) = c f \, dV$. The uniqueness of the constant follows from Corollary 13.12.1. $\square$

13.16 Local Hölder continuity in a big background

We now combine the stability estimate above ρ with the regularization of [Lemma 1.21.5](#), whose curvature error is linear in the regularization parameter. As in the proof of [Theorem 13.4.1](#), a small multiple of the strict barrier absorbs the curvature error of the transforms, and a lower bound for the minimizing radius converts the estimate for the transforms into an estimate for the smoothing on compact subsets of Ω . This gives a local Hölder modulus for solutions with minimal singularities.

Theorem 13.16.1 *Fix $C_0 > 0$. Let $u \in \text{PSH}(X, \theta)$ satisfy*

$$\sup_X u = 0, \quad V_\theta - C_0 \leq u \leq V_\theta, \quad \text{MA}_\theta(u) = f \, dV,$$

where $0 \leq f \in L^p(dV)$ and $p > 1$. Then u is locally Hölder continuous on Ω , with every exponent

$$0 < \beta < \frac{2(p-1)}{np + 3(p-1)}.$$

For fixed bounds on C_0 and $\|f\|_p$, the Hölder constants are uniform on each fixed compact subset of Ω .

Proof Since $u \geq V_\theta - C_0 \geq \rho - C_0$, we may subtract a constant from the strict barrier so that $\rho \leq u - 1$; it still satisfies $\theta + \text{dd}^c \rho \geq \kappa \omega$ for a fixed $\kappa > 0$. Choose $0 < \gamma < (p-1)/(np + p-1)$ and set $\alpha = 2\gamma < 1$. Apply [Lemma 1.21.5](#) with $a = u$, and let A, K, C and $\Phi_{c,\delta}$ be the constants and transforms given there. For small $\delta > 0$ set

$$c = \delta^\alpha, \quad e = Ac + C\delta, \quad s = e/\kappa, \quad v_\delta = \frac{\Phi_{c,\delta} + s\rho}{1+s}.$$

By the curvature bound of [Lemma 1.21.5](#), $v_\delta \in \text{PSH}(X, \theta)$. The lower bound for $\Phi_{c,\delta}$ in that lemma implies $\rho \leq \Phi_{c,\delta}$ when δ is small. Thus

$$v_\delta \leq \Phi_{c,\delta} \leq R_\delta u \leq 0.$$

In particular $v_\delta \leq V_\theta$, so [Theorem 13.14.1](#) applies with the reference V_θ and the comparison potential v_δ . Together with the L^1 smoothing estimate, it gives

$$\sup_\Omega (v_\delta - u)_+ \leq C \|(R_\delta u - u)_+\|_1^\gamma \leq C\delta^\alpha.$$

Fix a compact subset of Ω on which $\rho \geq -M$. Since $s \leq C\delta^\alpha$ and $u \leq 0$, the identity

$$\Phi_{c,\delta} - u = (1+s)(v_\delta - u) + s(u - \rho)$$

gives $\Phi_{c,\delta} - u \leq C_M \delta^\alpha$ there.

At a radius t where the infimum defining $\Phi_{c,\delta}$ is attained, the monotone lower bound yields

$$-c \log(t/\delta) \leq \Phi_{c,\delta} - u + K(\delta^2 + \delta) \leq C_M c.$$

Hence $t \geq a_M \delta$ for a fixed $a_M > 0$. As in the proof of [Theorem 13.4.1](#), monotonicity of the smoothing now gives

$$R_{a_M \delta} u - u \leq C_M \delta^\alpha, \quad R_{a_M \delta} u - u \geq -K(a_M \delta)^2$$

on the chosen compact set. Since every small radius has the form $a_M \delta$, we obtain $|R_t u - u| \leq C_M t^\alpha$ there for all small $t > 0$, with constants uniform on that compact set.

We apply this to a slightly larger compact neighborhood, on which also $\|\nabla R_t u\| \leq C_M/t$. For nearby points x, y at distance $d > 0$, the smooth function $R_t u$ and a short path in that neighborhood give

$$|u(x) - u(y)| \leq C_M(t^\alpha + d/t).$$

The choice $t = d^{1/(1+\alpha)}$ gives the exponent $\alpha/(1+\alpha)$, and letting γ approach its upper endpoint gives the asserted range. Pairs of points farther apart are handled by the boundedness of u on the compact neighborhood. $\square$

It suffices that the equation hold on Ω . Suppose that $\text{MA}_\theta(u) = cf \, dV$ on Ω , where $c > 0$ and $0 \leq f \in L^p(X, dV)$, and that u satisfies the same bounds as in the theorem. The lower bound $u \geq V_\theta - C_0 \geq \rho - C_0$ shows that u is locally bounded on Ω , so there $\text{MA}_\theta(u)$ is the local bounded product. Since Z has zero volume and is not charged by $\text{MA}_\theta(u)$, the equation holds on X , and the theorem applies with cf in place of f . The uniform estimates then depend on a bound for $\|cf\|_p$, which includes the constant c .

13.16.1 Limits of normalized exponential solutions

For the normalized exponential family (v_λ, c_λ) of [Lemma 13.15.2](#), the reference interval $[V_\theta - B, V_\theta]$ is uniform in $0 < \lambda \leq 1$. Stability therefore controls differences on all of Ω , and the local Hölder estimates strengthen the convergence on compact subsets. We fix the nonzero density $0 \leq f \in L^p(dV)$, $p > 1$, and use the constants B, C, m of that lemma.

Proposition 13.16.1 *For the family (v_λ, c_λ) of [Lemma 13.15.2](#), the normalized potentials are relatively compact for uniform convergence of differences on Ω . As $\lambda \downarrow 0$, every cluster limit v is normalized, has minimal singularities, and satisfies*

$$\text{MA}_\theta(v) = c f \, dV,$$

where $c > 0$ is the unique constant of [Theorem 13.15.2](#). Moreover,

$$c_\lambda \longrightarrow c, \quad c_\lambda e^{\lambda v_\lambda} f \longrightarrow c f \quad \text{in } L^p(dV).$$

Every sequence of parameters in $(0, 1]$ has a subsequence for which the potentials converge in C^β on each compact subset of Ω , for all

$$0 < \beta < \frac{2(p-1)}{np + 3(p-1)}.$$

Proof By [Lemma 13.15.2](#), all v_λ lie in a common reference interval, and their densities are bounded in L^p by $C\|f\|_p$. We may therefore apply [Corollary 13.14.1](#) with $\eta = V_\theta$. Given any sequence $\lambda_j \downarrow 0$, we pass to a subsequence with $v_{\lambda_j} \rightarrow v$ uniformly in differences on Ω and in $L^1(X)$, and with $c_{\lambda_j} \rightarrow c_* \in [m, C]$. The limit satisfies the same reference bounds and is normalized. Off the pole set,

$$0 \leq 1 - e^{\lambda v_\lambda} \leq 1 - e^{\lambda(V_\theta - B)} \longrightarrow 0$$

as $\lambda \downarrow 0$. Multiplying by f and using dominated convergence, we obtain $e^{\lambda v_\lambda} f \rightarrow f$ in L^p for the whole family. The compactness corollary therefore identifies the limit equation as $\text{MA}_\theta(v) = c_* f \, dV$, and the uniqueness of the constant gives $c_* = c$. Since every subsequential limit of c_λ as $\lambda \downarrow 0$ equals c , we conclude that $c_\lambda \rightarrow c$, and the stated convergence of the densities follows.

Finally, [Theorem 13.16.1](#) gives uniform local C^α bounds for every α below its endpoint, and the uniform limit inherits these bounds by pointwise convergence. For $0 < \beta < \alpha$, uniform convergence and the elementary interpolation inequality on smaller coordinate balls give

$$[v_{\lambda_j} - v]_{C^\beta} \leq C \|v_{\lambda_j} - v\|_\infty^{1-\beta/\alpha} [v_{\lambda_j} - v]_{C^\alpha}^{\beta/\alpha} \longrightarrow 0,$$

where the Hölder bounds are taken on slightly larger compact neighborhoods. The uniformly convergent subsequence given by compactness thus converges in C^β on every compact subset of Ω and for every exponent below the endpoint; no further extraction depending on the exponent is needed. $\square$

Corollary 13.16.1 *Suppose a group G of biholomorphisms of X preserves θ and the measure $f \, dV$. Then every v_λ and every cluster limit as $\lambda \downarrow 0$ is G -invariant. If the normalized zero-exponent equation has only one G -invariant solution with minimal singularities, then the whole family v_λ converges to it as $\lambda \downarrow 0$, uniformly in differences on Ω and in each local C^β topology of the proposition.*

Proof For $g \in G$, pullback by g preserves θ -plurisubharmonicity, and $V_\theta \circ g = V_\theta$ by the definition of the envelope. Pullback also preserves the positive-exponent equation, so its uniqueness gives $u_\lambda \circ g = u_\lambda$, and the normalization preserves this equality. Pullback by a fixed smooth biholomorphism is continuous on $L^1(X)$, since its Jacobian relative to the fixed smooth volume is bounded. Hence every cluster limit is invariant almost everywhere, and therefore everywhere for the canonical representatives. This argument does not require g to preserve the barrier ρ or the set Ω .

If the invariant solution is unique, every cluster limit is the same potential. Relative compactness then implies convergence of the whole family for uniform convergence of differences on Ω : a sequence staying at a fixed positive distance from that potential would have a convergent subsequence, a contradiction. The interpolation argument above upgrades this to the asserted local C^β convergence. $\square$

The proposition gives compactness and identifies the equation of every cluster limit, and the symmetry criterion is one way to identify the limit itself. In general, [Theorem 14.12.1](#) shows that the whole family converges, and it describes the limit through the greatest subsolution of the zero-exponent equation that satisfies a family of integral normalizations determined by how the constant c depends on the density. This holds even when the zero-exponent equation has several normalized solutions.

13.17 Interior smoothness on the regular locus

Throughout this section, θ is a smooth big real $(1, 1)$ -form, and $\rho, Z = \{\rho = -\infty\}$ and $\Omega = X \setminus Z$ are the strict analytic barrier and its regular locus fixed in [Section 13.12](#). Thus $\rho \leq 0$ has analytic singularities with smooth remainder, and $\theta + dd^c \rho \geq \omega$. If $\varphi \in \text{PSH}(X, \theta)$ has minimal singularities, then $\varphi \geq V_\theta - C \geq \rho - C$ for a constant C . Hence φ is locally bounded on Ω , and its Monge–Ampère measure there is the bounded-potential product.

For such a potential, [Theorem 13.16.1](#) gives local Hölder continuity on Ω when the density belongs to L^p for some $p > 1$. We show that a smooth strictly positive density on the whole of Ω then makes the potential smooth on Ω . Local information alone cannot give this: [Example 13.20.2](#) below is a locally Lipschitz plurisubharmonic function with constant Monge–Ampère density that is not C^1 . The argument therefore uses the barrier globally. By the proper gap of [Lemma 1.19.4](#), the difference between the solution and the barrier attains a minimum on the closed set where smoothness fails, and strict positivity of $\theta + dd^c \rho$ turns this minimum into a quadratic separation. Near the minimum, smooth Dirichlet approximants have traces of polynomial growth; the separation improves this growth until a uniform trace bound yields elliptic regularity.

Theorem 13.17.1 *Suppose $\varphi \in \text{PSH}(X, \theta)$ has minimal singularities and is locally Hölder continuous on Ω . Let $c > 0$ and let f be smooth and strictly positive on Ω . Assume*

$$(\theta + \text{dd}^c \varphi)^n = c f \omega^n \quad \text{on } \Omega.$$

Then $\varphi \in C^\infty(\Omega)$ and $\theta + \text{dd}^c \varphi > 0$ there.

The Hölder hypothesis holds when, in addition, $f \in L^p(X, \omega^n)$ for some $p > 1$, by [Theorem 13.16.1](#); see [Corollary 13.17.1](#). The theorem also applies when local Hölder continuity is obtained by another argument.

The proof is by contradiction and occupies the rest of the section. Let $\mathcal{S} \subset \Omega$ be the closed set of points near which φ is not smooth, suppose that $\mathcal{S} \neq \emptyset$, and let $p \in \mathcal{S}$ minimize $\varphi - \rho$ on $\mathcal{S}$. On a small ball centered at p the argument has four steps.

- (1) A comparison principle for continuous solutions ([Section 13.17.1](#)) and the smooth Dirichlet problem give smooth solutions u_j of the equation that converge uniformly to φ at a polynomial rate in j , while the traces of $\theta + \text{dd}^c u_j$, measured in Euclidean coordinates, grow at most polynomially in j ([Section 13.17.3](#)).
- (2) Near p , the quadratic separation along $\mathcal{S}$, together with uniform trace bounds on compact sets where φ is already smooth, improves the trace growth to $O(j^\gamma)$ for every $\gamma > 0$. Interpolation with the convergence rate then gives uniform $C^{1,\alpha}$ bounds for every $\alpha < 1$ ([Section 13.17.4](#)).
- (3) A third-order estimate whose constants depend polynomially on the ellipticity turns uniform $C^{1,\alpha}$ bounds, for α close to one, into a uniform trace bound ([Section 13.17.5](#)).
- (4) A continuous solution with bounded trace is smooth ([Section 13.17.2](#)). Hence φ is smooth near p , contradicting $p \in \mathcal{S}$ ([Section 13.17.6](#)).

13.17.1 Local comparison

The comparison principle below, for continuous sub- and supersolutions on a bounded domain, identifies the given continuous potential with limits of smooth Dirichlet solutions. Since the background need not be closed, the classical Bedford–Taylor comparison does not apply directly. We freeze the background at a point, apply the closed-current comparison formula (1.4) to quadratic modifications, and control the error by the mixed inequalities of [Lemmas 1.7.3](#) and [1.7.4](#).

The local arguments of this section take place in coordinate balls, always with compact closure in a larger coordinate chart. There we put $\beta = \text{dd}^c |z|^2$, write $\partial_i = \partial/\partial z_i$ and $\partial_{\bar{i}} = \partial/\partial \bar{z}_i$, and take coefficient matrices of real $(1, 1)$ -forms relative to β . For such a form A , $\text{tr}_\beta A$ and $\det_\beta A$ denote the trace and the determinant of its coefficient matrix, so that $A^n = (\det_\beta A) \beta^n$, and $\Delta_\beta = \text{tr}_\beta \text{dd}^c$. For a positive form T , tr_T is the trace computed with the inverse of the coefficient matrix of T . Indices run from 1 to n , repeated indices in tensor expressions are summed, and I denotes the identity matrix. In local statements, ϑ denotes a smooth real $(1, 1)$ -form, not necessarily closed, which plays the role of θ .

Proposition 13.17.1 *Let $D \Subset \mathbb{C}^n$ be a bounded domain and let ϑ be a smooth real $(1, 1)$ -form near $\overline{D}$. Suppose $u, v \in C(\overline{D})$ are ϑ -plurisubharmonic,*

$$(\vartheta + \text{dd}^c u)^n \geq F\beta^n, \quad (\vartheta + \text{dd}^c v)^n \leq F\beta^n,$$

where $F > 0$ is continuous on D . If $u \leq v$ on ∂D , then $u \leq v$ in D .

Proof *Step 1: v admits no strict smooth lower test.* Suppose, to the contrary, that a C^2 function q touches v from below at a point $p \in D$ and that, at p ,

$$\vartheta + \text{dd}^c q > 0, \quad \det_{\beta}(\vartheta + \text{dd}^c q) > F.$$

Choose a sufficiently small $a > 0$. After replacing q by $q - a|z - p|^2$, which makes the contact strict, and restricting to a small ball $B_r(p)$, there are fixed $\lambda, \eta > 0$ such that

$$A := \vartheta + \text{dd}^c q \geq \lambda\beta, \quad A^n \geq (F + \eta)\beta^n.$$

To compare with closed currents, freeze the background at p : put $\kappa = \sup_{B_r} \|\vartheta - \vartheta(p)\|_{\beta}$ and $B_0 = \vartheta(p) + \kappa\beta$. Then $S = B_0 - \vartheta$ satisfies $0 \leq S \leq 2\kappa\beta$. For small $s > 0$ the set $E = \{v < q + s\}$ is nonempty and relatively compact in B_r . If Q_0 is a quadratic potential for the constant form B_0 , then

$$P = \text{dd}^c(v + Q_0) = \vartheta + \text{dd}^c v + S, \quad Q = \text{dd}^c(q + s + Q_0) = A + S \geq \lambda\beta$$

are closed positive Hessians. Applying (1.4), expanding P , and using $S \leq 2\kappa\beta \leq 2\kappa\lambda^{-1}Q$, we obtain

$$\int_E P^n \leq \int_E F\beta^n + e_{\kappa} \int_E P^n, \quad e_{\kappa} = \left(1 + \frac{2\kappa}{\lambda}\right)^n - 1.$$

On the other hand, (1.4) with $j = n$ gives

$$\int_E P^n \geq \int_E Q^n \geq \int_E (F + \eta)\beta^n.$$

If M bounds F on the ball, the two estimates give $(1 - e_{\kappa})\eta \leq e_{\kappa}M$. Since $\kappa \rightarrow 0$, and hence $e_{\kappa} \rightarrow 0$, as $r \downarrow 0$, this is impossible for small r . Thus no such lower test exists.

Step 2: comparison.

Suppose that $\max_D(u - v) > 0$. We regularize u to produce a forbidden lower test for v . Let χ_{δ} be a nonnegative smooth mollifier of mass one and radius $\delta > 0$. For small $t > 0$ and $C \geq \sup_D |z|^2$, set

$$u_t = u + t(|z|^2 - C).$$

Then $u_t \leq v$ on ∂D , the positive maximum persists, and $T_t = \vartheta + \text{dd}^c u_t \geq t\beta$. Lemma 1.7.3 gives

$$T_t^n \geq (F^{1/n} + t)^n \beta^n.$$

Choose a relatively compact neighborhood W of the positive maximum set. By [Lemma 1.7.4](#),

$$(T_t * \chi_\delta)^n \geq ((F^{1/n} + t) * \chi_\delta)^n \beta^n.$$

Since

$$\vartheta + \text{dd}^c(u_t * \chi_\delta) = T_t * \chi_\delta + (\vartheta - \vartheta * \chi_\delta),$$

the convolution satisfies $T_t * \chi_\delta \geq t\beta$. If $\epsilon_\delta = \|\vartheta - \vartheta * \chi_\delta\|_{C^0(W)}$, then

$$\vartheta + \text{dd}^c(u_t * \chi_\delta) \geq (1 - \epsilon_\delta/t)(T_t * \chi_\delta).$$

For fixed $t > 0$, uniform convergence of the convolved density and $\epsilon_\delta \rightarrow 0$ show that the left-hand side is positive and has determinant strictly larger than F on W for small δ . Since $u_t * \chi_\delta \rightarrow u_t$ uniformly on W , the difference $u_t * \chi_\delta - v$ still attains its maximum over $\overline{W}$ at an interior point of W for small δ . Subtracting this maximum from $u_t * \chi_\delta$ produces a smooth function touching v from below with the properties excluded in Step 1, a contradiction. $\square$

13.17.2 Bounded traces and smoothness

We begin with the criterion used in the last step of the proof. A bounded trace of a positive current bounds all its coefficient measures, so a continuous solution with bounded trace is a strong solution with $W^{2,q}$ regularity for every finite q . The equation then bounds the eigenvalues from below, so it becomes uniformly elliptic. Since the solution is not yet known to be C^2 , the Evans–Krylov theory is applied to it as a viscosity solution of a concave extension of the operator.

Proposition 13.17.2 *Let $B \subset \mathbb{C}^n$ be a coordinate ball, let ϑ be a smooth real $(1, 1)$ -form there and let $F \in C^\infty(B)$ be strictly positive. Suppose u is continuous, $T = \vartheta + \text{dd}^c u \geq 0$, and*

$$T^n = F\beta^n. \quad (13.14)$$

For a point $p \in B$, the following conditions, each required on some neighborhood of p , are equivalent:

- (1) u is smooth;
- (2) $T \geq \delta\beta$ for some $\delta > 0$;
- (3) $\text{tr}_\beta T$ has a locally bounded measure density.

Proof Choose C so that $v = u + C|z|^2$ is plurisubharmonic, and use nonnegative radial mollifiers for which $v_\eta \downarrow v$. The smooth matrix convolutions $T_\eta = T * \chi_\eta$ can be written as

$$T_\eta = (\vartheta * \chi_\eta - C\beta) + \text{dd}^c v_\eta.$$

Bedford–Taylor monotone continuity and smooth convergence of the background imply $T_\eta^k \rightarrow T^k$ for every k .

(2) $\Rightarrow$ (3). Assume (2). For every Hermitian matrix $M \geq \delta I$,

$$\det M \geq \delta^{n-1} (\operatorname{tr} M - (n-1)\delta).$$

Apply this to the regularizations and pass to currents. Equation (13.14) gives

$$\operatorname{tr}_\beta T \leq \delta^{1-n} F + (n-1)\delta,$$

which is (3).

(3) $\Rightarrow$ (I). Assume (3), say $\operatorname{tr}_\beta T \leq L$. Positivity makes every coefficient of the matrix-valued current T a bounded density. Hence the Euclidean Laplacian of u is locally bounded, and interior Poisson estimates give $u \in W_{\text{loc}}^{2,q}$ for every finite q . Mollification converges in $W^{2,q}$; taking $q > 2n$ identifies the bounded-potential determinant with the ordinary almost-everywhere determinant. Thus $\det_\beta T = F$ almost everywhere. On a smaller ball with $F \geq m > 0$, all eigenvalues of T are at most L and their product is at least m , so

$$\frac{m}{L^{n-1}} I \leq T \leq LI$$

almost everywhere.

It remains to show that this strong solution is smooth. Let P be the real linear map from real symmetric $2n \times 2n$ Hessian matrices to Hermitian $n \times n$ matrices, sending D^2u to the coefficient matrix of $\operatorname{dd}^c u$ relative to β , and let $\Theta(x)$ be the matrix of ϑ . With $\delta = mL^{1-n}$, define the concave extension

$$G(x, M) = \inf_{\delta I \leq A \leq LI} \left\{ \log \det A + \operatorname{tr} [A^{-1} (\Theta(x) + P(M) - A)] \right\} - \log F(x).$$

For fixed A , write $\mathcal{E}_A(x, M)$ for the expression in braces minus $\log F(x)$. The tangent-plane formula for $\log \det$ gives

$$G(x, D^2u) = 0 \quad \text{almost everywhere.}$$

The operator G is concave and uniformly elliptic on real symmetric matrices. The affine operators $\mathcal{E}_A$ have constant principal matrices with eigenvalues bounded above and below in terms of δ and L . Their x -dependence is smooth uniformly in A , so G has a uniform local Lipschitz modulus in x .

We claim that u is a viscosity solution of $G(x, D^2u) = 0$. Suppose that a smooth function ψ touches u from above at x_0 and that $G(x_0, D^2\psi) < 0$. Some fixed matrix A then satisfies $\mathcal{E}_A(x, D^2\psi) < -\eta$ on a small ball. Since $G(x, D^2u) = 0$ almost everywhere, $\mathcal{E}_A(x, D^2u) \geq 0$ there. Thus $u - \psi$ has an interior maximum and satisfies

$$\operatorname{tr} (A^{-1} P(D^2(u - \psi))) \geq \eta \quad \text{almost everywhere.}$$

After a small quadratic perturbation makes the contact strict, this contradicts the Aleksandrov maximum principle [GT01, Chapter 9, Theorem 9.1]. If instead ψ touches u from below and $G(x_0, D^2\psi) > 0$, then $\mathcal{E}_A(x, D^2\psi) > \eta$ for every admissible A on a small ball. At almost every point choose an admissible $A(x)$ with $\mathcal{E}_{A(x)}(x, D^2u) <$

$\eta/2$. A measurable choice is obtained by taking the first qualifying element of a countable dense family. The function $\psi - u$ then violates the same maximum principle for the measurable uniformly elliptic coefficients $A(x)^{-1}$. This proves the claim.

The classical variable-coefficient Evans–Krylov theorem gives $u \in C_{\text{loc}}^{2,\alpha}$ for some $0 < \alpha < 1$. The original equation is now uniformly elliptic with smooth data. Difference quotients satisfy linear equations whose principal coefficients are averages of inverse matrices along positive definite segments. Interior Schauder estimates first give $u \in C_{\text{loc}}^{3,\alpha}$ and then, by iteration, $u \in C^\infty$. This proves (3) $\Rightarrow$ (1).

(1) $\Rightarrow$ (2). If u is smooth, then T is a smooth semipositive form with determinant $F > 0$, so it is positive definite; on a smaller neighborhood this gives (2). $\square$

13.17.3 Smooth exact approximants

We now construct the approximants of the first step. The smooth Dirichlet theorem, [Lemma 13.6.1](#), applies to every smooth positive density F . Approximating the Hölder boundary values of φ by smooth functions therefore gives smooth solutions, and the point is to control them quantitatively. The estimates below bound the trace of a smooth solution by a power of the C^4 norm of its boundary value. The C^4 norms of the boundary approximations grow polynomially while their uniform errors decay polynomially, so both the convergence and the trace growth have polynomial rates.

In this subsection balls are centered at the origin. On the boundary sphere, ν is the outward Euclidean unit normal and ∇_{tan} denotes tangential differentiation. For a positive form T , inner products $\langle \cdot, \cdot \rangle_T$ and norms $|\cdot|_T$ of $(1, 0)$ -covectors are computed with the inverse of the coefficient matrix of T .

Lemma 13.17.1 *Let B be a coordinate ball, let ϑ and $F > 0$ be smooth near $\overline{B}$, and let q be smooth with $R = \vartheta + \text{dd}^c q \geq \varepsilon\beta$ for a fixed $\varepsilon > 0$. Fix a finite $L \geq 0$. If $u \in C^\infty(B)$ satisfies*

$$T = \vartheta + \text{dd}^c u > 0, \quad T^n = F\beta^n, \quad |u - q| \leq L,$$

put $S = \text{tr}_\beta T$ and $v = u - q$. For $A > 0$, define

$$Q_A = \log S - Av + e^{-v}.$$

There are A_0, C , depending only on the fixed data and L , such that at every interior local maximum of Q_A , with $A \geq A_0$,

$$S \leq C\sqrt{A}. \quad (13.15)$$

The constants do not depend on any bound for the gradient of u .

Proof This is the maximum-principle computation behind the classical second-order estimate. The non-closedness of ϑ produces a first-order error term, which is absorbed by the convex term e^{-v} .

At the point in question make a constant unitary change of coordinates so that the matrix of T is diagonal, with eigenvalues λ_i . Write

$$\Delta_T = \sum_i \lambda_i^{-1} \partial_i \bar{\partial}_i, \quad H = \text{tr}_T \beta.$$

Differentiating $\log \det T = \log F$ and commuting derivatives gives

$$\Delta_T S = \Delta_\beta \log F + P + E_0, \quad P = \sum_{k,i,j} \frac{|\partial_k T_{i\bar{j}}|^2}{\lambda_i \lambda_j}, \quad |E_0| \leq C_0 H. \quad (13.16)$$

The non-closedness of ϑ enters through the bounded vector

$$E_p = \sum_k (\partial_p \vartheta_{k\bar{k}} - \partial_k \vartheta_{p\bar{k}}).$$

Since $\partial_p S - E_p = \sum_k \partial_k T_{p\bar{k}}$, weighted Cauchy–Schwarz gives $|\partial S - E|^2_T \leq SP$. From (13.16),

$$\Delta_T \log S \geq -\frac{C_0(1+H)}{S} - \frac{2}{S} \text{Re} \langle \partial \log S, E \rangle_T. \quad (13.17)$$

Set $g_A(s) = -As + e^{-s}$. At a local maximum of Q_A , $\partial \log S = -g'_A(v) \partial v$ and $\Delta_T v = n - \text{tr}_T R$. Combining these identities with (13.17), then completing the square in ∂v , yields

$$0 \geq \left[\varepsilon A - \frac{C_2}{S} - \frac{C_2(A+1)^2}{S^2} \right] H - C_3(A+1) - \frac{C_2}{S}. \quad (13.18)$$

Here $|E|_T^2 \leq CH$ and the bounds for v have been used. If $S \geq K\sqrt{A}$ and K is large, the bracket is at least $\varepsilon A/2$. Thus $H \leq C$ independently of A and u . The determinant upper bound then gives $S \leq C'$. Enlarging K makes this incompatible with $S \geq K\sqrt{A}$, proving (13.15). $\square$

We shall also use the following variant, in which a gradient bound replaces the convex term. If $|\nabla(u-q)|_\beta$ is bounded, then at an interior maximum of $\log S - A(u-q)$ the trace is bounded independently of A for all large A . Indeed, at the maximum $\partial \log S = A\partial(u-q)$, and (13.17) gives

$$0 \geq \left[A\varepsilon - \frac{C}{S} - \frac{CA}{S} \right] H - nA - \frac{C}{S}.$$

For S larger than a fixed constant the bracket is at least $A\varepsilon/2$; the determinant again controls S .

A polynomial boundary trace estimate

Proposition 13.17.3 *Let B be the unit ball. Fix smooth ϑ , smooth $F > 0$ near $\bar{B}$, and $M < \infty$. There are $C, N < \infty$, depending only on these fixed data, such that every smooth solution u with boundary value $g \in C^\infty(\partial B)$ of*

$$T = \vartheta + dd^c u > 0, \quad T^n = F\beta^n, \quad \|u\|_{L^\infty(B)} \leq M, \quad u|_{\partial B} = g,$$

satisfies

$$\sup_{\bar{B}} \text{tr}_\beta T \leq C(1 + \|g\|_{C^4(\partial B)})^N. \quad (13.19)$$

Proof We follow the classical boundary estimates for the Dirichlet problem on a ball and keep track of the dependence on $L = 1 + \|g\|_{C^4}$. Barriers bound the first derivatives, and differentiation along rotations bounds the mixed normal–tangential second derivatives on the boundary. A lower bound for the tangential block of T then bounds the double normal derivative through the equation, and Lemma 13.17.1 reduces the interior bound to the boundary bound.

Step 1: first derivatives. Fix a sufficiently large constant $K > 0$, depending only on the fixed data. Extend g to G on $\bar{B}$ with $\|G\|_{C^4} \leq CL$. For $A = CL$ large enough,

$$\underline{u} = G + A(|z|^2 - 1), \quad \underline{T} = \vartheta + dd^c \underline{u} \geq K\beta, \quad \underline{T}^n \geq F\beta^n.$$

Proposition 13.17.1 gives $\underline{u} \leq u$. If h solves $\Delta_\beta h = -C_\vartheta$ with $h = g$ on ∂B and $C_\vartheta \geq \sup \text{tr}_\beta \vartheta$, then $u \leq h$. Boundary differentiation of these barriers gives

$$|\partial_\nu u| + |\nabla_{\tan} u| \leq CL \quad \text{on } \partial B. \quad (13.20)$$

Let $H = \text{tr}_T \beta$, $\mathcal{L} = \text{tr}_T dd^c$, and $w = u - \underline{u} \geq 0$, the linearized operator and the barrier function used below. Taking K fixed and sufficiently large gives

$$\mathcal{L}w = n - \operatorname{tr}_T \underline{T} \leq -(1 + H). \quad (13.21)$$

Let $E = \sum_k (z_k \partial_{z_k} + \bar{z}_k \partial_{\bar{z}_k})$ be the real radial field. Write Θ for the coefficient matrix of ϑ . Differentiating $\log \det T = \log F$ and commuting E with complex second derivatives yields

$$\mathcal{L}(Eu) = E(\log F) + 2n - \operatorname{tr}_T(E\Theta + 2\Theta).$$

Hence $|\mathcal{L}(Eu)| \leq C(1+H)$. The same estimate holds for Zu when Z is an infinitesimal unitary rotation. Applying the minimum principle to $CL + C'w \pm Yu$, with $Y = E$ or Z , gives

$$|Eu| + |Zu| \leq CL \quad \text{on } B. \quad (13.22)$$

Step 2: mixed second derivatives on the boundary. For a rotation Z , the function $R_Z = Z(u - G)$ vanishes on ∂B and satisfies $|\mathcal{L}R_Z| \leq CL(1+H)$. The barriers $CLw \pm R_Z$ and (13.21) imply $|\partial_\nu R_Z| \leq CL^2$ on the boundary. Rotations span the real tangent space of ∂B , so all real mixed normal–tangential second derivatives are $O(L^2)$. Pure tangential second derivatives are $O(L)$ by differentiating $u = g$ twice and using (13.20). Thus all complex Hessian entries except the complex normal–normal entry are $O(L^2)$.

Step 3: the double normal derivative. It remains to bound the tangential block of T from below. For $n \geq 2$, let

$$\lambda_0 = \min\{T_p(\xi, \bar{\xi}) : p \in \partial B, \xi \in T_p^{1,0}(\partial B), |\xi|_\beta = 1\}.$$

Choose a minimizing pair (p, ξ) and extend ξ to a smooth unit tangential field near p , with uniformly bounded derivatives. On the sphere, any smooth function vanishing there satisfies

$$\operatorname{dd}^c(u - G)(\xi, \bar{\xi}) = \frac{1}{2}E(u - G).$$

Define

$$a(z) = (\vartheta + \operatorname{dd}^c G)_z(\xi(z), \overline{\xi(z)}) - \frac{1}{2}EG(z), \quad P = a + \frac{1}{2}Eu - \lambda_0.$$

Then $P \geq 0$ on the nearby spherical boundary and $P(p) = 0$. The boundary first-derivative bound also gives $\lambda_0 \leq CL$ by the tangential identity above. Consequently

$$|P| \leq CL, \quad |\mathcal{L}P| \leq CL(1+H).$$

On a fixed cap $D = B \cap B_r(p)$ consider

$$\Psi = P + C_1 Lw + C_2 L|z - p|^2.$$

Choose C_2 so that $\Psi \geq 0$ on the interior spherical part of ∂D , and then C_1 so that $\mathcal{L}\Psi \leq 0$ by (13.21). The minimum principle yields $\Psi \geq 0$. At p the normal derivative of $|z - p|^2$ vanishes, and therefore

$$\partial_v P + C_1 L \partial_v w \leq 0.$$

Equations (13.20)–(13.22) now give $D^2 u(v, v)(p) \leq CL^2$, hence $\text{tr}_\beta T(p) \leq CL^2$. Positivity and $\det_\beta T = F$ imply

$$\lambda_0 \geq cL^{-2(n-1)}. \quad (13.23)$$

At any boundary point write

$$T = \begin{pmatrix} B_0 & b \\ b^* & d \end{pmatrix}$$

in tangential–normal blocks, with B_0 an $(n-1) \times (n-1)$ Hermitian matrix, $b \in \mathbb{C}^{n-1}$ and $d \in \mathbb{R}$. We have $|b| \leq CL^2$ and $B_0 \geq \lambda_0 I$. The determinant equation and the Schur complement give

$$d = \frac{F}{\det B_0} + b^* B_0^{-1} b \leq (\sup F) \lambda_0^{-(n-1)} + CL^4 \lambda_0^{-1},$$

which is polynomial in L . For $n = 1$, the trace is F and this argument is unnecessary.

Step 4: the interior. Choose a fixed quadratic q with $\vartheta + \text{dd}^c q \geq \varepsilon \beta$. Apply **Lemma 13.17.1** with one fixed A . At an interior maximum of its auxiliary function the trace is uniformly bounded, while at a boundary maximum the preceding estimate applies. Since the remaining terms are uniformly bounded, (13.19) follows. $\square$

Exact approximation

We apply these estimates to smooth approximations of the boundary values of φ on a ball in Ω . Recall that θ , ω , c and f are the data of [Theorem 13.17.1](#).

Proposition 13.17.4 *Let $B \Subset \Omega$ be a coordinate ball, identified with $\{|z| < r_0\}$, with closure in a larger coordinate chart, and put*

$$F = \frac{cf\omega^n}{\beta^n}.$$

There are $a > 0$, $b, C < \infty$, and $u_j \in C^\infty(\overline{B})$ such that

$$\theta + \text{dd}^c u_j > 0, \quad (\theta + \text{dd}^c u_j)^n = F\beta^n, \quad (13.24)$$

and

$$\|u_j - \varphi\|_{L^\infty(B)} \leq Cj^{-a}, \quad \sup_{\overline{B}} \text{tr}_\beta(\theta + \text{dd}^c u_j) \leq Cj^b. \quad (13.25)$$

Proof Since φ is Hölder continuous near $\overline{B}$, mollification at scale $1/j$ gives smooth boundary approximations g_j with

$$\|g_j - \varphi\|_{L^\infty(\partial B)} \leq Cj^{-a}, \quad \|g_j\|_{C^4(\partial B)} \leq Cj^4.$$

Choose a fixed quadratic q with $\eta = \theta + \text{dd}^c q > 0$ near $\overline{B}$. Extend g_j smoothly to G_j . For a sufficiently large, polynomially bounded A_j , the function

$$\underline{w}_j = G_j - q + A_j(|z|^2 - r_0^2)$$

has boundary value $g_j - q$ and satisfies

$$\eta + \text{dd}^c \underline{w}_j = \theta + \text{dd}^c G_j + A_j\beta > 0, \quad (\eta + \text{dd}^c \underline{w}_j)^n \geq F\beta^n.$$

Apply the smooth Dirichlet theorem recalled at the beginning of this subsection, with density $H = F\beta^n/\eta^n$ to obtain a solution w_j for the Hermitian background η ; put $u_j = w_j + q$. Comparing u_j with $\varphi \pm \|g_j - \varphi\|_\infty$ by [Proposition 13.17.1](#) proves the first bound in (13.25). The functions u_j are therefore uniformly bounded. [Proposition 13.17.3](#) and the polynomial C^4 boundary norm give the second bound. $\square$

13.17.4 Localization near the nonregular set

In the auxiliary function of [Lemma 13.17.1](#), the term $-A(u_j - q)$ penalizes points where $u_j - q$ is large. A quadratic gap of $u - q$ along the nonregular set therefore suppresses the contribution of the boundary of a neighborhood of that set. Taking A proportional to $\log j$ makes this suppression beat the polynomial growth of the

boundary trace, and near the point of minimal $u - q$ the trace then grows more slowly than every positive power of j . Interpolation with the polynomial approximation rate gives uniform $C^{1,\alpha}$ bounds.

Distances and norms below are Euclidean. By a smooth exact solution for (ϑ, F) we mean a smooth function u_j with $\vartheta + \text{dd}^c u_j > 0$ and $(\vartheta + \text{dd}^c u_j)^n = F\beta^n$.

Proposition 13.17.5 *For $R > 0$, let $B = B_R(0)$, let ϑ and $F > 0$ be smooth near $\overline{B}$, and let $u \in C(\overline{B})$. Suppose q is smooth and $\vartheta + \text{dd}^c q \geq \varepsilon\beta$ for some $\varepsilon > 0$. Put $v = u - q$ and $m = v(0)$, and fix $\kappa > 0$. Let $\mathcal{S} \subset \overline{B}$ be closed, contain 0, and satisfy*

$$v(0) = m, \quad v(z) \geq m + \kappa|z|^2 \quad (z \in \mathcal{S}). \quad (13.26)$$

Assume that smooth exact solutions u_j , $j \geq 2$, satisfy, for fixed constants $a > 0$, $b \geq 0$ and $C > 0$,

$$\|u_j - u\|_\infty \leq Cj^{-a}, \quad (13.27)$$

$$\sup_{\overline{B}} \text{tr}_\beta(\vartheta + \text{dd}^c u_j) \leq Cj^b, \quad (13.28)$$

$$\sup_j \sup_K \text{tr}_\beta(\vartheta + \text{dd}^c u_j) < \infty \quad \text{for every } K \Subset \overline{B} \setminus \mathcal{S}. \quad (13.29)$$

Then for every $\gamma > 0$ there are a neighborhood U_γ of 0 and C_γ such that

$$\text{tr}_\beta(\vartheta + \text{dd}^c u_j) \leq C_\gamma j^\gamma \quad \text{on } U_\gamma. \quad (13.30)$$

For every $0 < \alpha < 1$, there is also a neighborhood U of 0 on which $u_j \rightarrow u$ in $C^{1,\alpha}$. In particular the approximants are uniformly bounded in that norm and $u \in C^{1,\alpha}(U)$.

Proof *Step 1: the trace bound (13.30).* Write $e_j = Cj^{-a}$, fix $d = \kappa R^2/2$, and choose $D > (b+1)/d$. Choose $\eta > 0$ so that $2D\eta < \gamma/2$. For small $\delta > 0$, the neighborhood

$$W_\delta = \{z \in B : \text{dist}(z, \mathcal{S}) < \delta\}$$

contains 0, has $v \geq m - \eta$ on its closure, and satisfies $v \geq m + d$ on $\partial B \cap \overline{W}_\delta$ with the fixed d above. These properties follow from (13.26), continuity, and compactness. The remaining part of the boundary of W_δ is a compact subset of $\overline{B} \setminus \mathcal{S}$, where (13.29) applies.

Set $A_j = D \log j$. Apply the maximum principle on $\overline{W}_\delta$ to

$$Q_j = \log \text{tr}_\beta(\vartheta + \text{dd}^c u_j) - A_j(u_j - q) + e^{-(u_j - q)}.$$

At an interior maximum, Lemma 13.17.1 gives $\log \text{tr}_\beta(\vartheta + \text{dd}^c u_j) \leq C + \frac{1}{2} \log A_j$. On the part of ∂W_δ inside B , which stays away from $\mathcal{S}$, the trace has a bound independent of j . On the outer part $\partial B \cap \overline{W}_\delta$, (13.28) and the gap d give

$$Q_j \leq C + b \log j - A_j(m + d - e_j),$$

and the choice $Dd > b + 1$ makes this smaller than the bound below for large j . Hence throughout W_δ ,

$$Q_j \leq C_\delta + \frac{1}{2} \log A_j - A_j(m - \eta - e_j).$$

On a small ball about 0 where $v \leq m + \eta$, this implies

$$\log \operatorname{tr}_\beta(\vartheta + \operatorname{dd}^c u_j) \leq C_\delta + \frac{1}{2} \log A_j + A_j(2\eta + 2e_j).$$

By the choice of η , the logarithmic factor and $A_j e_j$ are absorbed into the remaining power. This proves (13.30).

Step 2: $C^{1,\alpha}$ convergence. On a smaller ball, the real Laplacian of u_j is bounded by Cj^γ . Interior Poisson estimates give a W^{2,q_0} bound for every finite q_0 , and Sobolev embedding with q_0 large then gives, for every $\sigma < 1$,

$$\|u_j\|_{W^{2,q_0}} + \|u_j\|_{C^{1,\sigma}} \leq Cj^\gamma.$$

For $d_k = u_{2^{k+1}} - u_{2^k}$,

$$\|d_k\|_\infty \leq C2^{-ka}, \quad \|d_k\|_{C^{1,\sigma}} \leq C2^{k\gamma}.$$

If $\alpha < \sigma$ and $t = (1 + \alpha)/(1 + \sigma)$, Hölder interpolation gives

$$\|d_k\|_{C^{1,\alpha}} \leq C2^{k[-a(1-t) + \gamma t]}.$$

Since γ may be arbitrarily small, the exponent can be made negative. The dyadic series converges in $C^{1,\alpha}$ to its uniform limit u . If $2^k \leq j < 2^{k+1}$, interpolation applied to $u_j - u_{2^k}$ gives the same decaying bound. Hence the full sequence converges to u in $C^{1,\alpha}$ on a smaller ball. $\square$

Proposition 13.17.6 *Suppose u_j solve the same smooth equation as in Proposition 13.17.5, satisfy (13.27)–(13.28), and u is smooth with $\vartheta + \operatorname{dd}^c u > 0$ on an open set $O \subset B$. Then, for every $K \Subset O$,*

$$\sup_j \sup_K \operatorname{tr}_\beta(\vartheta + \operatorname{dd}^c u_j) < \infty. \quad (13.31)$$

Proof Where u is smooth and strictly ϑ -plurisubharmonic, it provides its own quadratic separation, so the argument of Proposition 13.17.5 applies around every point of O . A first application gives trace growth of order $\sqrt{\log j}$; the resulting gradient convergence then allows the variant of Lemma 13.17.1 with a gradient bound, which removes this growth.

For p in a fixed compact subset of O , take a uniformly sized ball $B_r(p) \Subset O$ and set

$$q_p(z) = u(z) - \kappa|z - p|^2$$

with $\kappa > 0$ small, so $\vartheta + \operatorname{dd}^c q_p \geq \varepsilon\beta$. If $e_j = Cj^{-a}$ and $v_{j,p} = u_j - q_p$, then

$$v_{j,p} \geq -e_j, \quad v_{j,p}(p) \leq e_j, \quad v_{j,p} \geq \kappa r^2 - e_j \text{ on } \partial B_r(p).$$

With $A_j = D \log j$ and $D\kappa r^2 > b + 1$, the same maximum argument as above gives

$$\mathrm{tr}_\beta(\vartheta + \mathrm{dd}^c u_j)(p) \leq C\sqrt{\log j}. \quad (13.32)$$

The constants are uniform on compact subsets of O .

Put $T_j = \vartheta + \mathrm{dd}^c u_j$ and $w_j = u_j - u$. On slightly larger compact sets, (13.32) bounds $|\Delta w_j|$ by $C\sqrt{\log j}$. Poisson estimates and Sobolev embedding give

$$\|w_j\|_{C^{1,\sigma}} \leq C_\sigma \sqrt{\log j}, \quad \sigma < 1.$$

Interpolating with $\|w_j\|_\infty \leq Cj^{-a}$ shows $\nabla w_j \rightarrow 0$ uniformly on smaller compact sets. The gradients of $v_{j,p}$ are therefore uniformly bounded. Repeat the maximum argument with $\log \mathrm{tr}_\beta T_j - A_j v_{j,p}$, now using the variant of Lemma 13.17.1 with a gradient bound. Its interior trace bound is now independent of A_j , while the boundary term is suppressed as before. Evaluation at p gives

$$\mathrm{tr}_\beta T_j(p) \leq C \exp(2A_j e_j) \leq C,$$

proving (13.31). $\square$

13.17.5 Derivative estimates and bounded traces

Uniform $C^{1,\alpha}$ bounds control averages of the trace $\mathrm{tr}_\beta(\vartheta + \mathrm{dd}^c u_j) = \mathrm{tr}_\beta \vartheta + \Delta_\beta u_j$ over small balls. To pass from averages to pointwise values we need a bound for the gradient of the trace, that is, a third-order estimate, whose dependence on the ellipticity constants is polynomial. We prove it by Calabi's maximum-principle argument, computed with the Chern connection of the solution so that the torsion of the nonclosed background appears explicitly. The resulting averaging inequality is nonlinear in the trace, and it closes under iteration when α is sufficiently close to one.

In this subsection B is the unit ball and $B_r(p)$ is the Euclidean ball of radius r centered at p . For a Hermitian metric g , ∂g denotes the ordinary coordinate derivatives of its coefficient matrix, while tensor derivatives in the proofs are taken with respect to the Chern connection of g .

Proposition 13.17.7 *Fix smooth ϑ and smooth $F > 0$ near the closed unit ball. There are $C, N < \infty$, depending only on finitely many derivatives of the fixed data, such that any smooth solution*

$$g = \vartheta + \mathrm{dd}^c u, \quad g^n = F\beta^n, \quad M^{-1}\beta \leq g \leq M\beta, \quad M \geq 1,$$

satisfies

$$\sup_{B_{1/2}} |\partial g|_\beta \leq CM^N. \quad (13.33)$$

If only $\sup_B \operatorname{tr}_\beta g \leq L$ is given, the same bound holds with a fixed power of $1 + L$. On a ball of radius $r \leq 1$,

$$\sup_{B_{r/2}} |\nabla \operatorname{tr}_\beta g|_\beta \leq Cr^{-1}(1+L)^N. \quad (13.34)$$

Proof The quantity $\mathcal{R}$ below is the squared norm of the difference between the Chern connection of g and the flat connection. We derive a differential inequality for $\mathcal{R}$ in which the torsion enters through fixed derivatives of ϑ , and combine it with the trace in a maximum principle; every constant is kept a power of M .

We compare the flat connection of β with the Chern connection ∇ of g . Write $g^{k\bar{\ell}}$ for the coefficients of the inverse matrix and $\bar{\nabla}$ for covariant differentiation in $(0, 1)$ directions; tensor norms and inner products without subscript are computed with g . The difference of the two connections and its squared norm are

$$\Psi_{ij}^k = g^{k\bar{\ell}} \partial_i g_{j\bar{\ell}}, \quad \mathcal{R} = |\Psi|_g^2.$$

The torsion of ∇ is determined by the fixed background, because the third derivatives of u cancel in it. Its lowered and raised components are

$$C_{ij\bar{\ell}} = \partial_i \vartheta_{j\bar{\ell}} - \partial_j \vartheta_{i\bar{\ell}}, \quad \mathcal{T}_{ij}^k = g^{k\bar{\ell}} C_{ij\bar{\ell}}. \quad (13.35)$$

Consequently, for a fixed integer N ,

$$\begin{aligned} |\mathcal{T}| &\leq CM^N, \\ |\nabla \mathcal{T}| + |\bar{\nabla} \mathcal{T}| &\leq CM^N(1 + \sqrt{\mathcal{R}}), \\ |\nabla^2 \mathcal{T}| + |\nabla \bar{\nabla} \mathcal{T}| + |\bar{\nabla}^2 \mathcal{T}| &\leq CM^N(1 + \mathcal{R} + |\nabla \Psi| + |\bar{\nabla} \Psi|). \end{aligned} \quad (13.36)$$

Every factor here is either a fixed derivative of ϑ , a connection factor Ψ , or a factor of $g^{\pm 1}$; this explains the polynomial dependence.

For tensor fields, use $\Delta_g = g^{p\bar{q}} \nabla_p \nabla_{\bar{q}}$. We need the following curvature identities. With

$$\operatorname{Rm}_{i\bar{j}l}^k = -\partial_{\bar{j}} \Psi_{il}^k, \quad \operatorname{Rm}_{i\bar{j}l\bar{k}} = g_{m\bar{k}} \operatorname{Rm}_{i\bar{j}l}^m,$$

set

$$\operatorname{Ric}_{l\bar{k}}^{(2)} = g^{i\bar{j}} \operatorname{Rm}_{i\bar{j}l\bar{k}}, \quad \operatorname{Ric}_{l\bar{k}}^{(1)} = g^{i\bar{j}} \operatorname{Rm}_{l\bar{k}i\bar{j}} = -\partial_l \partial_{\bar{k}} \log F.$$

The two curvature interchanges are

$$\begin{aligned} \operatorname{Rm}_{i\bar{j}l\bar{k}} - \operatorname{Rm}_{l\bar{j}i\bar{k}} &= -\nabla_{\bar{j}} C_{il\bar{k}}, \\ \operatorname{Rm}_{i\bar{j}l\bar{k}} - \operatorname{Rm}_{i\bar{k}l\bar{j}} &= -\nabla_i \bar{C}_{\bar{j}\bar{k}l}. \end{aligned}$$

They follow by differentiating the torsion identity and its conjugate. Successive interchange and contraction give

$$\operatorname{Ric}_{l\bar{k}}^{(2)} = \operatorname{Ric}_{l\bar{k}}^{(1)} - g^{i\bar{j}} (\nabla_l \bar{C}_{\bar{j}\bar{k}i} + \nabla_{\bar{j}} C_{il\bar{k}}). \quad (13.37)$$

Metric compatibility, (13.36), and the fixed smooth formula for $\text{Ric}^{(1)}$ imply

$$|\text{Ric}^{(2)}| \leq CM^N(1 + \sqrt{\mathcal{R}}), \quad |\nabla \text{Ric}^{(2)}| \leq CM^N(1 + \mathcal{R} + |\nabla \Psi| + |\bar{\nabla} \Psi|). \quad (13.38)$$

Moreover,

$$\nabla_{\bar{q}} \Psi_{ij}^k = -\text{Rm}^k_{i\bar{q}j},$$

and the Chern–Bianchi identity, including its torsion term, is

$$\nabla_p \text{Rm}^k_{i\bar{q}j} - \nabla_i \text{Rm}^k_{p\bar{q}j} = -\mathcal{T}_{pi}^r \text{Rm}^k_{r\bar{q}j}.$$

Consequently,

$$\Delta_g \Psi_{ij}^k = -\nabla_i (\text{Ric}^{(2)})^k_j + g^{p\bar{q}} \mathcal{T}_{pi}^r \text{Rm}^k_{r\bar{q}j}. \quad (13.39)$$

If $A^k_l = (\text{Ric}^{(2)})^k_l$, define its action on a tensor of type $(1, 2)$ by

$$(A \cdot \Psi)_{ij}^k = A^k_l \Psi_{ij}^l - A^l_i \Psi_{lj}^k - A^l_j \Psi_{il}^k.$$

Differentiating the squared norm and using metric compatibility gives

$$\Delta_g \mathcal{R} = |\nabla \Psi|^2 + |\bar{\nabla} \Psi|^2 + 2 \text{Re} \langle \Delta_g \Psi, \Psi \rangle - \text{Re} \langle A \cdot \Psi, \Psi \rangle. \quad (13.40)$$

There is no mixed torsion term because the Chern torsion has type $(2, 0)$. Using (13.36), (13.38), and (13.39) in (13.40), Young's inequality absorbs the products of $\sqrt{\mathcal{R}}$ with $|\nabla \Psi| + |\bar{\nabla} \Psi|$. We obtain

$$\Delta_g \mathcal{R} \geq -CM^N(\mathcal{R}^{3/2} + 1). \quad (13.41)$$

Let $s = \text{tr}_g g$. Direct differentiation as in (13.16) gives

$$\Delta_g s \geq M^{-1} \mathcal{R} - CM, \quad |\partial s|_g^2 \leq nM^2 \mathcal{R}. \quad (13.42)$$

Take a cutoff ζ supported in B , equal to one on $B_{1/2}$, set $\eta = \zeta^2$ and $h = 2nM - s$, so $nM \leq h \leq 2nM$, and maximize

$$Q = \frac{\eta \mathcal{R}}{h}.$$

At a positive interior maximum of Q , the identity $\partial \mathcal{R} / \mathcal{R} = \partial h / h - \partial \eta / \eta$ gives

$$0 \geq \frac{\Delta_g Q}{Q} = \frac{\Delta_g \mathcal{R}}{\mathcal{R}} + \frac{\Delta_g \eta}{\eta} - \frac{\Delta_g h}{h} - \frac{2|\partial \eta|_g^2}{\eta^2} + \frac{2 \text{Re} \langle \partial \eta, \partial h \rangle_g}{\eta h}.$$

We have $|\partial \eta|_g^2 \leq CM\eta$, $|\Delta_g \eta| \leq CM$ and $|\partial h|_g \leq \sqrt{n}M\sqrt{\mathcal{R}}$. Insert (13.41) and (13.42) and multiply by ηQ . The positive term is $M^{-1}Q^2$. The two terms involving $\sqrt{\mathcal{R}}$ are bounded in absolute value by a fixed power of M times $Q^{3/2}$, since $\mathcal{R} = hQ/\eta$ and $h \leq 2nM$. The remaining cutoff terms are bounded by $CM^N(Q + 1)$. Therefore

$$0 \geq M^{-1}Q^2 - CM^N(Q^{3/2} + Q + 1).$$

Thus Q , and then $\mathcal{R}$ on $B_{1/2}$, are bounded by a fixed polynomial in M . Since $|\partial g|_\beta^2 \leq M^3 \mathcal{R}$, this proves (13.33).

If $s \leq L$, the determinant lower bound gives $\lambda_{\min}(g) \geq (\inf F)L^{1-n}$, so M is a fixed power of $1 + L$. For a ball $B_r(p)$, set $u_r(z) = r^{-2}u(p + rz)$ and use the coefficient matrices $\vartheta_r(z) = \vartheta(p + rz)$, $g_r(z) = g(p + rz)$ and $F_r(z) = F(p + rz)$. Then $g_r = \vartheta_r + \text{dd}^c u_r$ in the unit coordinates and $\det g_r = F_r$. For $r \leq 1$ the derivatives of the fixed data remain uniformly bounded. The unit-ball estimate for the ordinary coefficient derivatives ∂g_r and their conjugates gives the factor r^{-1} in (13.34). $\square$

Proposition 13.17.8 *There is $\alpha_* < 1$, depending only on n and the exponent N in Proposition 13.17.7, with the following property. Let B_0 be a Euclidean ball, fix a smooth real $(1, 1)$ -form ϑ and a smooth function $F > 0$ near $\overline{B_0}$, and let u_j be smooth exact solutions of $(\vartheta + \text{dd}^c u_j)^n = F\beta^n$ with $\vartheta + \text{dd}^c u_j > 0$. If*

$$\sup_j \|u_j\|_{C^{1,\alpha}(B_0)} < \infty \quad \text{for some } \alpha_* < \alpha < 1,$$

then $\text{tr}_\beta(\vartheta + \text{dd}^c u_j)$ is uniformly bounded on every smaller ball.

Proof Fix a center for concentric balls $B_r \Subset B_0$, put $s_j = \text{tr}_\beta(\vartheta + \text{dd}^c u_j)$, and set

$$M_j(r) = 1 + \sup_{B_r} s_j.$$

For concentric balls $B_r \Subset B_R \Subset B_0$, $d = R - r \leq 1$, Proposition 13.17.7 gives

$$|\nabla s_j| \leq Cd^{-1}M_j(R)^N \quad \text{on } B_{r+d/2}. \quad (13.43)$$

Fix $p \in B_r$ and let χ_h be a nonnegative mollifier of radius $h \leq d/4$. Since

$$s_j = \text{tr}_\beta \vartheta + \Delta_\beta u_j,$$

integration by parts, after subtracting the constant vector $\nabla u_j(p)$, and the uniform $C^{1,\alpha}$ bound give

$$(s_j * \chi_h)(p) \leq C(1 + h^{\alpha-1}).$$

Equation (13.43) gives

$$|s_j(p) - (s_j * \chi_h)(p)| \leq Cd^{-1}M_j(R)^N h.$$

Choose

$$h = \frac{d}{4}M_j(R)^{-N/(2-\alpha)}.$$

Taking the supremum over $p \in B_r$ and absorbing fixed powers of d^{-1} , we obtain

$$M_j(r) \leq Cd^{-1}M_j(R)^q, \quad q = \frac{N(1-\alpha)}{2-\alpha}. \quad (13.44)$$

Choose α_* so close to one that $q < 1$ for $\alpha > \alpha_*$. Choose $0 < r_0 < R_0$ with $B_{R_0} \Subset B_0$. Let $r_k \uparrow R_0$ with $r_{k+1} - r_k = (R_0 - r_0)2^{-k-1}$. Iterating (13.44) gives

$$M_j(r_0) \leq \prod_{k=0}^{m-1} [C(r_{k+1} - r_k)^{-1}]^{q^k} M_j(r_m)^{q^m}.$$

The infinite product converges because $\sum q^k(1+k) < \infty$. For each fixed j , the final factor tends to one as $m \rightarrow \infty$. The resulting bound is independent of j . $\square$

13.17.6 Proof of the main theorem

We now assemble the four steps outlined after [Theorem 13.17.1](#). The barrier enters only once, but globally: it locates a point of the nonsmooth set at which the quadratic separation required in [Proposition 13.17.5](#) holds.

Proof (of [Theorem 13.17.1](#)) If $n = 1$, the equation is the linear identity

$$\mathrm{dd}^c \varphi = cf \omega - \theta \quad \text{on } \Omega.$$

Its right-hand side is smooth, so interior elliptic regularity gives $\varphi \in C^\infty(\Omega)$, and the original equation gives $\theta + \mathrm{dd}^c \varphi = cf \omega > 0$. We henceforth assume $n \geq 2$.

Let

$$\mathcal{S} = \{p \in \Omega : \varphi \text{ is not smooth on any neighborhood of } p\}.$$

This is closed in Ω . Suppose $\mathcal{S} \neq \emptyset$. By [Lemma 1.19.4](#), the restriction of $\varphi - \rho$ to $\mathcal{S}$ attains its minimum m at some $p \in \mathcal{S}$.

Choose nested coordinate balls

$$B \Subset B_0 \Subset \Omega$$

centered at p . On B_0 , [Proposition 13.17.4](#) gives smooth exact Dirichlet solutions u_j converging uniformly to φ at a polynomial rate and having polynomial global trace growth.

On the open set $\Omega \setminus \mathcal{S}$ the function φ is smooth, and $\theta + \mathrm{dd}^c \varphi$ is semipositive with positive determinant, hence positive definite. [Proposition 13.17.6](#) therefore gives a uniform trace bound for the u_j on every compact subset of $B_0 \setminus \mathcal{S}$.

In coordinates centered at p , take $\kappa > 0$ small and set

$$q(z) = \rho(z) - \kappa|z|^2.$$

After shrinking B , the lower bound $\theta + \mathrm{dd}^c \rho \geq \omega$ gives $\theta + \mathrm{dd}^c q > 0$ on $\overline{B}$. If $v = \varphi - q$, then the minimizing property of p gives

$$v(p) = m, \quad v(z) = (\varphi - \rho)(z) + \kappa|z|^2 \geq m + \kappa|z|^2 \quad (z \in \mathcal{S} \cap \overline{B}).$$

Thus **Proposition 13.17.5** applies on B with the closed set $S \cap \bar{B}$: the approximation rate and global polynomial trace bound come from **Proposition 13.17.4**, and the bound away from S comes from **Proposition 13.17.6**. Its second assertion gives, for every $0 < \alpha < 1$, a neighborhood of p on which the approximants have a uniform $C^{1,\alpha}$ bound.

Choose $\alpha > \alpha_*$ as in **Proposition 13.17.8**, and apply that proposition on a ball centered at p inside this neighborhood. It yields

$$\sup_j \operatorname{tr}_B(\theta + \operatorname{dd}^c u_j) < \infty$$

on a still smaller neighborhood of p . Since $u_j \rightarrow \varphi$ uniformly, $\operatorname{dd}^c u_j \rightarrow \operatorname{dd}^c \varphi$ as currents. The trace bound passes to the limit, so $\operatorname{tr}_B(\theta + \operatorname{dd}^c \varphi)$ has a bounded density near p . **Proposition 13.17.2** now implies that φ is smooth near p , contradicting $p \in S$.

Hence $S = \emptyset$ and $\varphi \in C^\infty(\Omega)$. The form $\theta + \operatorname{dd}^c \varphi$ is smooth and semipositive there, while

$$(\theta + \operatorname{dd}^c \varphi)^n = c f \omega^n > 0.$$

Its nonnegative eigenvalues have positive product, so every eigenvalue is positive. Therefore $\theta + \operatorname{dd}^c \varphi > 0$ on Ω . $\square$

Corollary 13.17.1 *Let $0 \leq f \in L^p(X, \omega^n)$, $p > 1$, be smooth and strictly positive on Ω . Every minimal-singularity solution of $(\theta + \operatorname{dd}^c \varphi)^n = c f \omega^n$, $c > 0$, is smooth and strictly θ -plurisubharmonic on Ω .*

Proof The analytic complement of Ω has zero mass for both measures, so it suffices to know the equation in the bounded-potential sense on Ω . Apply **Theorem 13.16.1** with density $c f$ to obtain local Hölder continuity. All hypotheses of **Theorem 13.17.1** are now satisfied. $\square$

By **Theorem 13.15.2**, such a solution exists, with a uniquely determined $c > 0$. For a smooth closed big representative on a compact Kähler manifold, **Theorem 27.10.1** applies this conclusion to the classical full-mass solution and identifies the regular open set with the ample locus.

13.18 Degenerating semipositive backgrounds

Adding a small multiple of a Hermitian form makes a semipositive background strictly positive, and the smooth theory then solves the normalized equation with a smooth positive density. We study these smooth solutions as the added multiple tends to zero. Bounded subsolutions give uniform bounds for the potentials and the normalizing constants, and a strict analytic barrier gives uniform bounds for the trace on compact sets away from its poles. Smooth local convergence then identifies the limiting equation, without any global continuity property of the Monge–Ampère operator.

The main example is a small resolution of a threefold with nodes (Section 13.18.1). There the background is the pullback of a positive form from the singular threefold, and it degenerates exactly along the exceptional curves. When this background is closed, the limit is unique and the whole family converges smoothly away from the exceptional curves. Convergence of the associated metric spaces then reduces to controlling the diameters of neighborhoods of these curves, in the limiting metric and in the approximating metrics (Section 13.18.3).

Throughout this section $n \geq 2$. The background θ , the barrier ρ and its pole set Z are new data, independent of those fixed in Section 13.12. Let $\theta \geq 0$ be a smooth real $(1, 1)$ -form, and fix a Hermitian form η and a smooth positive probability volume form μ on X . Suppose that there are $\delta > 0$ and $\rho \in \text{PSH}(X, \theta)$ with analytic singularities such that

$$\theta + \text{dd}^c \rho \geq \delta \eta, \quad \sup_X \rho = 0. \quad (13.45)$$

Write $Z = \{\rho = -\infty\}$ and assume that ρ is smooth on $X \setminus Z$. For $0 < \varepsilon \leq 1$, the form $\theta + \varepsilon \eta$ is Hermitian, and Theorem 9.1.1 gives $u_\varepsilon \in C^\infty(X)$ and $c_\varepsilon > 0$ with

$$\omega_\varepsilon := \theta + \varepsilon \eta + \text{dd}^c u_\varepsilon > 0, \quad \omega_\varepsilon^n = c_\varepsilon \mu, \quad \sup_X u_\varepsilon = 0. \quad (13.46)$$

Lemma 13.18.1 *There are constants $b, B, C > 0$, independent of ε , such that*

$$b \leq c_\varepsilon \leq B, \quad -C \leq u_\varepsilon \leq 0.$$

Proof Write $\mu = f \, dV$, where f is smooth and positive. The strict barrier makes θ big. By Lemma 13.2.1, there is a bounded $s \in \text{PSH}(X, \theta)$ with $-1 \leq s \leq 0$ and $\text{MA}_\theta(s) \geq b\mu$ for some fixed $b > 0$. If $c_\varepsilon < b$, positivity gives

$$\text{MA}_{\theta+\varepsilon\eta}(u_\varepsilon) \leq (c_\varepsilon/b) \text{MA}_{\theta+\varepsilon\eta}(s+A)$$

for every constant A . Strict bounded domination would imply $u_\varepsilon \geq s + A$ for every A , which is absurd. Hence $c_\varepsilon \geq b$.

For an upper bound, choose a fixed Gauduchon form γ . The arithmetic–geometric mean inequality and Stokes give

$$c_\varepsilon^{1/n} \int_X \left(\frac{\mu}{\gamma^n} \right)^{1/n} \gamma^n \leq \int_X \omega_\varepsilon \wedge \gamma^{n-1} = \int_X (\theta + \varepsilon \eta) \wedge \gamma^{n-1} \leq \int_X (\theta + \eta) \wedge \gamma^{n-1}.$$

The first integral is fixed and positive, giving $c_\varepsilon \leq B$.

For the lower bound on u_ε , note that all u_ε are normalized $(\theta + \eta)$ -plurisubharmonic functions. Uniform exponential integrability, Lemma 1.5.1, gives $a > 0$ such that $g_\varepsilon = e^{-au_\varepsilon} f$ has a common L^2 bound. Also $g_\varepsilon \geq f$. By Theorem 13.2.1, the solutions

$$w_\varepsilon \in \text{PSH}(X, \theta), \quad \text{MA}_\theta(w_\varepsilon) = e^{aw_\varepsilon} g_\varepsilon \, dV$$

are uniformly bounded. Put $B_0 = \max\{1, B\}$ and $z_\varepsilon = w_\varepsilon - a^{-1} \log B_0$. Then

$$\mathrm{MA}_{\theta+\varepsilon\eta}(z_\varepsilon) \geq e^{az_\varepsilon} c_\varepsilon g_\varepsilon dV, \quad \mathrm{MA}_{\theta+\varepsilon\eta}(u_\varepsilon) = e^{au_\varepsilon} c_\varepsilon g_\varepsilon dV.$$

The comparison principle for the exponential equation in the background $\theta + \varepsilon\eta$ gives $z_\varepsilon \leq u_\varepsilon \leq 0$, and z_ε is bounded below uniformly in ε . $\square$

Since θ may degenerate along Z , we do not estimate the trace by local arguments. Instead we apply the maximum principle on all of $X \setminus Z$ to the logarithm of the trace minus a multiple of $u_\varepsilon - \rho$. This function tends to $-\infty$ at Z , so its maximum is attained off Z , where $\theta + \mathrm{dd}^c \rho \geq \delta\eta$ provides positivity. An additional logarithmic term in the weight absorbs the torsion term without a gradient bound for ρ .

Lemma 13.18.2 *For every compact $K \Subset X \setminus Z$, there is $C_K > 1$, independent of ε , such that*

$$C_K^{-1}\eta \leq \omega_\varepsilon \leq C_K\eta \quad \text{on } K.$$

Proof For the differentiated calculation write $U = u_\varepsilon/(2\pi)$ and $P = \rho/(2\pi)$, so that $\mathrm{dd}^c u_\varepsilon = i\partial\bar{\partial}U$. Put

$$S = \mathrm{tr}_\eta \omega_\varepsilon, \quad R = \mathrm{tr}_{\omega_\varepsilon} \eta, \quad D = \omega_\varepsilon^n / \eta^n.$$

The previous lemma and the smooth positive density give $0 < d_1 \leq D \leq d_2$. Choose a fixed C_0 so that $v = U - P + C_0 > 1$, and set

$$H = \log S - \gamma(v), \quad \gamma(v) = Av + \log v,$$

where A will be fixed below. For each ε , S is smooth on X and v tends to infinity at Z . Thus $H \rightarrow -\infty$ there, and H attains its maximum on $X \setminus Z$. We bound this maximum independently of ε .

In local holomorphic coordinates, h and g denote the coefficient matrices of η and ω_ε with respect to $i\mathrm{d}z_j \wedge \mathrm{d}\bar{z}_k$, and commas denote coordinate derivatives, as in $h_{i\bar{j},k} = \partial_k h_{i\bar{j}}$ and $h_{i\bar{j},\bar{k}} = \partial_{\bar{k}} h_{i\bar{j}}$. At a maximum point choose holomorphic coordinates in which

$$h_{i\bar{j}} = \delta_{ij}, \quad h_{i\bar{i},k} = 0, \quad g_{i\bar{j}} = \lambda_i \delta_{ij}.$$

A linear change first normalizes h and diagonalizes g . In these coordinates, the quadratic change $z_i = w_i + \frac{1}{2} \sum_{j,k} a_{jk}^i w_j w_k$, with symmetric coefficients chosen so that $a_{ik}^i = -h_{i\bar{i},k}$, then kills $h_{i\bar{i},k}$. Its coefficients are uniformly bounded on a fixed finite cover. Write

$$\Delta_g = \sum_i \lambda_i^{-1} \partial_i \partial_{\bar{i}}, \quad T_{ij\bar{k}} = g_{j\bar{k},i} - g_{i\bar{k},j}, \quad E_i = \sum_j T_{ij\bar{j}}.$$

The lowered torsion coefficients $T_{ij\bar{k}}$ and their first derivatives are uniformly bounded: the potential Hessian cancels, leaving only derivatives of $\theta + \varepsilon\eta$.

Let μ_{loc} be the density of μ with respect to the coordinate volume form. Differentiating $S = h^{k\bar{\ell}} g_{k\bar{\ell}}$ and the equation $\log \det g = \log c_\varepsilon + \log \mu_{\mathrm{loc}}$ gives

$$\Delta_g S \geq Q - CRS - CR, \quad Q = \sum_{i,j} \frac{|g_{i\bar{j},j}|^2}{\lambda_i \lambda_j}. \quad (13.47)$$

The second derivatives of g contribute $\sum_{i,j,k} |g_{i\bar{j},k}|^2 / (\lambda_i \lambda_j)$, up to $-CR - C$, by commuting the potential derivatives. The first derivatives of h contribute $-2 \operatorname{Re} \sum_{i,j,k} \lambda_i^{-1} h_{j\bar{k},i} g_{k\bar{j},i}$. Its terms with $j = k$ vanish. Replace $g_{k\bar{j},i}$ by $g_{i\bar{j},k} + T_{ik\bar{j}}$ and apply weighted Cauchy–Schwarz. This consumes exactly the terms of the preceding square with $j \neq k$ and costs at most $CRS + CR$. The second derivatives of h^{-1} cost CRS . Finally the fixed density term $-C$ is absorbed using $SR \geq n^2$.

Since $\partial_i S = \sum_j g_{i\bar{j},j} + E_i$ at the maximum point, weighted Cauchy–Schwarz also gives

$$|\partial S|_g^2 \leq SQ + 2 \operatorname{Re} \langle E, \partial S \rangle_g.$$

Indeed expand around $\partial S - E$ and discard the resulting term $-|E|_g^2$. Combining with (13.47) yields

$$\Delta_g \log S \geq -CR - CR/S - \frac{2}{S} \operatorname{Re} \langle E, \partial \log S \rangle_g.$$

At the maximum, $\partial \log S = \gamma' \partial v$. Moreover (13.45) gives $\Delta_g v \leq n - \delta R$, and $|E|_g^2 \leq CR$. Young's inequality with the positive coefficient $-\gamma'' = v^{-2}$ therefore gives

$$0 \geq \Delta_g H \geq (\delta \gamma' - C)R - n\gamma' - CR/S - \frac{CR}{S^2} \frac{\gamma'^2}{-\gamma''}.$$

Since $\gamma' = A + v^{-1}$, choose A with $\delta A - C \geq 1$. The resulting inequality is

$$0 \geq R - C \left(1 + \frac{R}{S} + \frac{R(1+v^2)}{S^2} \right). \quad (13.48)$$

All constants are independent of ε .

If the maxima of H were unbounded, then at a sequence of maximizing points

$$\log(S/v) = H + Av \longrightarrow +\infty.$$

Thus $S/v \rightarrow \infty$ and $S \rightarrow \infty$. Inequality (13.48) would imply $R \leq 2C$ along this sequence. But

$$S = D \sum_i \prod_{j \neq i} \lambda_j^{-1} \leq nDR^{n-1} \leq nd_2(2C)^{n-1},$$

a contradiction. Hence H is uniformly bounded. On K , both U and P are bounded, so $S \leq C_K$. The determinant lower bound then gives $\lambda_i \geq d_1/C_K^{n-1}$, completing the proof. $\square$

Theorem 13.18.1 *In the preceding setting, c_ε decreases to a positive number c_0 as $\varepsilon \downarrow 0$. This number is independent of the perturbing Hermitian form η . For every sequence $\varepsilon_j \downarrow 0$, a subsequence satisfies*

$$u_{\varepsilon_j} \longrightarrow u_0 \quad \text{in } L^1(X) \cap C_{\text{loc}}^\infty(X \setminus Z),$$

where $u_0 \in \text{PSH}(X, \theta) \cap L^\infty(X)$, $\sup_X u_0 = 0$, and

$$\text{MA}_\theta(u_0) = c_0 \mu.$$

If θ is closed, then $c_0 = \int_X \theta^n$.

Proof Monotonicity of the constants. Let $\alpha \leq \beta$ be Hermitian forms, and let (u_α, c_α) and (u_β, c_β) be the normalized smooth solutions of $(\alpha + \text{dd}^c u_\alpha)^n = c_\alpha \mu$ and $(\beta + \text{dd}^c u_\beta)^n = c_\beta \mu$. At a maximum point of $u_\alpha - u_\beta$,

$$\alpha + \text{dd}^c u_\alpha \leq \beta + \text{dd}^c u_\beta,$$

so $c_\alpha \leq c_\beta$. Hence c_ε decreases as $\varepsilon \downarrow 0$, and [Lemma 13.18.1](#) gives $c_0 \geq b > 0$. Write $c_\eta(\varepsilon)$ for the constant c_ε defined with the perturbation η . For two perturbations with $M^{-1}\eta_1 \leq \eta_2 \leq M\eta_1$, the same comparison gives

$$c_{\eta_1}(\varepsilon/M) \leq c_{\eta_2}(\varepsilon) \leq c_{\eta_1}(M\varepsilon).$$

Letting $\varepsilon \downarrow 0$ shows that c_0 does not depend on η .

Local estimates. The trace bound of [Lemma 13.18.2](#) gives uniform ellipticity on compact subsets of $X \setminus Z$. The smooth coefficients of $\theta + \varepsilon\eta$ and all derivatives of $\log \mu_{\text{loc}}$ have common bounds there. Interior complex Evans–Krylov and Schauder estimates, as in the ellipticity argument of [Proposition 13.17.2](#), give uniform C^k bounds on smaller compact subsets for every k .

Convergence and the limiting equation. Normalized compactness in the fixed background $\theta + \eta$, followed by a diagonal extraction over an exhaustion of $X \setminus Z$, gives the stated convergence. The uniform bound $-C \leq u_\varepsilon \leq 0$ passes to the canonical limit, and normalized compactness preserves the supremum zero. Current convergence gives $\theta + \text{dd}^c u_0 \geq 0$, and smooth convergence identifies the equation on $X \setminus Z$. The bounded non-pluripolar measure $\text{MA}_\theta(u_0)$ and the smooth measure μ both vanish on the analytic set Z . This proves the equation on all of X . For closed θ , bounded closed-background Stokes gives $\int_X \text{MA}_\theta(u_0) = \int_X \theta^n$, proving the last assertion. $\square$

Since $\theta \geq 0$ is nef, [Theorem 25.10.1](#) identifies c_0 with the Gauduchon variational volume $\mathcal{V}_\mu(\theta)$. The proof uses no bound on Monge–Ampère masses: all estimates concern the solutions for the fixed smooth density μ . If the bounded normalized limiting equation has a unique solution, all cluster limits coincide, and the whole family converges in $L^1(X) \cap C_{\text{loc}}^\infty(X \setminus Z)$.

13.18.1 Small resolutions of nodes

The pullback of a positive form from a singular space loses positivity along the contracted curves. In the standard small resolution of a node, the logarithm of the

norm in the normal bundle of the exceptional curve provides the missing curvature along the curve. Cutting this logarithm off where the pullback is already positive gives a global strict barrier, so the results above apply.

Assume now $n = 3$. Let Y be a connected compact normal complex threefold, smooth outside a finite set Σ of nodes. A node is locally the hypersurface

$$\{x_1x_4 - x_2x_3 = 0\} \subset \mathbb{C}^4.$$

Let $\pi : X \rightarrow Y$ be a proper holomorphic map that is biholomorphic over $Y \setminus \Sigma$. Assume each local resolution is the standard small resolution: a neighborhood of its exceptional curve is identified with a neighborhood of the zero section of

$$\mathcal{O}_{\mathbb{P}^1}(-1) \oplus \mathcal{O}_{\mathbb{P}^1}(-1),$$

and the contraction, in bundle coordinates (z, y_1, y_2) , is

$$\pi(z, y_1, y_2) = (y_1, zy_1, y_2, zy_2). \quad (13.49)$$

Interchanging the two rulings gives the other standard model. Write $E = \pi^{-1}(\Sigma)$; its components E_j are disjoint copies of $\mathbb{P}^1$.

Fix a positive form ω_Y on Y in the local embedding sense: in each ambient chart it is induced by a smooth strictly positive real $(1, 1)$ -form. Set $\theta = \pi^* \omega_Y$, and let η be an arbitrary Hermitian form on X .

Lemma 13.18.3 *The form θ is smooth and semipositive, positive on $X \setminus E$. There are $\delta > 0$ and $\rho \in \text{PSH}(X, \theta)$ with analytic poles precisely on E , smooth on $X \setminus E$, such that*

$$\sup_X \rho = 0, \quad \theta + \text{dd}^c \rho \geq \delta \eta.$$

Proof Smoothness and positivity off E follow from the pullback and the biholomorphism. In one standard model put

$$r^2 = (1 + |z|^2)(|y_1|^2 + |y_2|^2), \quad b = \text{dd}^c \log(1 + |z|^2).$$

The function r^2 is the sum of the squared absolute values of the four contracted coordinates. It is therefore globally defined on the bundle; b is the pullback of the Fubini–Study form from its base. In the chart (13.49),

$$\text{dd}^c \log r^2 = b + \text{dd}^c \log(|y_1|^2 + |y_2|^2) \geq b. \quad (13.50)$$

This is an inequality of currents across the zero section as well as a smooth inequality off it.

Ambient positivity gives $\theta \geq c \text{dd}^c r^2$ on a sufficiently small tube, for some $c > 0$. The smooth form $\text{dd}^c r^2 + b$ is positive definite there. Indeed the contraction is an immersion off the zero section, and on that section $\text{dd}^c r^2$ is positive in both fiber directions while b is positive along the base. Compactness of the zero section and a smaller closed tube give a uniform lower bound by a positive multiple of η . Thus, for

every fixed $a > 0$,

$$\theta + \text{add}^c \log r^2 \geq \text{cdd}^c r^2 + ab \geq \delta_a \eta$$

near the zero section, with $\delta_a > 0$.

Choose disjoint model tubes with nonempty complement and numbers $0 < t_1 < t_2 < 1$ in each. Let $0 \leq \chi \leq 1$ be a smooth cutoff of r^2 , equal to one for $r^2 \leq t_1$ and zero for $r^2 \geq t_2$. Extend $\chi(r^2) \log r^2$ by zero outside its tube. On the compact transition annuli, the pullback θ is uniformly positive and the second derivatives of this cutoff potential are bounded. A sufficiently small positive rational a therefore makes

$$\rho = a \sum_j \chi_j(r_j^2) \log r_j^2$$

satisfy $\theta + \text{dd}^c \rho \geq \delta \eta$ there and near every E_j . On the remaining compact set, $\rho = 0$ and θ is positive, so decreasing δ proves the global inequality. Near E_j the function is $a \log(|y_1|^2 + |y_2|^2) + a \log(1 + |z|^2)$, hence has analytic singularities with rational coefficient and pole set exactly E_j . It is smooth elsewhere and nonpositive; its zero extension gives supremum zero. If E is empty, take $\rho = 0$ and use the positivity of θ on compact X . $\square$

Corollary 13.18.1 *For the preceding geometric data and every smooth positive probability volume form μ on X , the solutions of (13.46) have the bounds and subsequential convergence of Theorem 13.18.1, with $Z = E$. Moreover, for each exceptional curve,*

$$\int_{E_j} \omega_\varepsilon = \varepsilon \int_{E_j} \eta \longrightarrow 0.$$

Proof Apply the theorem using Lemma 13.18.3. Since π contracts E_j , the restriction of θ to it is zero. Stokes on the compact smooth curve gives $\int_{E_j} \text{dd}^c u_\varepsilon = 0$, proving the area identity. $\square$

When K_X is torsion, the density can be chosen so that these metrics are Chern–Ricci flat. Recall that the Chern–Ricci form $\text{Ric}^{\text{Ch}}(\omega)$ of a Hermitian metric ω is $-i\partial\bar{\partial}$ of the logarithm of the density of ω^n with respect to a coordinate volume form. Choose a nowhere vanishing holomorphic section of $K_X^{\otimes m}$ for some $m \geq 1$. If its local expression is $f(dz_1 \wedge dz_2 \wedge dz_3)^{\otimes m}$, use $|f|^{2/m}$ as the density relative to the standard coordinate volume form. The coordinate Jacobians cancel, so this defines a smooth positive volume form on X ; normalize it to total mass one and take it as μ . Its logarithmic density is pluriharmonic. Applying $-i\partial\bar{\partial} \log$ to $\omega_\varepsilon^3 = c_\varepsilon \mu$ therefore gives $\text{Ric}^{\text{Ch}}(\omega_\varepsilon) = 0$, and the same holds for the smooth limiting metric on $X \setminus E$.

13.18.2 Measures and bounded potentials at a node

We keep the standard small resolution $\pi : X \rightarrow Y$ and a smooth positive probability volume form μ on X . Write $\mu_Y = \pi_* \mu$, and let ν_Y be ω_Y^3 on the regular locus, extended

by zero at the nodes. The pullback of the ambient volume form ω_Y^3 vanishes along the exceptional curves, and its order of vanishing determines the integrability of the density of μ_Y with respect to ν_Y .

Lemma 13.18.4 *The measures μ_Y and ν_Y are finite and give the nodes zero mass. There is a positive density F with $\mu_Y = F\nu_Y$. If Σ is nonempty, then for $1 \leq p < \infty$,*

$$F \in L^p(Y, \nu_Y) \iff p < 3.$$

At each node, F is comparable to r^{-2} , where $r^2 = \sum_{j=1}^4 |x_j|^2$ in the local model $\{x_1x_4 - x_2x_3 = 0\}$ of the node. There are $c, C, T_0 > 0$ such that

$$cT^{-3} \leq \nu_Y(\{F > T\}) \leq CT^{-3} \quad (T \geq T_0).$$

Thus the endpoint is weak L^3 , with $F \notin L^3$. If Σ is empty, F is smooth and bounded.

Proof The map is biholomorphic off E , and both smooth measures μ and θ^3 give E zero mass. Hence $\nu_Y = \pi_*\theta^3$ is finite, μ_Y has no node atom, and on the regular locus

$$F \circ \pi = \mu/\theta^3.$$

In the chart (13.49), put $h = 1 + |z|^2$ and $s = |y_1|^2 + |y_2|^2$, so $r^2 = hs$. The fiber block of the complex Hessian of r^2 is h times the identity, and its Schur complement is s/h . Consequently

$$\det((r^2)_{j\bar{k}}) = hs = r^2, \quad \frac{(\mathrm{dd}^c r^2)^3}{3!} = \frac{r^2}{\pi^3} d\lambda_6, \quad (13.51)$$

where λ_6 is Euclidean volume in (z, y_1, y_2) . Ambient positivity bounds θ above and below by positive multiples of $\mathrm{dd}^c r^2$ on a smaller tube. The smooth density of μ is bounded above and below there. On compact subcharts covering the base $\mathbb{P}^1$, it follows that

$$\theta^3 \asymp r^2 d\lambda_6, \quad F \circ \pi \asymp r^{-2}.$$

The other bundle chart gives the same comparison, since r is the norm of the contracted coordinates.

On each bounded base subchart, r is comparable to the Euclidean radius R in the two complex fiber variables. Up to fixed positive constants, the contribution to $\int F^p d\nu_Y$ is therefore

$$\int_0^{R_0} R^{2-2p} R^3 dR = \int_0^{R_0} R^{5-2p} dR.$$

Two compact base subcharts give the upper estimate; a fixed open base subchart gives the lower estimate. The integral is finite precisely when $p < 3$, and diverges logarithmically at $p = 3$. Away from the finitely many nodes the density is smooth. The same comparisons give $\nu_Y(\{r < t\}) \asymp t^6$ near a node. The two bounds for F sandwich $\{F > T\}$ between such tubes of radii comparable to $T^{-1/2}$, proving the endpoint estimate. $\square$

The descent theorem [Theorem A.2.1](#) applies to the normal space Y and its resolution π , also when the ambient background is not closed. Every bounded θ -plurisubharmonic function is therefore constant on each exceptional curve and is the pullback of a unique bounded ω_Y -plurisubharmonic function. In particular each cluster limit has the form $u_0 = \psi_0 \circ \pi$, with $\sup_Y \psi_0 = 0$. Let $\text{MA}_{Y, \omega_Y}^{\text{ext}}$ be the extended Monge–Ampère measure on Y , defined in [\(A.1\)](#) as the pushforward of the extended measure of the pullback to a resolution; it does not depend on the resolution. Then

$$\text{MA}_{Y, \omega_Y}^{\text{ext}}(\psi_0) = c_0 \mu_Y = c_0 F \nu_Y. \quad (13.52)$$

The equality holds also at the nodes, since both measures give them zero mass. Thus ψ_0 is a bounded solution of an equation on the singular space; nothing is claimed about its continuity at a node.

Theorem 13.18.2 *Suppose additionally that θ is closed. The equation*

$$\text{MA}_\theta(u) = c\mu, \quad u \in \text{PSH}(X, \theta) \cap L^\infty(X), \quad \sup_X u = 0,$$

has a unique pair (c, u) with $c > 0$. Its scalar is $c = c_0 = \int_X \theta^3$. The entire family u_ε converges to u in $L^1(X)$ and smoothly on compact subsets of $X \setminus E$. The limit is independent of η , and its descended potential is the unique bounded normalized solution of [\(13.52\)](#).

Proof Existence follows from [Corollary 13.18.1](#). For uniqueness we use an energy identity, which is available because θ is closed. Fix one cluster limit u_0 and put $A = \theta + \text{dd}^c u_0$. This is a positive closed current with bounded local potentials, smooth and strictly positive on $X \setminus E$ by the trace bounds. If v is another bounded solution with scalar c , bounded closed-background Stokes gives $c = \int_X \theta^3 = c_0$. Put $B = \theta + \text{dd}^c v$ and $w = v - u_0$. The bounded integration-by-parts calculus of [Section 1.6](#) gives

$$0 = \int_X w(B^3 - A^3) = - \sum_{j=0}^2 \int_X \text{d}w \wedge \text{d}^c w \wedge B^j \wedge A^{2-j}.$$

All three energies are nonnegative, so each of them vanishes, in particular the one with A^2 . On every relatively compact chart of $X \setminus E$, the smooth positive factor A^2 controls the weak gradient of w , so $\text{d}w = 0$ there. The complement of a proper complex analytic subset in the connected manifold X is connected. Thus w is constant almost everywhere off E . Since E has ordinary volume zero, canonical almost-everywhere equality of quasi-plurisubharmonic functions, [Lemma 1.3.3](#), gives $v = u_0 + C$ on all of X . Normalization fixes $C = 0$.

The compactness and smooth local estimates of [Theorem 13.18.1](#) now make every subsequential limit equal to u_0 , proving convergence of the whole family. The equation and its unique normalized solution do not depend on η . Descent and the zero exceptional mass identify bounded solutions upstairs and downstairs, proving the final assertion. $\square$

13.18.3 Distances across finitely many contracting regions

On the small resolutions above, the potential limit for a closed background gives smooth convergence of the metrics away from the exceptional curves. Global distances, however, are also affected by paths through neighborhoods of these curves, so their convergence requires control of the diameters of such neighborhoods. The criterion of [Proposition 13.18.1](#) separates the two controls: uniform convergence on compact subsets of the regular part, and small diameters of neighborhoods of the contracted sets, in the limiting metric and uniformly in the approximating metrics. We first recall the Gromov–Hausdorff distance.

Definition 13.18.1 For nonempty subsets E, F of a metric space (W, d_W) , their Hausdorff distance is

$$d_H^W(E, F) = \max \left\{ \sup_{x \in E} \inf_{y \in F} d_W(x, y), \sup_{y \in F} \inf_{x \in E} d_W(x, y) \right\}.$$

For nonempty bounded metric spaces E, F , put

$$d_{GH}(E, F) = \inf_{W, \iota, j} d_H^W(\iota(E), j(F)),$$

where ι, j are isometric embeddings into a common metric space W . A correspondence is a subset $R \subset E \times F$ whose two coordinate projections are surjective. Its distortion is

$$\text{dis } R = \sup_{(x, y), (x', y') \in R} |d_E(x, x') - d_F(y, y')|.$$

Lemma 13.18.5 *For any correspondence R between nonempty bounded metric spaces,*

$$\frac{1}{2} |\text{diam } E - \text{diam } F| \leq d_{GH}(E, F) \leq \frac{1}{2} \text{dis } R.$$

Proof Choose $\varepsilon > 0$ with $2\varepsilon \geq \text{dis } R$. Give the disjoint union $E \sqcup F$ its original distances within each space, and use the symmetric cross distance

$$D(x, y) = \inf_{(x_0, y_0) \in R} (d_E(x, x_0) + \varepsilon + d_F(y_0, y)), \quad x \in E, y \in F.$$

It is finite and at least ε . The triangle inequalities involving one cross distance follow from the triangle inequality within the corresponding space and the infimum. For two cross distances, take $(x_0, y_0), (x_1, y_1) \in R$. The distortion bound gives

$$\begin{aligned} d_E(x, x') &\leq d_E(x, x_0) + d_F(y_0, y_1) + 2\varepsilon + d_E(x_1, x') \\ &\leq d_E(x, x_0) + d_F(y_0, y) + \varepsilon + \varepsilon + d_F(y, y_1) + d_E(x_1, x'). \end{aligned}$$

Taking the two infima gives $d_E(x, x') \leq D(x, y) + D(y, x')$. The same argument with E, F exchanged treats the other case. Hence D is a metric extending both metrics.

Each point has a correspondent at cross distance ε , so the Hausdorff distance between E and F in $(E \sqcup F, D)$ is at most ε . Letting ε decrease to half the distortion proves the upper bound, including zero distortion.

For the lower bound, suppose two isometric images have Hausdorff distance h . For every $\delta > 0$, two points in the first image have points in the second within $h + \delta$. Their distance is at most $\text{diam } F + 2h + 2\delta$. Taking the supremum and then $\delta \downarrow 0$ gives $\text{diam } E \leq \text{diam } F + 2h$. Exchanging the images and taking the infimum over embeddings proves the lower bound. $\square$

We now work in a purely metric setting, which contains the nodal one. Let Y be a compact metrizable space and let $S = \{s_1, \dots, s_N\} \subset Y$ be finite. Assume $Y^\circ = Y \setminus S$ is a dense connected smooth manifold. Let g_0 be a smooth Riemannian metric on Y° , and denote its intrinsic length distance by d_0 .

Lemma 13.18.6 *Suppose every s_a has a neighborhood basis of open sets $V_{a,r}$ such that*

$$\lim_{r \downarrow 0} \text{diam}_{d_0}(V_{a,r} \setminus S) = 0.$$

Then the metric completion $(\widehat{Y}, \widehat{d}_0)$ of (Y°, d_0) is compact, and the identity on Y° extends to a homeomorphism $\iota : Y \rightarrow \widehat{Y}$.

Proof The neighborhoods can be chosen nested, with closures avoiding the other points of S . Every sequence of regular points converging to s_a is d_0 -Cauchy: its tail lies in each prescribed neighborhood, whose punctured diameter tends to zero. Interleaving two such sequences shows that they define the same completion point, denoted by $\widehat{s}_a$. Density of Y° guarantees the existence of these sequences.

For each prescribed positive diameter, remove sufficiently small neighborhoods of all the points of S . Their complement is a compact subset of Y° and hence is totally bounded for d_0 . The removed punctured neighborhoods each have the prescribed small diameter. Thus Y° is totally bounded, and its completion is compact.

The points $\widehat{s}_a$ are distinct from one another and from the regular points. To see this, fix s_a and a different point $y \in Y$. Choose an open neighborhood V of s_a whose closure avoids y and $S \setminus \{s_a\}$, and choose $W \Subset V$ containing s_a . There is a smooth function χ on Y° , equal to one on $W \setminus S$ and zero outside V , whose derivative has compact support in Y° . Indeed the transition takes place in the compact regular set $\overline{V} \setminus W$, where smooth cutoffs exist. Therefore $|\mathrm{d}\chi|_{g_0} \leq C$ for some finite C . Integration along curves gives

$$|\chi(p) - \chi(q)| \leq C d_0(p, q), \quad p, q \in Y^\circ.$$

The Lipschitz extension of χ to the completion has value one at $\widehat{s}_a$ and zero at the regular point y , or at $\widehat{s}_b$ if $y = s_b$. This proves the assertion.

Define ι by the identity on the regular locus and by $\iota(s_a) = \widehat{s}_a$. The intrinsic distance induces the smooth topology at each regular point. At s_a , adjoining $\widehat{s}_a$ to a punctured neighborhood does not increase its diameter, so the diameter hypothesis proves continuity of ι . Every completion point is represented by a Cauchy sequence

in Y° . Compact metrizability of Y gives a subsequence converging topologically either to a regular point or to some s_a ; the preceding arguments give its metric limit. Hence ι is surjective as well as injective. A continuous bijection from compact Y to Hausdorff $\widehat{Y}$ is a homeomorphism. $\square$

Let X be a compact connected smooth manifold and let $\pi : X \rightarrow Y$ be a continuous surjection, with $E = \pi^{-1}(S)$ and with $\pi : X \setminus E \rightarrow Y^\circ$ a diffeomorphism. Assume that the identity of Y° extends to a homeomorphism $\iota : Y \rightarrow \widehat{Y}$, for instance under the hypothesis of [Lemma 13.18.6](#), and write $G = \iota \circ \pi$. For a smooth Riemannian metric g on X and an open subset U , let $\text{diam}^{\text{int}}(U, g)$ denote the intrinsic diameter of U , computed with the lengths of piecewise smooth curves contained in U .

Proposition 13.18.1 *Let g_j be smooth Riemannian metrics on X such that $g_j \rightarrow \pi^* g_0$ uniformly on every compact subset of $X \setminus E$. Suppose each s_a has a nested neighborhood basis $V_{a,r}$, with $U_{a,r} = \pi^{-1}(V_{a,r})$, satisfying*

$$\lim_{r \downarrow 0} \text{diam}_{\widehat{d}_0}(\iota(V_{a,r})) = 0, \quad \lim_{r \downarrow 0} \limsup_{j \rightarrow \infty} \text{diam}^{\text{int}}(U_{a,r}, g_j) = 0.$$

Then, for the global length distances d_j of g_j ,

$$\lim_{j \rightarrow \infty} \sup_{x, x' \in X} |d_j(x, x') - \widehat{d}_0(G(x), G(x'))| = 0.$$

Consequently (X, d_j) converges to $(\widehat{Y}, \widehat{d}_0)$ in Gromov–Hausdorff distance.

Proof If S is empty, uniform metric comparison on compact X proves the distance convergence. Assume $N \geq 1$. Fix $\tau > 0$. Choose pairwise disjoint neighborhoods V_a from the specified bases with

$$\text{diam}_{\widehat{d}_0}(\iota(V_a)) < \tau, \quad \text{diam}^{\text{int}}(U_a, g_j) < \tau$$

for all sufficiently large j , where $U_a = \pi^{-1}(V_a)$. Pick $q_a \in V_a \setminus S$, and then choose open neighborhoods W_a of s_a with $\overline{W}_a \subset V_a$ and $q_a \notin \overline{W}_a$. The regular cores

$$K_Y = Y \setminus \bigcup_a W_a, \quad K_X = \pi^{-1}(K_Y)$$

are compact and identified by π . Uniform convergence and positivity of g_0 on this core give numbers $A_j \geq 1$, with $A_j \rightarrow 1$, such that lengths of curves contained in the cores compare in both directions by the factor A_j .

Consider a piecewise smooth path in Y° joining two points of K_Y . The preimages of the closed sets $\overline{W}_a$ are compact subsets of its parameter interval. At its first visit to any such set, delete the portion from that visit through its last visit to the same set. Resume with the remaining tail. That set is never visited again; thus there are at most N deleted portions. Each retained segment lies in K_Y , and each deleted portion has endpoints in a single $\overline{W}_a \subset V_a$. The lifts of those endpoints can be joined in U_a with g_j -length less than τ , up to an arbitrarily small error. Applying this procedure to

almost minimizing paths, comparing retained lengths, and letting the errors tend to zero gives, for $x, x' \in K_X$,

$$d_j(x, x') \leq A_j \widehat{d}_0(G(x), G(x')) + N\tau.$$

Conversely start with an almost minimizing g_j -path in X and apply the same deletion procedure to the closed sets $\pi^{-1}(\overline{W}_a)$. Project its retained segments, which avoid E , to K_Y . The two images of each deleted portion have completion distance less than τ . The triangle inequality in $\widehat{Y}$ therefore gives

$$\widehat{d}_0(G(x), G(x')) \leq A_j d_j(x, x') + N\tau, \quad x, x' \in K_X.$$

For any $x \notin K_X$ with $\pi(x) \in W_a$, replace x by $p = \pi^{-1}(q_a) \in U_a \cap K_X$. Then $d_j(x, p) < \tau$ and $\widehat{d}_0(G(x), G(p)) < \tau$. Leave points of K_X fixed. Replacing both endpoints extends the two inequalities to all $x, x' \in X$, with the same error

$$C_j = (N + 2 + 2A_j)\tau.$$

If $D = \text{diam}(\widehat{Y}, \widehat{d}_0)$, the first inequality gives $\text{diam}(X, d_j) \leq A_j D + C_j$. The positive and negative distance errors are consequently bounded by

$$(A_j - 1)D + C_j, \quad (A_j - 1)(A_j D + C_j) + C_j,$$

respectively. Their upper limits are at most $(N + 4)\tau$. Letting $\tau \downarrow 0$ proves uniform convergence.

The graph of G is a correspondence between X and $\widehat{Y}$, and its distortion b_j for the distances d_j and $\widehat{d}_0$ is the supremum in the statement. By [Lemma 13.18.5](#),

$$d_{\text{GH}}((X, d_j), (\widehat{Y}, \widehat{d}_0)) \leq b_j/2 \longrightarrow 0.$$

For the standard nodal small resolutions of [Section 13.18.1](#) with closed θ , the smooth convergence of the whole family off E in [Theorem 13.18.2](#) gives the uniform convergence on compact subsets of $X \setminus E$ required in [Proposition 13.18.1](#). What remains are the two conditions on the diameters of neighborhoods. The next estimates control the approximating neighborhoods by metric bounds along and normal to the exceptional curves.

13.18.3.1 Curve areas and radial tube lengths

The approximating metrics give each exceptional curve an area tending to zero, by [Corollary 13.18.1](#). Along the curve, small area forces small diameter as long as the metrics are bounded above; in the normal directions, an integrable bound for the speed of radial rays has the same effect.

Let C be a connected compact Riemann surface. Fix a smooth Hermitian metric h of area one on C , and use the associated Riemannian metrics for lengths and areas.

Lemma 13.18.7 *There is $K_h > 0$ such that every smooth Hermitian metric $g \leq Mh$, with $M > 0$ and $A = \text{Area}_g(C)$, satisfies*

$$\text{diam}(C, g) \leq K_h \sqrt{A(1 + \log(M/A))}.$$

Here $0 < A \leq M$. In particular, for a fixed upper bound M , area tending to zero implies diameter tending to zero.

Proof Replace g by g/M . Its area is $a = A/M \leq 1$, and it is bounded above by h . We prove the estimate for this normalized metric.

Choose a finite cover by holomorphic coordinate disks U_i represented by $\{|z| < 1\}$, with each coordinate defined on the larger disk $\{|z| < 2\}$. Write $g = \rho_i |dz|^2$ there. There is a common $L > 0$ such that $0 < \rho_i \leq L$ on all the closed unit disks, and

$$\int_{U_i} \rho_i d\lambda_2 \leq a,$$

where λ_2 is Euclidean area. For $p, z \in U_i$, let $\ell_p(z)$ be the g -length of their straight coordinate segment, which stays in U_i . Polar coordinates about p and Fubini give

$$\int_{U_i} \ell_p(z) d\lambda_2(z) \leq 2 \int_{U_i} \frac{\sqrt{\rho_i(w)}}{|w-p|} d\lambda_2(w).$$

Indeed each ray meets the convex unit disk in an interval of length $R \leq 2$. Interchanging the radial integrals multiplies the length integrand at radius s by $(R^2 - s^2)/2 \leq 2$.

For $0 < a \leq 1/4$, put $t = \sqrt{a}$. The integral on the right, without its factor two, is bounded by

$$\begin{aligned} \sqrt{L} \int_{\{|w-p|<t\}} \frac{d\lambda_2(w)}{|w-p|} + \left(\int_{U_i} \rho_i d\lambda_2 \right)^{1/2} \left(\int_{\{t<|w-p|<2\}} \frac{d\lambda_2(w)}{|w-p|^2} \right)^{1/2} \\ \leq 2\pi\sqrt{L}t + \sqrt{2\pi a \log(2/t)} \leq K\sqrt{a(1 + \log(1/a))}. \end{aligned}$$

Thus for any $p, q \in U_i$, averaging $\ell_p(z) + \ell_q(z)$ over $z \in U_i$ gives a two-segment path of length at most $K\sqrt{a(1 + \log(1/a))}$. The constant is common to the finite cover.

The overlap graph of this cover is connected because C is connected. Choose points in consecutive overlaps along a simple path in this finite graph. The local estimates join any two points of C through at most the number of covering disks, proving the global bound for $a \leq 1/4$. For $1/4 \leq a \leq 1$, the comparison $g \leq h$ gives $\text{diam}(C, g) \leq \text{diam}(C, h)$, and increasing K_h gives the same estimate. Restoring the factor M scales lengths by $\sqrt{M}$ and proves the assertion. $\square$

Example 13.18.1 On every such (C, h) there are smooth Hermitian metrics $g_\varepsilon \leq h$, for $\varepsilon \downarrow 0$, such that

$$A_\varepsilon := \text{Area}_{g_\varepsilon}(C) \asymp \varepsilon^2 \log(1/\varepsilon),$$

$$\text{diam}(C, g_\varepsilon) \asymp \varepsilon \log(1/\varepsilon).$$

Consequently the preceding diameter bound has sharp order under its uniform upper bound. Without that bound, area can tend to zero while diameter stays bounded below by a positive constant.

Proof Choose a coordinate disk $\{|z| < R\}$ with $0 < R < 1$, on whose closure $h = \lambda(z)|dz|^2$ with $\lambda > 0$ smooth. Choose a smooth cutoff $0 \leq \chi \leq 1$, supported in this disk and equal to one for $|z| \leq R/2$, and a constant $c > 0$ with $c \leq \min \lambda$. For sufficiently small $\varepsilon > 0$, set

$$g_\varepsilon = \left(\chi \frac{c\varepsilon^2}{\lambda(z)(\varepsilon^2 + |z|^2)} + (1 - \chi)\varepsilon^2 \right) h$$

in the disk, and set $g_\varepsilon = \varepsilon^2 h$ outside it. The cutoff makes this a smooth positive metric, and both coefficients in its convex combination are at most one.

On $|z| \leq R/2$ its metric density is $c\varepsilon^2/(\varepsilon^2 + |z|^2)$, whose area is

$$\pi c \varepsilon^2 \log \left(1 + \frac{R^2}{4\varepsilon^2} \right).$$

The remaining area is $O(\varepsilon^2)$, proving the asserted area comparison. Any path from the origin to a point outside this smaller disk must first cross its boundary. Radial variation is bounded by Euclidean speed, so that initial portion has length at least

$$\sqrt{c} \varepsilon \int_0^{R/2} \frac{dr}{\sqrt{\varepsilon^2 + r^2}} = \sqrt{c} \varepsilon \operatorname{arsinh}(R/(2\varepsilon)) \asymp \varepsilon \log(1/\varepsilon).$$

This gives the diameter lower bound. The upper bound follows from [Lemma 13.18.7](#), since $A_\varepsilon(1 + \log(1/A_\varepsilon)) \asymp \varepsilon^2 \log^2(1/\varepsilon)$. Finally rescale by

$$\tilde{g}_\varepsilon = \frac{g_\varepsilon}{\varepsilon^2 \log^2(1/\varepsilon)}.$$

Its area is comparable to $1/\log(1/\varepsilon)$ and tends to zero, whereas its diameter is comparable to one. At the origin its ratio to h tends to infinity, so it has no uniform upper bound. $\square$

Let $V \rightarrow C$ be a holomorphic vector bundle of positive rank with a fixed smooth Hermitian fiber norm. Write $U_\delta = \{v \in V : |v| < \delta\}$ and identify its zero section with C .

Proposition 13.18.2 *Let g_j be smooth Hermitian metrics on U_{δ_0} . Suppose their restrictions to C satisfy*

$$g_j|_C \leq Mh, \quad A_j = \text{Area}_{g_j|_C}(C) \rightarrow 0$$

for a fixed $M > 0$. Suppose also that there are $B > 0$ and $0 < \alpha \leq 1$ such that, for every unit fiber vector v over any $x \in C$, the ray $\gamma_{x,v}(s) = sv$ satisfies

$$g_j(\gamma'_{x,v}(s), \gamma'_{x,v}(s)) \leq Bs^{2\alpha-2}, \quad 0 < s < \delta_0,$$

uniformly in j, x, v . Then

$$\text{diam}^{\text{int}}(U_\delta, g_j) \leq \frac{2\sqrt{B}}{\alpha} \delta^\alpha + K_h \sqrt{A_j(1 + \log(M/A_j))}, \quad 0 < \delta < \delta_0.$$

In particular,

$$\lim_{\delta \downarrow 0} \limsup_{j \rightarrow \infty} \text{diam}^{\text{int}}(U_\delta, g_j) = 0.$$

Proof A point of fiber radius $r < \delta$ joins its base point on the zero section along the radial segment, entirely inside U_δ . Its length is at most

$$\sqrt{B} \int_0^r s^{\alpha-1} ds = \frac{\sqrt{B}}{\alpha} r^\alpha.$$

The metric is smooth at the zero section for each j ; the integrable uniform bound controls the whole segment. Join the two base points by an almost minimizing path in $(C, g_j|_C)$. This path also lies in U_δ , and up to an arbitrarily small excess its length is bounded by [Lemma 13.18.7](#). Together with the two radial segments, this gives the asserted bound for the intrinsic diameter. Since $A_j(1 + \log(M/A_j)) \rightarrow 0$, taking $j \rightarrow \infty$ and then $\delta \downarrow 0$ proves the final assertion. $\square$

Return to the standard nodal small resolutions of [Section 13.18.1](#). On a nodal tube put $r^2 = \sum_{k=1}^4 |x_k \circ \pi|^2$, the squared bundle norm used in [Lemma 13.18.3](#). Let $V_\delta \subset Y$ be the nodal coordinate ball $\sum_k |x_k|^2 < \delta^2$. For sufficiently small δ , properness gives $\pi^{-1}(V_\delta) = \{r < \delta\}$. Write g_ε for the Riemannian metric associated to ω_ε . Its area on E_a is $\varepsilon \int_{E_a} \eta$ by [Corollary 13.18.1](#). Fix an area-one Hermitian metric h_a on E_a . If $g_\varepsilon|_{E_a} \leq Mh_a$ uniformly and the radial bound of [Proposition 13.18.2](#) holds with $\alpha = 1/2$, substitution in that proposition gives

$$\text{diam}^{\text{int}}(\{r < \delta\}, g_\varepsilon) \leq K\delta^{1/2} + K\sqrt{\varepsilon(1 + \log(1/\varepsilon))}$$

for sufficiently small ε and δ , with K independent of both. Under these two pointwise metric bounds, the condition on approximating neighborhoods in [Proposition 13.18.1](#)

therefore holds. The condition on punctured neighborhoods in the limiting metric does not follow from it, as the next example shows.

In the following surface example the volume form is fixed and the approximating tubes shrink, but the punctured neighborhoods of the contracted point keep a positive diameter in the limiting metric.

Example 13.18.2 There are a compact complex surface X , a holomorphic map $\pi : X \rightarrow Y = \mathbb{P}^2$ contracting a curve E to a point p , and smooth Hermitian metrics g_j, g_* on X with the following properties. The map is biholomorphic from $X \setminus E$ to $Y \setminus \{p\}$, and $g_j = g_*$ eventually on each compact subset of $X \setminus E$. Their associated Hermitian forms satisfy

$$\omega_j^2 = \omega_*^2.$$

The curve areas tend to zero, and the metrics have a uniform integrable radial bound near E . For a neighborhood basis V_δ of p , with $U_\delta = \pi^{-1}(V_\delta)$,

$$\lim_{\delta \downarrow 0} \limsup_{j \rightarrow \infty} \text{diam}^{\text{int}}(U_\delta, g_j) = 0.$$

Nevertheless, for the intrinsic distance d_0 of $g_0 = (\pi^{-1})^*g_*$ on $Y \setminus \{p\}$, there is $c > 0$ such that

$$\text{diam}_{d_0}(V_\delta \setminus \{p\}) \geq c$$

for every sufficiently small δ .

Proof Put $p = [1 : 0 : 0]$ and take the incidence surface

$$\begin{aligned} X &= \{([z_0 : z_1 : z_2], [u : v]) \in \mathbb{P}^2 \times \mathbb{P}^1 : z_1 v = z_2 u\}, \\ \pi([z], [u : v]) &= [z]. \end{aligned}$$

Off p , the second coordinate is $[z_1 : z_2]$, so π is biholomorphic there. Its exceptional curve is $E = \{p\} \times \mathbb{P}^1$. In the affine chart $z_0 = 1$, a chart of X is

$$(t, w) \mapsto ([1 : w : tw], [1 : t]).$$

The other chart is $([1 : t'w' : w'], [t' : 1])$, with $t' = 1/t$ and $w' = tw$ on their overlap. These are the charts of the tautological line bundle $L = \mathcal{O}_{\mathbb{P}^1}(-1)$. They also show smoothness along E ; smoothness elsewhere follows from the biholomorphism. Thus X is a compact smooth complex surface. Its connected dense complement $X \setminus E$ makes it connected.

Let $q : L \rightarrow \mathbb{P}^1$ be the bundle projection. Give L the norm induced by its tautological inclusion into $\mathbb{P}^1 \times \mathbb{C}^2$. In the first chart its squared norm is

$$r^2 = (1 + |t|^2)|w|^2 = |z_1|^2 + |z_2|^2.$$

Fix an area-one Hermitian metric h on $\mathbb{P}^1$. The Chern connection of the fiber norm defines a smooth semipositive Hermitian tensor k on L by the squared norm of the covariant fiber differential. Explicitly, with $\lambda = 1 + |t|^2$,

$$k = \lambda |dw + w\partial \log \lambda|^2.$$

Under $t' = 1/t$, $w' = tw$, the differential in this formula multiplies by t and λ divides by $|t|^2$, so the tensor is globally defined. It has complex rank one, is positive on nonzero vertical tangent vectors, and restricts to zero on TE . Consequently $q^*h + k$ is a smooth positive Hermitian metric on L .

Choose $0 < \delta_0 < 1$ and extend this metric from $U_{\delta_0} = \{r < \delta_0\}$ to a smooth Hermitian metric g_* on X . Such an extension follows by a smooth cutoff supported in a slightly larger bundle tube and a convex combination with any global Hermitian metric. It agrees exactly with $q^*h + k$ on U_{δ_0} .

Choose $0 < \varepsilon_j < 1$ tending to zero, with $2\varepsilon_j^2 < \delta_0$, and a smooth function $0 \leq \chi \leq 1$ on $[0, \infty)$, equal to zero on $[0, 1]$ and to one on $[4, \infty)$. Set

$$\begin{aligned} f_j(r) &= \varepsilon_j^2 + (1 - \varepsilon_j^2)\chi(r^2/\varepsilon_j^4), \\ g_j &= f_j q^*h + f_j^{-1}k, \end{aligned}$$

on U_{δ_0} , and set $g_j = g_*$ elsewhere. The function f_j is smooth at E , is at least ε_j^2 , and equals one for $r \geq 2\varepsilon_j^2$. Hence the metrics glue smoothly and are positive. They equal g_* eventually on every compact subset of $X \setminus E$.

Let β, κ be the Hermitian forms of q^*h, k . Their complex rank one gives $\beta^2 = \kappa^2 = 0$. On the tube,

$$(f_j\beta + f_j^{-1}\kappa)^2 = 2\beta \wedge \kappa = (\beta + \kappa)^2.$$

Outside it the metrics coincide. This proves the global volume identity. On E , the restriction is $g_j|_E = \varepsilon_j^2 h$, so its area is ε_j^2 .

For any unit fiber vector a , a radial ray $\gamma(s) = sa$ has k -squared speed one and zero base component. Thus its g_j -squared speed is $f_j(s)^{-1}$. If $s < 2\varepsilon_j^2$, this is at most $\varepsilon_j^{-2} \leq 2/s$; otherwise it is one, still at most $2/s$ for $s < \delta_0$. This is the uniform integrable radial bound with exponent $1/2$.

A radial segment of radius $r < \delta$ has length at most $r + 2\varepsilon_j$: its portion below $2\varepsilon_j^2$ has speed at most ε_j^{-1} and length at most $2\varepsilon_j$, and its remaining speed is one. Connect two points by their radial segments and an almost minimizing path on E . All three segments stay inside U_δ , giving

$$\text{diam}^{\text{int}}(U_\delta, g_j) \leq 2\delta + \varepsilon_j(4 + \text{diam}(\mathbb{P}^1, h)).$$

Taking $j \rightarrow \infty$ before $\delta \downarrow 0$ proves the asserted shrinking condition. The affine balls

$$V_\delta = \{[1 : z_1 : z_2] : |z_1|^2 + |z_2|^2 < \delta^2\}$$

have precisely these tubes as their preimages.

Let d_* be the global distance of the fixed smooth metric g_* . Choose distinct points $a, b \in E$, and put $c = d_*(a, b) > 0$. Choose points a_r, b_r of fiber norm $r > 0$ over these base points. They tend to a, b as $r \downarrow 0$. Every path in $Y \setminus \{p\}$ lifts to a path in $X \setminus E$ with the same g_0 -length as its g_* -length. Therefore

$$d_0(\pi(a_r), \pi(b_r)) \geq d_*(a_r, b_r) \longrightarrow c.$$

For any fixed $\delta > 0$, these two images lie in V_δ when $r < \delta$. Taking the supremum and then $r \downarrow 0$ gives its punctured diameter at least c . $\square$

13.19 Symmetry and the selected projective limit

Let ω be a Hermitian form and $0 \leq f \in L^p(dV)$, $p > 1$, a nonzero density. When the normalized equation $\text{MA}_\omega(u) = cf \, dV$ has several solutions, the positive-exponent equations $\text{MA}_\omega(u) = e^{\lambda u} f \, dV$ still have unique solutions, and their normalized limits as $\lambda \downarrow 0$ single out particular solutions of the normalized equation. We study this selection in the projective example of [Theorem 11.6.1](#), whose density vanishes on an open band. The starting point is a general observation: uniqueness at positive exponent preserves the symmetries of the data, and uniform compactness carries them to every normalized cluster limit. For the projective data this already gives a solution distinct from the two smooth solutions exchanged by the involution. The radial form of the equation then identifies the selected limit ([Theorem 13.19.1](#)) and shows that the positive-exponent solutions fail to be C^2 along the same hypersurfaces ([Proposition 13.19.2](#)).

Proposition 13.19.1 *Let ω be a Hermitian form on X , let dV be a smooth positive volume form, and let $0 \leq f \in L^p(dV)$, $p > 1$, be nonzero. Let $c > 0$ be the unique scalar for the bounded equation $\text{MA}_\omega(u) = cf \, dV$ ([Theorem 10.1.1](#)). For $\lambda > 0$ denote by u_λ the unique bounded solution of*

$$\text{MA}_\omega(u_\lambda) = e^{\lambda u_\lambda} f \, dV, \quad a_\lambda = u_\lambda - \sup_X u_\lambda.$$

The family $\{a_\lambda : 0 < \lambda \leq 1\}$ is relatively compact in $C(X)$. Every cluster limit as $\lambda \downarrow 0$ is a normalized bounded solution of $\text{MA}_\omega(a) = cf \, dV$.

Suppose a group G of biholomorphisms of X preserves ω and the measure $f \, dV$. Then every a_λ and every such cluster limit is G -invariant. In particular, the zero-exponent equation has a G -invariant normalized solution.

Proof The barriers of [Proposition 10.5.1](#) give a uniform oscillation bound for u_λ and uniform convergence $e^{\lambda u_\lambda} \rightarrow c$. Thus the equation densities are uniformly bounded in L^p for $0 < \lambda \leq 1$ and tend to cf in L^p as $\lambda \downarrow 0$. Apply [Theorem 10.3.2](#) to obtain relative compactness of a_λ in $C(X)$ and the asserted equation for every cluster limit.

For each $g \in G$, pullback of the positive-exponent equation shows that $u_\lambda \circ g$ solves the same equation. Its uniqueness gives $u_\lambda \circ g = u_\lambda$. Surjectivity of g preserves

the supremum, so $a_\lambda \circ g = a_\lambda$. Uniform convergence preserves these equalities for every g . Compactness gives at least one cluster limit as $\lambda \downarrow 0$, yielding the invariant solution. $\square$

Corollary 13.19.1 *On $\mathbb{P}(\mathbb{C}^2 \oplus \mathbb{C}^2)$, with block homogeneous coordinates $[A : B]$, the data in [Theorem 11.6.1](#) can be chosen so that the same zero-exponent equation has at least three distinct normalized bounded solutions. Two are smooth, and a third is Hölder continuous and fixed by the involution $\iota[A : B] = [B : A]$.*

Proof Use the radial coordinate r , rank-one forms P, Q, R , Fubini–Study form ω_X , and scalar functions F, x, y, z from [Sections 11.6.1](#) and [11.6.2](#). Set $w = F(r)$, $\omega_0 = xP + yQ + zR$, $H = \text{dd}^c w/2$, $A_0 = \omega_0 - H$ and $B_0 = \omega_0 + H$ as in [Section 11.6.3](#). The Hermitian form is $\omega = \omega_0 + \text{dd}^c \rho$, with $\rho = \varepsilon(r^2 - 1)\kappa(r)$ from [Section 11.6.4](#). Choose the cutoff κ even; all its required support and plateau properties are preserved by this choice. Then ρ is even, while $w = F(r)$ is odd. The involution sends r to $-r$, interchanges P, Q , and fixes R . The coefficient identities $x(-r) = y(r)$ and $z(-r) = z(r)$ show that $\iota^* \omega_0 = \omega_0$. Thus $\iota^* \omega = \omega$, and $\iota^* \omega_X = \omega_X$.

Since $\iota^* H = -H$, the involution interchanges A_0 and B_0 . Their cubes are equal, so $f\omega_X^3$ is invariant. It also interchanges $\tilde{u} = -w/2 - \rho$ and $\tilde{v} = w/2 - \rho$. These functions therefore have the same supremum, and the normalized solutions u, v are interchanged. They are distinct, so neither is invariant.

Apply [Proposition 13.19.1](#) to the group generated by ι . Here $c = 1$, as the two constructed solutions already have that scalar. An invariant cluster solution a cannot equal either u or v . Its bounded equation with smooth density gives Hölder regularity by [Theorem 13.4.1](#). This gives a third solution. Its regularity is determined in [Sections 13.19.1](#) and [13.19.2](#): it is $C^{1,1}$ but not C^2 . $\square$

To identify the whole normalized limit for these symmetric data, we now use the radial form of the equation. It determines the invariant solution even among bounded potentials whose differentiability is not known in advance.

13.19.1 The invariant projective solution

We keep the symmetric projective data of [Corollary 13.19.1](#). Thus $X = \mathbb{P}^3$ with block coordinates $[A : B]$ and Fubini–Study form ω_X ; on $U = \{A \neq 0, B \neq 0\}$ we use the radial coordinate r , the rank-one forms P, Q, R and the coefficients x, y, z, p, z_0 of [Sections 11.6.1](#) and [11.6.2](#). The function $\rho(r)$ is the even correction of [Section 11.6.4](#), not a barrier, and $\omega = \omega_0 + \text{dd}^c \rho$ is the resulting Hermitian form, with $\omega_0 = xP + yQ + zR$; the density f is that of [Theorem 11.6.1](#). Let K be the group generated by the block unitary group $U(2) \times U(2)$ and the exchange $\iota[A : B] = [B : A]$. Both preserve ω and $f\omega_X^3$. Denote by u_* the normalized ι -invariant solution of [Proposition 11.6.1](#), given by the symmetric transition pair $(-t_*, t_*)$.

Theorem 13.19.1 *For the symmetric projective data, u_* is the unique normalized bounded K -invariant solution of*

$$\mathrm{MA}_\omega(u) = f\omega_X^3.$$

If u_λ is the unique solution of

$$\mathrm{MA}_\omega(u_\lambda) = e^{\lambda u_\lambda} f\omega_X^3, \quad \lambda > 0,$$

then

$$u_\lambda - \sup_X u_\lambda \longrightarrow u_* \quad \text{uniformly as } \lambda \downarrow 0.$$

The selected limit u_ is $C^{1,1}$.*

Uniqueness holds only within the K -invariant class: by [Proposition 11.6.1](#), the same equation has uncountably many normalized solutions. Since a cluster limit is a priori only bounded, the proof needs the radial form of the equation for bounded invariant solutions, which we derive first. For a real scalar s , define the coefficient polynomial $A(r, s)$ and its primitive $\Phi(r, s)$ by

$$A(r, s) = (x(r) + s)(y(r) - s), \quad \Phi(r, s) = \int_0^s A(r, t) \, dt.$$

Partial derivatives of Φ with respect to r below keep s fixed.

Lemma 13.19.1 *Suppose u is a bounded block-unitary-invariant solution of the zero-exponent equation. On U write $u + \rho = G(r)$. Then G is locally Lipschitz, its derivative $h = G'$ has locally bounded variation, and its one-sided representatives satisfy*

$$-x(r) \leq h(r\pm) \leq y(r), \quad dh + z \, dr \geq 0.$$

In fact h is continuous. With

$$k(r) = \begin{cases} 0, & |r| \leq 1, \\ x(r)y(r)z(r), & |r| > 1, \end{cases}$$

it satisfies the distributional identity on $\mathbb{R}$

$$d(\Phi(r, h(r))) = (k(r) - A(r, h(r))z(r) + \partial_r \Phi(r, h(r))) \, dr. \quad (13.53)$$

On every open interval where $A(r, h(r)) > 0$, h is smooth and

$$h' = \frac{k(r)}{A(r, h)} - z.$$

Proof *Reduction to one variable.* Block-unitary orbits in U are exactly the level sets of r : normalize the sum of the squared norms of the two coordinate blocks, and map the two vectors of the same respective lengths by their unitary groups. Thus invariance gives a function G of one real variable.

On a compact r -interval, the radial direction annihilates P, Q , while R is strictly positive in that direction. Testing positivity of $\omega_0 + dd^c G(r)$ in this direction gives $G'' + z \geq 0$ as a one-dimensional distribution. One may obtain this first by smooth approximation of the scalar distribution and then by testing with nonnegative functions. Adding a twice integrated primitive of z makes G convex. A finite bounded convex function on an interval is locally Lipschitz, and its derivative is locally of bounded variation. The quasi-plurisubharmonic representative is the corresponding continuous representative. The horizontal directions give $x + h \geq 0, y - h \geq 0$ almost everywhere. Continuity of x, y and the one-sided limits of a function of bounded variation give these bounds for both one-sided representatives. The radial inequality is precisely $dh + z dr \geq 0$; in particular jumps of h can only be upward.

The radial form of the measure. We next justify the formula for the measure, including possible jumps. Identify U smoothly with $\mathbb{R} \times Y$, where $Y = \{r = 0\}$, by real scaling of one block. The forms P, Q are independent of r in this identification. So is $d^c r$: in local coordinates it is the angular differential of the relative complex scale plus fixed base terms. Therefore

$$P \wedge Q \wedge R = dr \wedge \nu,$$

where ν is a fixed smooth positive volume form on the compact orbit Y , with the orientation chosen by this equality.

For smooth G , the rank-one wedge formula gives the radial coefficient of its Monge–Ampère measure, after dividing by 6ν , as

$$A(r, h)(z + h') dr = A(r, h)z dr + d(\Phi(r, h)) - \partial_r \Phi(r, h) dr.$$

This identity passes to a locally Lipschitz G with the preceding lower Hessian bound. Indeed, convolve G on a slightly larger compact interval. The derivatives h_ϵ are uniformly bounded and converge to h almost everywhere and in every finite L^q space. Their second derivatives have a uniform lower bound. Consequently the functions $G_\epsilon(r)$ have a common quasi-plurisubharmonic lower Hessian bound on compact subsets of U , and converge uniformly to $G(r)$. A fixed smooth local correction and bounded Bedford–Taylor continuity give convergence of their signed products. On the right-hand side of the formula, the two ordinary terms converge in L^1 , and $\Phi(r, h_\epsilon) \rightarrow \Phi(r, h)$ in L^1 , giving distributional convergence of its derivative. This proves the same formula for the bounded product of G .

Continuity of h . After the same division by 6ν , the right-hand side $f\omega_X^3$ has radial coefficient $k(r) dr$. This gives (13.53), initially for the almost-everywhere representative of h . If h jumped at r_0 , the atom of its left side would be

$$\Phi(r_0, h(r_0+)) - \Phi(r_0, h(r_0-)) = \int_{h(r_0-)}^{h(r_0+)} (x(r_0) + s)(y(r_0) - s) ds.$$

The right side has no atom. An upward jump of positive size lies in $[-x(r_0), y(r_0)]$, where the integrand is strictly positive in the interior. Since $x + y > 0$ everywhere, such an integral is strictly positive. Thus there are no jumps. A locally bounded-variation

function whose jumps all vanish has a continuous representative here: its distributional derivative consists of an absolutely continuous measure and a nonnegative singular measure, so its one-sided representatives coincide at every point. We henceforth use this representative. In particular G is C^1 and $G' = h$ everywhere.

All coefficients on the right of (13.53) are now continuous, so $\Phi(r, h(r))$ is C^1 . Where $\partial_s \Phi = A > 0$, the implicit function theorem gives $h \in C^1$ and the stated ordinary differential equation. Smoothness then follows by the smooth coefficients of that equation. The function k is smooth, since the original density and its flat joins are smooth. $\square$

Proof (of Theorem 13.19.1) We first show that a normalized bounded K -invariant solution u coincides with u_* , by computing its slope h on the band $|r| \leq 1$ and outside it. Apply Lemma 13.19.1. Because ρ and u are invariant under block exchange, G is even, so h is odd and $h(0) = 0$.

The slope on the band. On $0 < r < 1$ we have $x = p > 0$ and $y = p + b \geq p > 0$. Starting from zero, as long as $-p < h < y$, the equation is $h' = -z_0$. Thus $h(r) = -\int_0^r z_0(s) ds$. This decreasing function cannot meet the positive upper boundary y . Its first meeting with the lower boundary $-p$ occurs at the unique $t_* \in (0, 1)$ satisfying

$$\int_0^{t_*} z_0(s) ds = p(t_*),$$

whose existence and uniqueness were proved in Proposition 11.6.1.

After that meeting, h must stay on $-p$ until $r = 1$. To prove it, suppose a connected component (a_0, b_0) of $\{h + p > 0\}$ lies to its right. Its left endpoint has $a_0 \geq t_*$ and $h(a_0) = -p(a_0) < 0$. Near that endpoint, $h < 0 < y$; hence on the component the interior equation applies for as long as $h < 0$. It forces $h' = -z_0 < 0$, so h cannot first reach zero. The equation therefore holds throughout the component. But then

$$(h + p)' = p' - z_0 < 0,$$

contradicting positivity of $h + p$ immediately to the right of its zero at a_0 . Thus $h = -p$ on $[t_*, 1]$. Oddness determines the entire negative half of the band. The slope on $[-1, 1]$ is exactly that of the symmetric explicit solution.

The slope outside the band. Here boundedness of u at the projective ends matters. On $r > 1$, $k = xyz > 0$. Neither horizontal coefficient can vanish at a finite point of this interval. For the lower one define

$$\Psi(r) = \int_{-x(r)}^{h(r)} A(r, s) ds \geq 0.$$

Equation (13.53) and the smooth lower endpoint show that Ψ is C^1 . If $h(r_0) = -x(r_0)$, its derivative at that point is $k(r_0) > 0$: the Az term vanishes, and the two partial- r terms agree at the common endpoint. This contradicts that the nonnegative C^1 function Ψ has an interior minimum zero there. The upper-endpoint integral $\int_{h(r)}^{y(r)} A(r, s) ds$ gives the same contradiction, with derivative $-k(r_0)$, when $h = y$. Thus $-x < h < y$

everywhere on $r > 1$, and the smooth ordinary differential equation of the lemma applies.

For $r \geq 2$ the background is Fubini–Study:

$$x = \sigma, \quad y = 1 - \sigma, \quad z = \sigma', \quad \sigma = \frac{e^r}{1 + e^r}.$$

Set $a = \sigma + h \in (0, 1)$. Its equation is

$$a(1 - a)a' = \sigma(1 - \sigma)\sigma' > 0.$$

Hence a is increasing and has a limit in $(0, 1]$ at $+\infty$. If that limit were less than one, $h = a - \sigma$ would approach a negative constant and its primitive G would be unbounded below, contrary to boundedness of u and ρ . The limit is therefore one. Integrating the equation gives

$$\frac{a^2}{2} - \frac{a^3}{3} = \frac{\sigma^2}{2} - \frac{\sigma^3}{3} + C.$$

Taking the limit at infinity gives $C = 0$. The scalar function $s^2/2 - s^3/3$ is strictly increasing on $(0, 1)$, so $a = \sigma$ and $h = 0$ for $r \geq 2$. Ordinary uniqueness propagates this zero solution throughout $r > 1$, since the coefficients are smooth and the two horizontal coefficients stay positive there. Oddness gives $h = 0$ on $r < -1$ as well.

We have proved that G' agrees everywhere with the symmetric explicit slope. Thus u differs from u_* by a constant on U . The two quasi-plurisubharmonic functions then agree up to that constant on X by their canonical representatives. Their supremum normalization removes the constant. This proves uniqueness within the bounded K -invariant class.

Convergence. Finally [Proposition 13.19.1](#) gives uniform precompactness of the normalized positive-exponent family. Every cluster limit solves the zero-exponent equation and is K -invariant, because the data are K -invariant. The scalar is one for these data. The uniqueness just proved identifies every cluster limit with u_* . If convergence of the whole family failed, a sequence staying a fixed positive uniform distance from u_* would have a convergent subsequence, contradicting that identification. This proves uniform convergence and the asserted $C^{1,1}$ regularity of the limit. $\square$

13.19.2 Second derivatives at positive exponent

On the band where the density vanishes, the exponential factor plays no role, and the radial equation determines the slope of the solution independently of the exponent. Consequently the positive-exponent solutions have the same failure of second differentiability as the selected limit u_* . We keep the notation A , Φ , k and the transition radius t_* of [Section 13.19.1](#).

Proposition 13.19.2 *For the symmetric projective data of [Theorem 13.19.1](#), let u_λ solve*

$$\mathrm{MA}_\omega(u_\lambda) = e^{\lambda u_\lambda} f \omega_X^3, \quad \lambda > 0.$$

On the open band $\{-1 < r < 1\}$, $u_\lambda - u_$ is constant. Both potentials are $C^{1,1}$ there and fail to be C^2 at every point of the two hypersurfaces $r = \pm t_*$. In particular, none of these positive-exponent solutions is a globally C^2 potential.*

Proof Uniqueness and invariance of the data imply that u_λ is K -invariant. Write $u_\lambda + \rho = G_\lambda(r)$ on U . The positivity argument in [Lemma 13.19.1](#) uses only boundedness and invariance, so G_λ is locally Lipschitz and $h_\lambda = G'_\lambda$ is locally of bounded variation, with

$$-x \leq h_\lambda(r \pm) \leq y, \quad dh_\lambda + z \, dr \geq 0.$$

Its weak flux equation is the same one, with the prescribed coefficient replaced by

$$k_\lambda(r) = e^{\lambda(G_\lambda(r) - \rho(r))} k(r).$$

Indeed, the scalar convolution and signed-product argument of that lemma is unchanged, and k_λ is exactly the radial coefficient of the right-hand measure. Since G_λ is bounded on compact r -intervals, k_λ is locally bounded. Hence the right side of the flux equation has no atoms. The same strictly positive jump integral eliminates every jump of h_λ . Thus h_λ is continuous and G_λ is C^1 . The coefficient k_λ is consequently continuous. Where $A(r, h_\lambda) > 0$, inversion of the C^1 flux gives

$$h'_\lambda = \frac{k_\lambda(r)}{A(r, h_\lambda)} - z.$$

On $-1 < r < 1$ the coefficient k_λ is identically zero. Exchange invariance gives $h_\lambda(0) = 0$ and oddness. On the positive half-band, the first-contact and no-departure arguments in the proof of [Theorem 13.19.1](#) apply verbatim: the first branch solves $h' = -z_0$, reaches $-p$ at t_* , and cannot leave that lower boundary to its right because $(h + p)' = p' - z_0 < 0$ on every proposed departure interval. Therefore

$$h_\lambda(r) = \begin{cases} p(r), & -1 < r \leq -t_*, \\ -\int_0^r z_0(s) \, ds, & -t_* \leq r \leq t_*, \\ -p(r), & t_* \leq r < 1. \end{cases}$$

This is the derivative of $u_* + \rho$. Its primitive differs from G_λ by one constant on the connected band. The claimed local $C^{1,1}$ regularity follows from the explicit slope.

At $t_* \in (0, 1)$ the two one-sided derivatives of this slope are

$$h'_\lambda(t_*-) = -z_0(t_*) < 0, \quad h'_\lambda(t_*+) = -p'(t_*) > 0.$$

These unequal derivatives prevent the scalar primitive from having a second derivative at t_* . Through every point of that level set, the submersion r provides a smooth curve

parametrized by r , transferring the failure to u_λ . Smooth ρ cannot cancel the jump. Oddness gives the conclusion at $-t_*$, and the identical slope proves it for u_* . $\square$

The zero set of f contains the whole band. This example therefore does not concern the smooth strictly positive densities in the Hermitian Calabi–Yau theorem. It does show why smoothness of a nonnegative density alone is insufficient for second-order regularity, even when the equation includes a strictly increasing exponential factor.

13.20 Local density and boundary control

Theorem 13.17.1 requires a smooth positive density on the whole regular locus of a global strict barrier, and the global minimum of the difference between the solution and the barrier drives its proof. If the density is smooth and positive only on a smaller open set, smoothness can fail there. A bounded solution with minimal singularities can be discontinuous on a ball where its density is constant (**Theorem 13.20.2**), and a locally Lipschitz plurisubharmonic function with constant density need not be C^1 (**Example 13.20.2**). Boundary data give a different route to regularity: if the solution has smooth boundary values on small balls, uniqueness for the bounded Dirichlet problem identifies it with the smooth Dirichlet solution.

In this section θ is a smooth real $(1, 1)$ -form on X , and $\rho \in \text{PSH}(X, \theta)$ satisfies $\theta + \text{dd}^c \rho \geq \varepsilon \omega$ for some $\varepsilon > 0$; in particular θ is big. We fix an open set $\Omega \subset X$ on which ρ is smooth and $d\theta = 0$.

13.20.1 Smooth boundary traces

Let $B \Subset \Omega$ be a coordinate ball. A function u on B has *boundary trace* g , a function on ∂B , if $u(z) \rightarrow g(\xi)$ as $B \ni z \rightarrow \xi$, for every $\xi \in \partial B$.

Theorem 13.20.1 *Suppose that $u \in \text{PSH}(X, \theta)$ has minimal ordinary singularities and*

$$\text{MA}_\theta(u) = f \, dV \quad \text{on } \Omega, \quad f \in C^\infty(\Omega), \quad f > 0.$$

Assume that Ω is covered by coordinate Euclidean balls $B_j \Subset \Omega$ such that θ has a smooth local potential near $\overline{B_j}$ and u has a smooth boundary trace on ∂B_j . Then $u \in C^\infty(\Omega)$ and $\theta + \text{dd}^c u > 0$ there.

Proof Since $\rho - \sup_X \rho \leq V_\theta$, minimal singularities give $u \geq \rho - C$ for a constant C . Thus u is locally bounded on Ω . Fix one of the balls, write it as $B = B_R(z_0)$, let g be the boundary trace of u on ∂B , and choose a smooth function h near $\overline{B}$ with $\text{dd}^c h = \theta$. By **Proposition 1.7.1**, the bounded plurisubharmonic function $v = u + h$ has Bedford–Taylor measure $f \, dV$ and smooth boundary trace $\varphi = g + h|_{\partial B}$.

For a smooth function V and the Euclidean volume $d\Lambda$,

$$(\mathrm{dd}^c V)^n = \frac{n!}{\pi^n} \det(V_{j\bar{k}}) d\Lambda. \quad (13.54)$$

The smooth Dirichlet theorem recalled in [Section 13.17.3](#), with zero background and density $f dV$, gives a smooth strictly plurisubharmonic V on $\bar{B}$ with $(\mathrm{dd}^c V)^n = f dV$ and boundary value φ ; a smooth extension Φ of φ gives the required strict subsolution $\Phi + A(|z - z_0|^2 - R^2)$ for large A . In dimension one this is the Dirichlet problem for the Poisson equation.

The difference $v - V$ tends to zero at every boundary point. Compactness of ∂B makes this convergence uniform near the boundary: otherwise a sequence approaching the boundary with difference bounded away from zero would have a subsequence approaching one fixed boundary point. Uniqueness for the bounded Dirichlet problem, that is, the Bedford–Taylor comparison principle, gives $v = V$. Therefore $u = V - h$ is smooth on B , and $\theta + \mathrm{dd}^c u = \mathrm{dd}^c V > 0$ there. Since the balls cover Ω , the theorem follows. $\square$

The proof uses minimal singularities only to obtain the local lower bound by ρ . Consequently the same conclusion holds for any solution already known to be locally bounded on Ω and satisfying the same trace condition. Closedness of θ on Ω provides the local potentials h once the coordinate balls are small enough; the background may be nonclosed elsewhere.

Example 13.20.1 For every $n \geq 1$, the trace criterion applies to a bounded continuous solution whose global density belongs to L^1 but to no L^p with $p > 1$, and which is not Hölder continuous at the points of $X \setminus \Omega$.

Let $E = \mathbb{C}/(\mathbb{Z} + i\mathbb{Z})$, $X = E^n$, and

$$\omega_j = \frac{i}{2\pi} dz_j \wedge d\bar{z}_j, \quad \theta = \sum_{j=1}^n \omega_j, \quad D = \{0\} \times E^{n-1}.$$

Take $dV = \theta^n$ and $\rho = 0$. Choose a nonnegative smooth cutoff χ supported in a coordinate disk $|z| < r_0 < 1$ of E and equal to one near zero. For $\beta > 0$, define

$$\psi(z) = \chi(z)(-\log |z|^2)^{-\beta} \quad (z \neq 0), \quad \psi(0) = 0,$$

and extend by zero. On the smaller punctured disk put $t = |z|^2$ and $L = -\log t$. Differentiation gives

$$\psi_{z\bar{z}} = \frac{\beta(\beta+1)}{tL^{\beta+2}}, \quad t \frac{d}{dt} L^{-\beta} = \beta L^{-\beta-1} \longrightarrow 0. \quad (13.55)$$

The first expression is integrable and the second is the radial flux. Integration by parts on punctured disks, using also $\psi \rightarrow 0$, shows that the distributional Hessian has no atom at zero. On the cutoff annulus its negative part is bounded. Hence, for a sufficiently small fixed $\eta > 0$, $u = \eta\psi(z_1)$ satisfies $\theta + \mathrm{dd}^c u \geq \theta/2$.

Only one coordinate contributes to $\mathrm{dd}^c u$. Locally approximate the bounded subharmonic potential in that coordinate from above and use [Theorem 1.6.1](#); the smooth diagonal determinant identity passes to the limit and yields

$$\mathrm{MA}_\theta(u) = f\theta^n, \quad f = 1 + \eta\psi_{z\bar{z}}(z_1).$$

Give f any positive value on the null set D . It is smooth and positive on $\Omega = X \setminus D$, where u is smooth and has smooth traces on all relatively compact coordinate balls. Near D its singular term is comparable to $|z_1|^{-2}(-\log|z_1|^2)^{-\beta-2}$. Its radial L^1 integral converges, whereas

$$\int_0^{r_0} s^{1-2p} (-\log s^2)^{-p(\beta+2)} ds = +\infty \quad (p > 1).$$

Also $(-\log|z|^2)^{-\beta}/|z|^\alpha \rightarrow +\infty$ for every $\alpha > 0$, so u is not Hölder at D . Finally, boundedness gives minimal ordinary singularities, since every global θ -plurisubharmonic competitor is bounded above.

13.20.2 A bounded discontinuous potential

We construct a bounded plurisubharmonic function on a bidisk whose Monge–Ampère measure is a constant multiple of Lebesgue measure, but which is discontinuous. The construction places logarithmic poles with summable weights at points accumulating at the origin; the resulting weight b vanishes at the poles but not at their limit. It is the local model for [Theorem 13.20.2](#).

Let $U = W = \{|z| < 1/4\} \subset \mathbb{C}$, with coordinates z and w on the two factors. Write dA for planar Lebesgue measure and set

$$a_k = \alpha_k = 2^{-k-4}, \quad A = \sum_{k \geq 1} \alpha_k = \frac{1}{16}, \quad S = \{0\} \cup \{a_k : k \geq 1\}.$$

Define on U

$$h(z) = \sum_{k \geq 1} \alpha_k \log |z - a_k|^2, \quad b(z) = e^{h(z)}, \quad (13.56)$$

with $b = 0$ where $h = -\infty$.

Lemma 13.20.1 *The function*

$$a(z) = \frac{1}{\pi} \int_U \log |z - \zeta|^2 b(\zeta)^{-1} dA(\zeta)$$

is bounded and continuous on U . The bounded function

$$P(z, w) = a(z) + b(z)|w|^2$$

is plurisubharmonic on $U \times W$, is smooth off $S \times W$, and satisfies

$$(\text{dd}^c P)^2 = \frac{2}{\pi^2} dA(z) dA(w). \quad (13.57)$$

It is discontinuous at every $(0, w_0)$ with $w_0 \neq 0$.

Proof The summands defining h are negative on U , so their partial sums decrease. Since $h(0) = 2 \sum_k \alpha_k \log a_k > -\infty$, the limit is subharmonic. On compact subsets of $U \setminus S$, the series and its derivatives converge uniformly, making h harmonic there. Moreover $0 \leq b \leq 1$, $b(a_k) = 0$, and $b(0) > 0$.

Weighted arithmetic–geometric mean gives, almost everywhere,

$$b(z)^{-2} \leq \sum_{k \geq 1} \frac{\alpha_k}{A} |z - a_k|^{-4A}. \quad (13.58)$$

For the countable inequality, first use the first N weights and assign the remaining weight to the factor 1; then let N increase. Since $4A = 1/4 < 2$, the integrals of the terms $|z - a_k|^{-4A}$ on U are bounded uniformly in k . Thus $b^{-1} \in L^2(U)$.

The logarithmic kernel has uniformly bounded L^2 norm on the translates of U that occur in the definition of a . Cauchy–Schwarz bounds a uniformly. Choose a compactly supported $L^2(\mathbb{C})$ kernel agreeing with $\log |z|^2$ on $U - U$. Translation continuity in L^2 , paired with $b^{-1} \mathbf{1}_U \in L^2$, proves continuity of a . The distribution identity $\partial_z \partial_{\bar{z}} \log |z|^2 = \pi \delta_0$ gives $a_{z\bar{z}} = b^{-1}$. In particular a is subharmonic and, by local elliptic regularity, smooth off S .

The second summand of P is $\exp(h(z) + \log |w|^2)$, a convex increasing composition of a plurisubharmonic function, extended by zero at its poles. Thus P is bounded and plurisubharmonic. At smooth points the harmonicity of $h = \log b$ gives $bb_{z\bar{z}} = |b_z|^2$, and hence

$$\det(P_{j\bar{k}}) = ba_{z\bar{z}} + |w|^2 (bb_{z\bar{z}} - |b_z|^2) = 1.$$

The set $S \times W$ is contained in the pole set of $h(z) + \log |z|$, a plurisubharmonic function not identically $-\infty$. It is also Lebesgue-null. Pluripolar nullity in [Theorem 1.6.1](#) and [\(13.54\)](#) prove [\(13.57\)](#) throughout the bidisk. Finally,

$$P(a_k, w_0) = a(a_k) \longrightarrow a(0) < a(0) + b(0)|w_0|^2 = P(0, w_0)$$

when $w_0 \neq 0$. □

13.20.3 Compact gluing

We now glue the local example into a compact torus by a regularized maximum with a quadratic function. The result is a bounded solution with minimal singularities whose density is constant on a ball, where the solution is discontinuous; in the transition region the density acquires singularities that destroy every L^p bound with $p > 1$.

We work on the flat complex torus $X = (\mathbb{C}/(\mathbb{Z} + i\mathbb{Z}))^2$, identifying a small coordinate ball with a ball in $U \times W$. For a smooth function v on the ball write $H_v = (v_{j\bar{k}})$ for its complex Hessian and I for the two-dimensional identity matrix.

Theorem 13.20.2 *There are a positive flat Kähler form θ on X , a bounded $u \in \text{PSH}(X, \theta)$ with minimal ordinary singularities, and a density $F > 0$ almost everywhere such that*

$$\text{MA}_\theta(u) = F\theta^2, \quad F \in L^1(X, \theta^2), \quad F \notin L^p(X, \theta^2) \quad (p > 1).$$

On an open coordinate ball Ω , F is a positive constant and u is discontinuous. The constant function $\rho = 0$ is a smooth strict barrier on X .

Proof Set $R = 1/8$ and choose M so that $P_0 = P + M$ satisfies $0 \leq P_0 \leq L$ on $B_R \Subset U \times W$ for some finite L . Choose $C > 0$ with

$$\frac{3CR^2}{16} \geq 2, \quad \frac{5CR^2}{16} > L + 2, \quad (13.59)$$

and put $Q(Z) = C(|Z|^2 - R^2/4)$ for $Z = (z, w)$. Let χ be the convolution of $|t|$ with an even nonnegative smooth probability kernel supported in $(-1, 1)$. Then χ is smooth and convex, $|\chi'| \leq 1$, $\chi'(0) = 0$, and $\chi(t) = |t|$ for $|t| \geq 1$. The function

$$m(s, t) = \frac{s + t + \chi(s - t)}{2}, \quad v = m(P_0, Q)$$

is bounded and plurisubharmonic, because m is convex and nondecreasing in each variable. The collar inequalities imply

$$v = P_0 \quad \text{on } B_{R/4}, \quad v = Q \quad \text{when } 3R/4 \leq |Z| < R.$$

Indeed, $Q \leq -2 \leq P_0 - 2$ on the first ball and $Q > L + 2 \geq P_0 + 2$ on the collar. Define

$$\theta = \frac{iC}{2\pi} (dz \wedge d\bar{z} + dw \wedge d\bar{w}), \quad u = \begin{cases} v - Q & \text{on } B_R, \\ 0 & \text{outside } B_R. \end{cases}$$

The collar identity makes u identically zero near ∂B_R and gives a global bounded potential with $\theta + \text{dd}^c u = \text{dd}^c v$ on the ball and $\theta + \text{dd}^c u = \theta$ outside. Thus u is admissible and has minimal ordinary singularities.

Outside the pluripolar set $(S \times W) \cap B_R$, set $\lambda = (1 + \chi'(P_0 - Q))/2$. Differentiating the regularized maximum gives

$$H_v = \lambda H_P + (1 - \lambda)CI + \frac{\chi''(P_0 - Q)}{2} \partial(P_0 - Q) \otimes \overline{\partial(P_0 - Q)}. \quad (13.60)$$

Both H_P and CI are positive definite there; the final term is positive semidefinite. Hence the classical density is positive. Bounded products charge no pluripolar sets, so there is no further measure on the exceptional set. Their mass on compact X is finite by [Proposition 1.7.1](#). This proves $\text{MA}_\theta(u) = F\theta^2$ for an almost-everywhere positive $F \in L^1$. On $\Omega = B_{R/4}$, [\(13.57\)](#) gives the representative $F = C^{-2}$. There $u = P + M - Q$ is discontinuous at $(0, w_0)$ for $0 < |w_0| < R/4$.

We prove failure of every global L^p directly in the transition region. For large k , set

$$m_k = a(a_k) + M \in [0, L], \quad w_k = (R^2/4 + m_k/C - |a_k|^2)^{1/2}, \quad Z_k = (a_k, w_k).$$

Then $w_k > 0$, $P_0(Z_k) = Q(Z_k) = m_k$, and [\(13.59\)](#) gives $|Z_k|^2 < 9R^2/16$. Near the isolated pole a_k ,

$$h(z) = \alpha_k \log |z - a_k|^2 + H_k(z),$$

where H_k is smooth and harmonic. Consequently b and P_0 are continuous near Z_k . There is a product neighborhood $V_k \Subset B_R$ of Z_k , with $|w|$ bounded below by a positive number, on which $1/4 \leq \lambda \leq 3/4$.

At smooth points of V_k , positivity and the two-dimensional determinant expansion give

$$\begin{aligned} \det H_v &\geq \det(\lambda H_P + (1 - \lambda)CI) \\ &\geq \lambda(1 - \lambda)C \operatorname{tr} H_P \geq c_k b_{z\bar{z}}, \end{aligned}$$

where $c_k > 0$ may depend on k and C . Here $P_{z\bar{z}} = b^{-1} + |w|^2 b_{z\bar{z}}$. With $\zeta = z - a_k$, shrink the first factor of V_k so that

$$b_{z\bar{z}} = |\zeta|^{2\alpha_k} e^{H_k} \left| \frac{\alpha_k}{\zeta} + \partial_z H_k \right|^2 \geq c'_k |\zeta|^{2\alpha_k - 2}$$

for some $c'_k > 0$. Since $F = C^{-2} \det H_v$, this lower bound implies $F \notin L^p$ whenever $p(1 - \alpha_k) \geq 1$: the w -disk has positive area and the radial integral in z contains

$$\int_0^{\delta_k} r^{1-2p(1-\alpha_k)} dr = +\infty.$$

For each $p > 1$ such a k exists because $\alpha_k \downarrow 0$. □

The bounded-product capacity estimate in [Section 1.6](#) also holds for the discontinuous potential P . Thus a first-order capacity bound, even together with a constant positive density, cannot supply the missing boundary control.

Example 13.20.2 On the bidisk in $\mathbb{C}^2$ with coordinates (z, w) , the function

$$H(z, w) = 2|z|(1 + |w|^2)$$

is locally Lipschitz, plurisubharmonic and not C^1 along $\{z = 0\}$. Plurisubharmonicity follows by writing its two summands as convex exponential compositions of $\log |z|$ and $\log |z| + \log |w|^2$. At $z \neq 0$,

$$H_{z\bar{z}} = \frac{1 + |w|^2}{2|z|}, \quad H_{w\bar{w}} = 2|z|, \quad |H_{z\bar{w}}|^2 = |w|^2.$$

Hence $\det(H_{j\bar{k}}) = 1$, and pluripolar nullity gives $(dd^c H)^2 = 2\pi^{-2} d\Lambda$ on the entire bidisk.

The last example rules out a purely local implication from Hölder continuity and a smooth positive density to smoothness; being local, it says nothing about the global hypotheses of [Theorem 13.17.1](#). Nor does [Theorem 13.20.2](#) contradict that theorem: there the solution is not locally Hölder continuous on the ball Ω , and its density is not smooth on the rest of X , which is the regular locus of the barrier $\rho = 0$. The trace criterion of [Theorem 13.20.1](#) avoids both global hypotheses by identifying the bounded solution with a smooth Dirichlet solution on each ball.

13.21 Equations with resolved logarithmic poles

We now prescribe a singularity type with logarithmic poles. If the poles become a divisor on a modification, the singular part can be removed there, and what remains is a smooth residual form. When this residual form is strictly positive, the bounded Hermitian theory on the modification provides the remaining bounded potential, and pushing forward solves the equation in the prescribed type.

In this section $n \geq 2$, and the background is a Hermitian form h on X . Let $\psi \leq 0$ be a quasi-plurisubharmonic function that is smooth outside a nonempty analytic set A , its pole set. Assume that there is a modification $\pi : Y \rightarrow X$, biholomorphic over $X \setminus A$, such that $\pi^{-1}(A)$ is the support $|D|$ of a simple normal crossing divisor $D = \sum_j D_j$ and

$$\psi \circ \pi = \sum_j c_j \log |s_j|^2 + b, \quad \beta = \pi^* h + dd^c b - \sum_j c_j \Theta_j > 0, \quad (13.61)$$

where $c_j > 0$, b is smooth on Y , s_j is a holomorphic section of $\mathcal{O}(D_j)$ defining D_j , and Θ_j is the curvature form of a smooth Hermitian metric on $\mathcal{O}(D_j)$, so that $dd^c \log |s_j|^2 = [D_j] - \Theta_j$. Thus β is the smooth part of the current $\pi^* h + dd^c(\psi \circ \pi)$, which we call the *residual form*.

Theorem 13.21.1 *For every nonzero nonnegative $f \in L^p(X, h^n)$, $p > 1$, there are $\kappa > 0$ and a normalized $u \in \text{PSH}(X, h)$ such that*

$$\text{MA}_h^{\text{ext}}(u) = \kappa f h^n, \quad u = \psi + O(1). \quad (13.62)$$

The lifted remainder $v = (u - \psi) \circ \pi$ extends Hölder continuously over Y , so u is locally Hölder on $X \setminus A$. Its current is

$$\pi^* h + \text{dd}^c(u \circ \pi) = \sum_j c_j [D_j] + \beta + \text{dd}^c v. \quad (13.63)$$

The positive residual current $\beta + \text{dd}^c v$ has zero Lelong numbers. If h is Kähler, then $\kappa = \int_Y \beta^n / \int_X f h^n$, and the normalized solution is unique among all normalized solutions u' of (13.62) with $u' = \psi + O(1)$, continuous or not. If the density $g = (f \circ \pi) \pi^* h^n / \beta^n$ is smooth and strictly positive on Y , the residual current $\beta + \text{dd}^c v$ may be chosen smooth and strictly positive.

Proof Define $J = \pi^* h^n / \beta^n$ and $g = (f \circ \pi)J$ off the exceptional set, assigning any value to g on that volume-zero set. The smooth nonnegative J is bounded. Change of variables on the biholomorphic locus gives

$$\int_Y g \beta^n = \int_X f h^n, \quad \int_Y g^p \beta^n \leq \|J\|_\infty^{p-1} \int_X f^p h^n. \quad (13.64)$$

Thus g is a nonzero L^p density. Theorems 10.1.1 and 13.4.1 give a bounded Hölder β -plurisubharmonic v and $\kappa > 0$ with $(\beta + \text{dd}^c v)^n = \kappa g \beta^n$. If h is Kähler, then β is Kähler and the mass identity fixes the stated scalar. For smooth positive g , Theorem 9.1.1 gives a smooth solution instead.

Set $u = \psi + v \circ \pi^{-1}$ on $X \setminus A$ and $u = -\infty$ on A . Push forward the positive current $\sum c_j [D_j] + \beta + \text{dd}^c v$. Pushforward commutes with dd^c , $\pi_* \pi^* h = h$, and the pushed locally integrable potential is u almost everywhere. Its quasi-plurisubharmonic representative equals $\psi + v \circ \pi^{-1}$ off A and tends to $-\infty$ at A because v is bounded. Hence $h + \text{dd}^c u \geq 0$ and $u = \psi + O(1)$ in the two-sided ordinary sense. The pulled-back identity is (13.63); bounded residuals have zero Lelong number. The equation holds off A by (13.64), and Theorem 6.1.1 extends it as (13.62). Subtracting $\sup_X u$ changes neither the equation nor the ordinary type.

For uniqueness when h is Kähler, let u' be a normalized solution with $u' = \psi + O(1)$. On $Y \setminus D$, $w = (u' - \psi) \circ \pi$ is bounded and β -plurisubharmonic. Since w is bounded, Lemma 1.3.7 extends it across D to a bounded β -plurisubharmonic function on Y . On each relatively compact subset of $Y \setminus D$, sufficiently deep truncations of u' equal u' . Thus locality in Theorem 6.1.1 gives the bounded equation $\kappa g \beta^n$ there; both sides give D zero mass. The global equation follows, its mass fixes κ , and closed full-mass uniqueness gives $w = v + \text{constant}$ as recalled in Section 33.17. Normalization fixes that constant. $\square$

The Hölder constants depend on the fixed geometry and divisor metrics, the c_j , a lower bound for the positivity of β , p , and the L^p norm of the density κg itself. In particular, the argument gives no estimate that is uniform as β degenerates or as κ becomes unbounded. In simple normal crossing coordinates a density comparable to $\prod_j |z_j|^{-2a_j}$ belongs locally to L^p exactly when

$$pa_j < 1 \quad \text{for every } j, \quad (13.65)$$

by the factors $\int_0^\epsilon r_j^{1-2pa_j} dr_j$. A smooth positive density f on X need not give a strictly positive g on Y , since the Jacobian factor $J = \pi^* h^n / \beta^n$ of the proof can vanish on the exceptional set.

Example 13.21.1 Take $X = \mathbb{P}^n$, $h = \lambda \omega_{\text{FS}}$, $\int_X \omega_{\text{FS}}^n = 1$, and $0 < c < \lambda$. Put

$$\psi_c = c \log \frac{\sum_{j=1}^n |Z_j|^2}{\sum_{j=0}^n |Z_j|^2}.$$

Its pole is $P = [1 : 0 : \cdots : 0]$. On the point blowup $\pi : Y \rightarrow X$, let $q : Y \rightarrow \mathbb{P}^{n-1}$ be the direction map. In affine blowup coordinates $x = (z, zw)$, Poincaré–Lelong gives

$$\pi^* h + \text{dd}^c(\psi_c \circ \pi) = c[E] + (\lambda - c)\pi^* \omega_{\text{FS}} + cq^* \omega_{\text{FS}}.$$

The residual form $\beta = (\lambda - c)\pi^* \omega_{\text{FS}} + cq^* \omega_{\text{FS}}$ is positive: $\pi^* \omega_{\text{FS}}$ is positive in the directions normal to E , and $q^* \omega_{\text{FS}}$ in the directions tangent to E . Write $H = \pi^* [\omega_{\text{FS}}]$. Since $H|_E = 0$ and $E^n = (-1)^{n-1}$, its mass is

$$\int_Y ((\lambda - c)\pi^* \omega_{\text{FS}} + cq^* \omega_{\text{FS}})^n = \lambda^n - c^n. \quad (13.66)$$

Hence, for every nonzero nonnegative $f \in L^p$ with $\int_X f h^n = \lambda^n - c^n$, **Theorem 13.21.1** gives $\kappa = 1$ and a solution of $\text{MA}_h^{\text{ext}}(u) = f h^n$ with the nonminimal type $u = \psi_c + O(1)$.

For an explicit solution, choose a smooth function v on Y with $v|_E$ nonconstant, small enough that $S = \beta + \text{dd}^c v$ is still positive, and put $u = \psi_c + v \circ \pi^{-1}$ off P . The density f of its measure, given by $f \circ \pi = S^n / \pi^* h^n$ off E , lies in every L^p with $1 < p < n/(n-1)$: $\pi^* h^n$ vanishes to order $|z|^{2(n-1)}$ along E , so the local integral of f^p is finite precisely when $(n-1)(p-1) < 1$. Different directions of approach to P give different limits of $u - \psi_c$. The divisor $c[E]$ of the current upstairs leaves no divisor downstairs, since E is contracted to a point. On $X \setminus \{P\}$, where u is smooth and strictly h -plurisubharmonic, the Hermitian metric $h + \text{dd}^c u$ is isometric to $(Y \setminus E, S)$. Its metric completion is Y with the metric S , so the whole divisor E is restored: removing the smooth real codimension-two submanifold E does not change the infimum of path lengths in Y . Finally, if h is replaced by a sufficiently small nonclosed perturbation, both h and the residual form remain positive, so the existence part of **Theorem 13.21.1** still applies.

13.21.1 Residual mass

When h is not Kähler, the scalar in **Theorem 13.21.1** is still determined by masses if h satisfies the power condition $\text{dd}^c(h^k) = 0$, $1 \leq k \leq n-1$, of **Theorem 2.2.2**, which fixes the mass of every bounded solution. The condition persists under pullback and under addition of a smooth closed form: expand each power and apply the original

identities to its terms. For $n = 2$ the condition is simply $\text{dd}^c h = 0$, so it includes the nonclosed Hopf metric of [Proposition 19.6.1](#). The residual form then has strictly smaller mass than h , the difference being carried by the divisor.

Proposition 13.21.1 *Under (13.61), assume $\text{dd}^c(h^k) = 0$ for $1 \leq k \leq n-1$, and put $H = \pi^* h$. Then*

$$\int_X h^n - \int_Y \beta^n = \sum_j c_j \sum_{i=0}^{n-1} \int_{D_j} H^i \wedge \beta^{n-1-i} > 0. \quad (13.67)$$

Thus the constructed solution of [Theorem 13.21.1](#) has $\kappa = \int_Y \beta^n / \int_X f h^n$. If $\int_X f h^n = \int_X h^n$, its scalar is strictly less than one.

Proof Let $C = \sum_j c_j \Theta_j - \text{dd}^c b$, so $\beta = H - C$ with C closed. The mixed forms $Q_i = H^i \wedge \beta^{n-1-i}$ satisfy $\text{dd}^c Q_i = 0$: expand $\beta = H - C$ and apply the power condition to each H^k . With $\Psi = \psi \circ \pi$, $\text{dd}^c \Psi = \sum_j c_j [D_j] - C$. Distributional integration by parts against the smooth dd^c -closed Q_i gives

$$\int_Y (H^n - \beta^n) = \sum_i \int_Y C \wedge Q_i = \sum_j c_j \sum_i \int_{D_j} Q_i.$$

Change of variables gives $\int_Y H^n = \int_X h^n$. Every integrand on the right is nonnegative, since H is semipositive and β positive; the $i = 0$ term on each nonempty D_j is strictly positive. This includes exceptional divisors. By [Theorem 2.2.2](#), the residual solution has mass $\int_Y \beta^n$, giving the scalar. $\square$

13.22 Minimal singularities on blowups

On a blowup, the background itself can force an exceptional divisor into every positive current. The coefficient of this divisor is then part of the minimal ordinary type, while the rest of the potential descends to the target of the blowup, so the equation reduces to one on the target. The density changes by the Jacobian of the blowup, which determines the loss of integrability.

In this section the roles of the letters differ from those in [Section 13.21](#): X is a blowup and Y its target. Let (Y, h) be a connected compact Hermitian n -fold, $n \geq 2$, let $Z \subset Y$ be a connected smooth center of codimension $r \geq 2$, and write $\pi : X = \text{Bl}_Z Y \rightarrow Y$ for the blowup, with exceptional divisor E . Let s_E be the canonical section of $\mathcal{O}(E)$, choose a smooth Hermitian metric on $\mathcal{O}(E)$ with curvature form Θ_E , so that $\text{dd}^c \log |s_E|^2 = [E] - \Theta_E$, put $L = \log |s_E|^2$, and fix $c > 0$. The smooth background

$$\theta = \pi^* h + c \Theta_E \quad (13.68)$$

can be indefinite, and it is nonclosed when h is nonclosed. Positivity is imposed on $\theta + \text{dd}^c u$, not on θ .

Proposition 13.22.1 *Every $u \in \text{PSH}(X, \theta)$ has, up to an additive constant, a unique h -plurisubharmonic target potential q such that*

$$u = cL + q \circ \pi + C, \quad \theta + \text{dd}^c u = \pi^*(h + \text{dd}^c q) + c[E]. \quad (13.69)$$

The potentials with minimal ordinary singularities are exactly those of the form $cL + O(1)$, and u is one of them if and only if q is bounded. There is a strict θ -plurisubharmonic barrier with logarithmic coefficient $c + \delta$ for some $\delta > 0$.

Proof Put $T = \theta + \text{dd}^c u$ and $q = \pi_*(u - cL)$ as a scalar distribution. The latter is locally integrable: off Z it is the inverse-coordinate function, and a smooth target volume pulls back with bounded Jacobian, so its absolute integral is controlled by that of $u - cL$ on X . Since $\pi_*[E] = 0$,

$$S = \pi_* T = h + \text{dd}^c q \geq 0.$$

A smooth local strictly plurisubharmonic shift gives a quasi-plurisubharmonic representative of q . Its pullback $q \circ \pi$ is not identically $-\infty$ and satisfies $\pi^*(h + \text{dd}^c q) \geq 0$, by [Lemma 1.22.1](#): since π is dominant, the composition of a local plurisubharmonic function with π is again plurisubharmonic and not identically $-\infty$.

Off E , $T = \pi^* S$. The difference is an order-zero current supported on E , and it is closed: both derivatives equal $\pi^* dh$. To identify it, write $R = T - \pi^* S$. In a chart where $E = \{z = 0\}$, order zero gives $zR = \bar{z}R = 0$. Closedness then gives $d\bar{z} \wedge R = d\bar{z} \wedge R = 0$. Thus only its normal $(1, 1)$ coefficient remains, a measure on E ; the tangential equations in $dR = 0$ make that measure a constant multiple of integration on E . Connectedness of E identifies one constant a globally, so $R = a[E]$. Its cohomology class is $c[E]$. On a line in an exceptional fiber, $\mathcal{O}(E)$ has degree -1 , so $[E]$ is nonzero and $a = c$. The difference between the two scalar potentials in (13.69) has dd^c zero. Local elliptic regularity makes it pluriharmonic; compactness and connectedness make it constant.

Since $h > 0$, $q = 0$ is admissible, and every h -plurisubharmonic q is bounded above on compact Y . Hence cL is minimal and two-sided bounded comparison with it is exactly boundedness of q . For the barrier choose the divisor metric so that $-\Theta_E$ is positive on the vertical tangent bundle of $E \rightarrow Z$, using the tautological $\mathcal{O}(-1)$. In adapted coordinates

$$\pi(y, z, w) = (y, z, zw), \quad (13.70)$$

$\pi^* h$ controls the nonvertical directions and $|z|^2 |dw|^2$. For small $\delta > 0$, the vertical positivity of $-\delta\Theta_E$ dominates its mixed errors by completing the square; away from E , compactness allows the same δ . Thus $\pi^* h - \delta\Theta_E > 0$, and the potential $(c + \delta)L$ has current $(c + \delta)[E] + \pi^* h - \delta\Theta_E$, dominating a positive Hermitian form. Changing the divisor metric changes this potential only by a smooth correction. $\square$

Theorem 13.22.1 *Fix a smooth positive volume form μ on X and a nonzero nonnegative $f \in L^p(X, \mu)$, $p > 1$. There exist $\kappa > 0$ and a normalized minimal-type solution*

of

$$\mathrm{MA}_\theta^{\mathrm{ext}}(u) = \kappa f \mu, \quad u = cL + q \circ \pi + C, \quad (13.71)$$

where q is Hölder on Y . The divisor coefficient is exactly c . In (13.70), $u - cL = q(y, 0) + C + O(|z|^\alpha)$ on smaller charts for some $\alpha > 0$, so its limit is constant along each exceptional fiber.

If $\pi_*(f\mu) = Fh^n$, then $F \in L^s(Y, h^n)$ for every

$$1 < s < \frac{rp}{(r-1)p+1}. \quad (13.72)$$

For a point center, data bounded above and below by positive constants near E attain the strict threshold $s < n/(n-1)$, and for finite p no strictly larger universal exponent than $np/((n-1)p+1)$ can be guaranteed. If h is Kähler, the class $[\theta]$ is big and non-nef, has volume $\int_Y h^n$, and $\kappa = \int_Y h^n / \int_X f \mu$; the normalized solution is unique among all normalized solutions of (13.71) with minimal ordinary singularities. Under $\mathrm{dd}^c(h^j) = 0$, $1 \leq j \leq n-1$, the scalar of the constructed solution has the same integral formula.

Proof Integrability and existence. In (13.70) the complex Jacobian is z^{r-1} . Put $J = \pi^* h^n / \mu$, so $J \asymp |z|^{2(r-1)}$ on nested charts and $F \circ \pi = f/J$ off E . For $1 < s < p$, change of variables and Hölder's inequality give

$$\int_Y F^s h^n = \int_X f^s J^{1-s} \mu \quad (13.73)$$

$$\leq \|f\|_{L^p(\mu)}^s \left(\int_X J^{-(s-1)p/(p-s)} \mu \right)^{(p-s)/p}. \quad (13.74)$$

The normal complex integral is finite precisely if $(r-1)(s-1)p/(p-s) < 1$, which is (13.72). Theorems 10.1.1 and 13.4.1 on (Y, h) supply q and κ with $(h + \mathrm{dd}^c q)^n = \kappa F h^n$. Use (13.69) off E and Theorem 6.1.1 across it. Hölder continuity gives $q(\pi(y, z, w)) = q(y, 0) + O(|z|^\alpha)$ uniformly on smaller charts.

Sharpness of the exponent. For f bounded above and below by positive constants near the exceptional divisor of a point center, F is comparable to $\mathrm{dist}_h(\cdot, Z)^{-2(n-1)}$ near Z , giving the strict threshold. More generally, $f \asymp |s_E|^{-2a}$ with $0 \leq a < 1/p$ belongs to L^p upstairs, while its pushforward has threshold $s < n/(n-1+a)$. Letting $a \uparrow 1/p$ proves the stated limitation; it makes no finite- p endpoint assertion.

The Kähler case. When h is Kähler, the positive form $\pi^* h - \delta \Theta_E$ makes $[\theta]$ big. Its degree on an exceptional-fiber line is $-c$, so it is not nef. The minimal current $c[E] + \pi^* h$ has non-pluripolar top mass $\int_Y h^n$, and the minimal mass theorem identifies this with $\mathrm{vol}([\theta])$ as recalled in Section 33.14. Full-mass uniqueness and mass integration fix the scalar and normalized current as recalled in Section 33.17. A normalized solution of minimal ordinary type, possibly discontinuous, still has bounded q by Proposition 13.22.1; on every relatively compact set off E , deep truncations equal that competitor, so locality in Theorem 6.1.1 gives the bounded target equation off Z . Both target measures give Z zero mass, so closed uniqueness applies globally. If only the power conditions hold, Theorem 2.2.2 fixes the scalar

of the constructed solution. Quantitative Hölder bounds depend on κF , not on an unnormalized F alone. $\square$

For the prescribed pullback measure $\pi^*(h^n)$, choose $q = 0$ and $\kappa = 1$. The current is $c[E] + \pi^*h$. Its smooth part π^*h is degenerate on E exactly in the directions tangent to the exceptional fibers, and its density relative to a smooth volume form is $|z|^{2(r-1)}$ times a smooth positive factor. On $X \setminus E$, where the solution $u = cL$ is smooth and strictly θ -plurisubharmonic, the metric $\theta + dd^c u = \pi^*h$ is isometric to $(Y \setminus Z, h)$; its metric completion is Y , so each exceptional fiber collapses to a point of Z . The distance to E is comparable to $|z|$ on bounded adapted charts. Neither the density order nor this distance exponent depends on c .

Example 13.22.1 If $n = 2$ and Z is a point on a compact Kähler surface, $[\theta] = \pi^*[h] + c[E]$ has Zariski positive part $\pi^*[h]$ and negative part cE : $E^2 = -1$ and $\pi^*[h] \cdot E = 0$. Its volume is $\int_Y h^2$, although it is non-nef. The solution with $\kappa = 1$ for the measure $\pi^*(h^2)$ has logarithmic coefficient exactly c , its density vanishes to order $|z|^2$ along E , and the completion of its metric on $X \setminus E$ collapses E to the point Z . The stronger barrier from **Proposition 13.22.1** has coefficient $c + \delta$.

Theorem 13.22.2 *Let $\pi : Y_m \rightarrow Y_0$ be a finite nonempty sequence of blowups of connected smooth centers of codimensions $r_j \geq 2$ over a compact Hermitian (Y_0, h_0) . Let E_j be the exceptional divisor at stage j , let $\pi_{>j}$ denote the subsequent map, choose $a_j > 0$, and set*

$$\Delta = \sum_j a_j \pi_{>j}^* E_j, \quad \text{dd}^c L_\Delta = [\Delta] - \Theta_\Delta, \quad \theta = \pi^* h_0 + \Theta_\Delta,$$

where $L_\Delta = \sum_j a_j \log |s_j|^2$, with s_j the canonical section of $\pi_{>j}^* \mathcal{O}(E_j)$ for a smooth Hermitian metric, and Θ_Δ is the corresponding combination of curvature forms. Every θ -positive current is $\pi^*(h_0 + \text{dd}^c q) + [\Delta]$ and every potential is $L_\Delta + q \circ \pi + C$, with $q \in \text{PSH}(Y_0, h_0)$. Minimal ordinary type is exactly $L_\Delta + O(1)$, equivalent to bounded q . For potentials of this type, every prime exceptional coefficient is the one prescribed by the effective total transform Δ . There is a strict barrier with divisor $\Delta + B$ for an effective exceptional B positive on every exceptional component. For nonzero nonnegative upstairs L^p data, $p > 1$, a minimal solution has Hölder q , with pushed density in every L^s satisfying

$$1 < s < \frac{Rp}{(R-1)p+1}, \quad R = \prod_j r_j. \quad (13.75)$$

For Kähler h_0 the mass, scalar, and closed full-mass uniqueness are those of the target; the power conditions on h_0 fix the scalar for the constructed nonclosed solution. For the pullback measure $\pi^*(h_0^n)$, the metric $\pi^* h_0$ on the complement of the exceptional set has metric completion Y_0 , each fiber collapsing to a point, and the zero divisor of the density is that of the squared modulus of the holomorphic Jacobian, independently of the a_j .

Proof Apply [Proposition 13.22.1](#) successively, allowing an intermediate smooth background to be indefinite. The difference between each current and the pullback of its pushforward is closed of order zero, and exceptional-fiber degree fixes its coefficient. Pullback of earlier divisor currents produces the total transforms, proving the representation without an SNC requirement. The initial $q = 0$ is admissible; upper bounds on compact targets prove minimality and the bounded- q criterion. At SNC charts this is the usual sum of logarithms.

At each stage the positive vertical curvature construction in [Proposition 13.22.1](#) gives $h_j = \pi_j^* h_{j-1} - \delta_j \Theta_{E_j} > 0$ for a sufficiently small $\delta_j > 0$. Expanding yields $h_m = \pi^* h_0 - \Theta_B$ for $B = \sum_j \delta_j \pi_{>j}^* E_j$, effective with a positive coefficient on every exceptional component. Hence $h_m + [\Delta + B]$ is the strict barrier current. The Jacobian calculation and Hölder estimate apply stagewise. If $s = rp/((r-1)p+1)$, then $1 - 1/s = (1 - 1/p)/r$; iteration over the stages gives (13.75), with strict inequality. The target Hölder equation, mass and uniqueness are obtained as in [Theorem 13.22.1](#). For the pullback measure take $q = 0$ and use the target path comparison away from the exceptional set. The Jacobian fixes the density, while $[\Delta]$ fixes the divisor current; these are independent pieces of the equation. $\square$

13.23 Representing measures in an ordinary type

We return to the general setting of the chapter, with the Hermitian form ω fixed at its beginning. Locally, every finite non-pluripolar measure is absolutely continuous with respect to the Monge–Ampère measure of a bounded plurisubharmonic function ([Lemma 1.6.2](#)). We globalize this statement in a prescribed ordinary type. The local potentials are glued to a strictly θ -plurisubharmonic potential lying below the reference and are then truncated relative to the reference. A decreasing convex sum of the resulting countable family has a Monge–Ampère measure that dominates every local piece in the sense of absolute continuity. Its potential has the prescribed ordinary type, and the given measure has an integrable density with respect to its Monge–Ampère measure.

Proposition 13.23.1 *Let $\theta \geq 0$ be a smooth big real $(1,1)$ -form, and let $\varphi \in \text{PSH}(X, \theta)$ be such that the envelope $P_{\epsilon\theta}(\varphi)$ of [Section 1.19](#) is not identically $-\infty$ for some $0 < \epsilon < 1$. For every finite non-pluripolar measure μ there are*

$$\psi \in \text{PSH}(X, \theta), \quad \psi \sim \varphi, \quad 0 \leq f \in L^1(\text{MA}_\theta^{\text{ext}}(\psi))$$

such that

$$\mu = f \text{MA}_\theta^{\text{ext}}(\psi).$$

The measure $\text{MA}_\theta^{\text{ext}}(\psi)$ may have infinite mass, but the density f is integrable with respect to it.

Proof Translate φ below zero. Put $q = P_{\epsilon\theta}(\varphi) \leq \varphi$, and choose a strict big potential $\rho \leq 0$ with $\theta + \text{dd}^c \rho \geq a\omega$, where $a > 0$. Then

$$s = q + (1 - \epsilon)\rho \leq \varphi, \quad \theta + \text{dd}^c s \geq (1 - \epsilon)a\omega.$$

In particular s is θ -plurisubharmonic and not identically $-\infty$. Its pole set is pluripolar, as is that of φ , so both are negligible for μ .

Cover X by finitely many closed coordinate balls K_i , each contained in a larger coordinate ball B_i . Apply [Lemma 1.6.2](#) to $\mu_i = \mathbf{1}_{K_i}\mu$. This gives bounded local plurisubharmonic v_i , normalized by $1 \leq v_i \leq 2$, with

$$\mu_i \ll v_i := (\text{dd}^c v_i)^n.$$

Take a smooth cutoff χ_i which is zero near K_i and -3 on a boundary collar of B_i . Choose $\delta_i > 0$ so small that

$$\theta + \text{dd}^c (s + \delta_i(v_i + \chi_i)) \geq \frac{1}{2}(1 - \epsilon)a\omega + \delta_i \text{dd}^c v_i.$$

Let S_i equal $\max(s, s + \delta_i(v_i + \chi_i))$ on B_i and s elsewhere. The boundary collar makes this a global θ -plurisubharmonic function. Since $\chi_i \leq 0$ may be arranged,

$$s \leq S_i \leq s + 2\delta_i \leq \varphi + 2\delta_i.$$

For every positive integer m , set

$$q_{i,m} = \max(\varphi - m, S_i) - 2\delta_i.$$

These potentials have the same ordinary type as φ , and

$$\varphi - m - 2\delta_i \leq q_{i,m} \leq \varphi. \quad (13.76)$$

On a neighborhood of K_i , $S_i = s + \delta_i v_i$ away from the pole set of s . Let

$$D_{i,m} = \{s + \delta_i v_i > \varphi - m\}$$

in that neighborhood, restricting to points where the potentials are finite. This is a plurifinely open set there. Locality and positive mixed products give

$$\mathbf{1}_{D_{i,m}} \text{MA}_{\theta}^{\text{ext}}(q_{i,m}) \geq \delta_i^n \mathbf{1}_{D_{i,m}} v_i. \quad (13.77)$$

Here s need not be bounded. After a local smooth correction, the positive product inequality holds at every common finite truncation level of s and the bounded potential v_i . Exhaust the complement of the pole set of s . The measure v_i is non-pluripolar, so it loses no mass in that exhaustion. Then restrict the resulting inequality by plurifine locality. This proves (13.77) for the extended measures.

For μ_i -almost every point of K_i , both s and φ are finite, and hence that point belongs to $D_{i,m}$ for some m . Consequently, a Borel set which is null for every $\text{MA}_{\theta}^{\text{ext}}(q_{i,m})$ is null for every μ_i , and therefore for μ .

Enumerate the countable family $q_{i,m}$ as q_k , and write its bounds as $\varphi - C_k \leq q_k \leq \varphi$ with $C_k < \infty$. Choose positive t_k such that

$$\sum_k t_k < 1, \quad B := \sum_k t_k C_k < \infty.$$

The finite convex combinations

$$\psi_N = \sum_{k=1}^N t_k q_k + \left(1 - \sum_{k=1}^N t_k\right) \varphi$$

decrease and lie between $\varphi - B$ and φ . Their limit ψ is θ -plurisubharmonic, satisfies $\psi \geq \varphi - B$, and hence $\psi \sim \varphi$. For any fixed k , separate its summand to write

$$\psi = t_k q_k + (1 - t_k) w_k, \quad w_k \in \text{PSH}(X, \theta), \quad w_k \sim \varphi.$$

The remainder is obtained by the same decreasing convex-sum construction. Positive non-pluripolar mixed products give

$$\text{MA}_{\theta}^{\text{ext}}(\psi) \geq t_k^n \text{MA}_{\theta}^{\text{ext}}(q_k).$$

This is valid also for infinite measures: first restrict away from the common pole set, which is the pole set of φ by the ordinary-type bounds, and then exhaust by finite truncations. All measures ignore that pole set. The preceding null-set conclusion now gives $\mu \ll \text{MA}_\theta^{\text{ext}}(\psi)$.

By **Theorem 6.1.1**, the measure $\text{MA}_\theta^{\text{ext}}(\psi)$ is σ -finite. The Radon–Nikodym theorem applies to this σ -finite measure and the finite μ . It gives a nonnegative density f with

$$\int_X f \text{MA}_\theta^{\text{ext}}(\psi) = \mu(X) < \infty,$$

as claimed. If $\mu = 0$, one may simply take $\psi = \varphi$ and $f = 0$. $\square$

Lemma 13.23.1 *Let $\theta \geq 0$ be a smooth big real $(1, 1)$ -form, and let μ be a finite non-pluripolar measure on X . There are a bounded $\psi \in \text{PSH}(X, \theta)$ and a nonnegative $f \in L^1(\text{MA}_\theta(\psi))$ such that*

$$\mu = f \text{MA}_\theta(\psi).$$

Proof Apply **Proposition 13.23.1** with $\varphi = 0$. Semipositivity of θ gives $P_{\epsilon\theta}(0) = 0$ for every $0 < \epsilon < 1$, and $\psi \sim 0$ means that ψ is bounded. $\square$

These representations give only an L^1 density, whereas **Theorem 13.9.1** requires a bounded density with respect to the measure of a bounded potential; for an unbounded prescribed type, moreover, the representing potential is itself unbounded. The existence argument for general measures in **Section 30.6** therefore uses a bounded Hermitian reference and relative compactness instead.

13.24 Lower mass and solvability for all measures

Throughout the rest of the chapter, h denotes a Hermitian form on X , used as the background, and densities are taken with respect to the fixed smooth positive probability volume form dV ; the sections that use another background say so explicitly. No singularity type is prescribed: the unknown potentials range over all of $\text{PSH}(X, h)$. Constants belong to $\text{PSH}(X, h)$, and every $u \in \text{PSH}(X, h)$ is bounded above, so $u \preceq v$ for every bounded $v \in \text{PSH}(X, h)$.

The masses of bounded potentials are measured by the lower and upper masses of **Definition 6.5.1**,

$$v_-(h) = \inf_v \int_X (h + \text{dd}^c v)^n, \quad v_+(h) = \sup_v \int_X (h + \text{dd}^c v)^n,$$

where v ranges over the bounded functions in $\text{PSH}(X, h)$. The form h has *positive lower mass* if $v_-(h) > 0$. If h is Kähler, Stokes' theorem gives $v_-(h) = v_+(h) = \int_X h^n$; on a non-Kähler manifold the lower mass can vanish (**Theorem 25.17.1**).

For a nonzero nonnegative $q \in L^p(dV)$ with $p > 1$, **Theorem 10.1.1** gives a constant $c > 0$ and a continuous $u \in \text{PSH}(X, h)$ with $\text{MA}_h(u) = cq \, dV$, and **Proposition 10.5.1** shows that c is determined by q . We call $c_h(q) = c$ the *normalization*

scalar of q , and for the measure $\nu = q \, dV$ we also write $c_h(\nu) = c_h(q)$. We say that a finite measure ν admits a *positive scaled subsolution* if there are $u \in \text{PSH}(X, h)$ and a constant $a > 0$ such that $\text{MA}_h^{\text{ext}}(u) \geq a\nu$.

If ν admits a solution of $\text{MA}_h^{\text{ext}}(u) = c\nu$ with $c > 0$, then it admits in particular a positive scaled subsolution. We show that every nonzero finite non-pluripolar measure admits such a solution if and only if h has positive lower mass. The key estimate is a consequence of strict domination: if $\text{MA}_h^{\text{ext}}(u) \geq aq \, dV$, then $a \leq c_h(q)$. When $\nu_-(h) = 0$, there are smooth probability densities with arbitrarily small normalization scalars, and a weighted sum of such densities, with scalars decreasing fast enough, is a single probability density admitting no positive scaled subsolution.

Lemma 13.24.1 *Let $0 \leq q \in L^p(dV)$, $p > 1$, be nonzero. If $u \in \text{PSH}(X, h)$ and $a > 0$ satisfy*

$$\text{MA}_h^{\text{ext}}(u) \geq aq \, dV,$$

then $a \leq c_h(q)$. Consequently, for nonzero nonnegative bounded densities q, r ,

$$q \leq r \implies c_h(q) \geq c_h(r), \quad c_h(tq) = t^{-1}c_h(q) \quad (t > 0).$$

Proof Let v be a continuous solution of $\text{MA}_h(v) = c_h(q)q \, dV$, and suppose, to reach a contradiction, that $a > c_h(q)$. Then $\tau = c_h(q)/a < 1$ and, for every real A ,

$$\text{MA}_h(v + A) = c_h(q)q \, dV \leq \tau \text{MA}_h^{\text{ext}}(u).$$

The translate $v + A$ is bounded, so $P_{h/2}(v + A) \geq \inf_X v + A$ is not identically $-\infty$, and $u \preceq v + A$. **Theorem 13.1.1**, with $\delta = 1/2$ and $c = \tau$, therefore gives $v + A \geq u$ for every real A . Letting $A \rightarrow -\infty$ at a point where u is finite gives a contradiction. Hence $a \leq c_h(q)$.

If $q \leq r$, a continuous solution of $\text{MA}_h(w) = c_h(r)r \, dV$ satisfies $\text{MA}_h(w) \geq c_h(r)q \, dV$, so the first assertion gives $c_h(r) \leq c_h(q)$. Finally, the equation $\text{MA}_h(v) = c_h(q)q \, dV$ can be written as $\text{MA}_h(v) = t^{-1}c_h(q)(tq) \, dV$, and uniqueness of the scalar gives $c_h(tq) = t^{-1}c_h(q)$. $\square$

The proof uses only that v is bounded. Hence, more generally, if a nonnegative density g satisfies $\text{MA}_h(v) = c \, g \, dV$ for some bounded $v \in \text{PSH}(X, h)$ and some $c > 0$, then every $u \in \text{PSH}(X, h)$ and $a > 0$ with $\text{MA}_h^{\text{ext}}(u) \geq ag \, dV$ satisfy $a \leq c$.

Lemma 13.24.2 *Fix $p > 1$. If nonzero nonnegative densities $q_j, q \in L^p(dV)$ satisfy $q_j \rightarrow q$ in L^p , then $c_h(q_j) \rightarrow c_h(q)$.*

Proof We first show that the scalars $c_h(q_j)$ lie in a compact subset of $(0, +\infty)$. Fix a Gauduchon metric γ on X (**Definition 4.1.1**; in dimension one, any Hermitian metric). Pairing the equation for q_j with γ^{n-1} , as in **Proposition 13.13.1** with $\theta = h$ and barrier $\rho = 0$, gives

$$c_h(q_j)^{1/n} \int_X \left(\frac{q_j \, dV}{\gamma^n} \right)^{1/n} \gamma^n \leq \int_X h \wedge \gamma^{n-1}.$$

Since $q_j^{1/n} \rightarrow q^{1/n}$ in L^n , the integrals on the left converge to the corresponding integral for q , which is positive. Hence the scalars are bounded above. The lower-density estimate of [Theorem 10.3.1](#) gives $c_h(q_j)\|q_j\|_{L^p} \geq c_p > 0$, so they are also bounded away from zero.

Consequently, the normalized continuous solutions u_j of $\text{MA}_h(u_j) = c_h(q_j)q_j \, dV$ have uniformly bounded L^p densities. By [Theorem 10.3.2](#), every subsequence has a further subsequence along which u_j converges uniformly to some u and $c_h(q_j)$ converges to some $c > 0$. Continuity of bounded Monge–Ampère products under uniform convergence gives $\text{MA}_h(u) = cq \, dV$, and uniqueness of the scalar gives $c = c_h(q)$. Since every subsequence of $(c_h(q_j))$ has a further subsequence converging to $c_h(q)$, the whole sequence converges to $c_h(q)$. $\square$

Theorem 13.24.1 *Suppose $v_-(h) = 0$. There is a probability measure $\mu = f \, dV$, with $f \in L^1(dV)$ and $f \geq m$ almost everywhere for a constant $m > 0$, such that no $u \in \text{PSH}(X, h)$ and $a > 0$ satisfy*

$$\text{MA}_h^{\text{ext}}(u) \geq a\mu. \quad (13.78)$$

In particular, the equation $\text{MA}_h^{\text{ext}}(u) = c\mu$ has no solution $u \in \text{PSH}(X, h)$ for any $c > 0$; neither a singularity type nor finiteness of the mass of u is imposed.

Proof By [Theorems 25.1.1](#) and [25.13.1](#), $v_-(h)$ is the infimum of the normalization scalars $c_h(\nu)$ over smooth strictly positive probability measures ν . Since $v_-(h) = 0$, we can choose such measures $\nu_j = f_j \, dV$ with

$$c_h(\nu_j) \leq 2^{-2j} \quad (j \geq 1).$$

Set

$$\mu = \sum_{j=1}^{\infty} 2^{-j} \nu_j, \quad f = \sum_{j=1}^{\infty} 2^{-j} f_j.$$

By monotone convergence, $\int_X f \, dV = 1$, so $f \in L^1$. Moreover $f \geq \frac{1}{2} \min_X f_1 =: m > 0$, and μ is non-pluripolar, being absolutely continuous with respect to dV .

Suppose that [\(13.78\)](#) held for some u and $a > 0$. Since $\mu \geq 2^{-j} \nu_j$, we would have

$$\text{MA}_h^{\text{ext}}(u) \geq a2^{-j} \nu_j$$

for every j , and [Lemma 13.24.1](#) would give $a2^{-j} \leq c_h(\nu_j) \leq 2^{-2j}$. Thus $a \leq 2^{-j}$ for every j , contradicting $a > 0$. $\square$

For the reference 0, [Definition 12.4.1](#) says that $u \in \text{PSH}(X, h)$ belongs to the relative envelope class $\mathcal{E}_{\text{env}}(X, h, 0)$ if, for every $b \geq 1$, some $g \in \text{PSH}(X, h)$ satisfies $g \leq bu$.

Corollary 13.24.1 *The following conditions are equivalent:*

- (1) $v_-(h) > 0$.

- (2) For every nonzero finite non-pluripolar measure μ there are $c > 0$ and $u \in \mathcal{E}_{\text{env}}(X, h, 0)$ such that $\text{MA}_h^{\text{ext}}(u) = c\mu$.
- (3) For every probability density $f \in L^1(dV)$ bounded below by a positive constant, there are $u \in \text{PSH}(X, h)$ and $a > 0$ such that $\text{MA}_h^{\text{ext}}(u) \geq af dV$.

Proof The Hermitian form h is semipositive and big, and the reference 0 satisfies (12.20), since $P_h[0] = 0$ and $P_{\varepsilon h}(0) = 0$ for every $0 < \varepsilon < 1$. Hence, if $v_-(h) > 0$, Theorem 30.1.1, applied with $\theta = h$ and $\varphi = 0$, gives (2). Condition (2) implies (3), because a finite measure that is absolutely continuous with respect to dV is non-pluripolar. Finally, if $v_-(h) = 0$, the density of Theorem 13.24.1 violates (3); thus (3) implies (1). $\square$

Corollary 13.24.2 Assume $v_-(h) = 0$, and let $\mu = f dV$ be the measure of Theorem 13.24.1. Then $f \notin L^p(dV)$ for every $p > 1$. Moreover, for every probability density $g \in L^1(dV)$ and every $0 < t < 1$, the probability density

$$g_t = (1 - t)g + tf$$

admits no positive scaled subsolution, although $\|g_t - g\|_{L^1} \leq 2t$. In particular, the probability densities admitting no positive scaled subsolution are dense among all probability densities in $L^1(dV)$.

Proof If $f \in L^p$ for some $p > 1$, Theorem 10.1.1 would give a continuous solution of $\text{MA}_h(u) = cf dV$ with $c > 0$, contradicting the theorem. Since $g_t dV \geq t\mu$, a positive scaled subsolution for $g_t dV$ would also give one for μ . Finally, $\|g_t - g\|_{L^1} = t\|f - g\|_{L^1} \leq 2t$. $\square$

Smooth strictly positive probability densities are also dense in $L^1(dV)$, and each of them admits a smooth solution of the normalized equation. Thus, when the lower mass vanishes, solvability is not preserved under L^1 approximation. The obstruction comes from the way the density concentrates, not from its size: the density in Theorem 13.24.1 is bounded below by a positive constant. It occurs, for instance, on the compact threefold of Theorem 25.17.1, where every Hermitian form has zero lower mass.

Theorem 13.24.1 does not exclude unbounded solutions of the exponential equation $\text{MA}_h^{\text{ext}}(u) = e^{\lambda u}\mu$ with $\lambda > 0$, because the factor $e^{\lambda u}$ need not have a positive lower bound. It does exclude bounded solutions, since a bounded solution would satisfy $\text{MA}_h^{\text{ext}}(u) \geq e^{\lambda \inf_X u}\mu$. On suitable products, Theorem 13.30.3 chooses the concentrating components of such a density so that its exponential equation has a solution for every positive exponent. We do not know whether this holds for every density admitting no positive scaled subsolution, nor which individual measures admit a solution of the normalized equation when $v_-(h) = 0$.

13.25 Subsolutions for an individual density

When $v_-(h) = 0$, some densities admit no positive scaled subsolution. For one fixed density f , we now determine the largest coefficient a for which $\text{MA}_h^{\text{ext}}(u) \geq af \, dV$ has a solution. The bounded truncations of f have normalization scalars, and their limit is the answer. Moreover, the largest coefficient is attained: the normalized continuous solutions for the truncations have an L^1 cluster limit, and a lower bound for Monge–Ampère densities passes to L^1 limits of potentials by means of monotone upper envelopes.

Let $0 \leq f \in L^1(dV)$ have positive integral. Its truncations are bounded and nonzero, and we put

$$f_k = \min(f, k), \quad b_h(f) = \lim_{k \rightarrow \infty} c_h(f_k). \quad (13.79)$$

By [Lemma 13.24.1](#), the scalars $c_h(f_k)$ decrease as k increases, so the limit exists in $[0, c_h(f)]$. We call $b_h(f)$ the *subsolution threshold* of f ; [Theorem 13.25.1](#) below justifies the name. The same lemma gives

$$b_h(f) = \inf\{c_h(q) : 0 \leq q \leq f, q \in L^\infty, \int_X q \, dV > 0\}. \quad (13.80)$$

Indeed, every such q satisfies $q \leq f_k$ for $k \geq \|q\|_{L^\infty}$, hence $c_h(q) \geq c_h(f_k) \geq b_h(f)$, while the truncations f_k are themselves admissible.

The Monge–Ampère operator is not continuous under L^1 convergence of potentials, but a lower bound for a Monge–Ampère density survives such convergence. The proof replaces the sequence by monotone upper envelopes, which converge in capacity, and uses the continuity of damped measures, [Theorem 7.3.1](#), applied with the Hermitian form h and the weight $t \mapsto e^{-t}$. For nonpositive $v \in \text{PSH}(X, h)$, the corresponding damped measure is $e^v \text{MA}_h^{\text{ext}}(v)$, with weight zero on the pole set; it has finite mass and depends weakly continuously on v under convergence in capacity.

Lemma 13.25.1 *Let $s_j, s \in \text{PSH}(X, h)$ be bounded above by a common constant and satisfy $s_j \rightarrow s$ in $L^1(X)$. Suppose $g_j, g \geq 0$, $g_j \rightarrow g$ in $L^1(dV)$, and*

$$\text{MA}_h^{\text{ext}}(s_j) \geq g_j \, dV \quad \text{for every } j.$$

Then $\text{MA}_h^{\text{ext}}(s) \geq g \, dV$.

Proof Subtracting a common constant, which does not change the extended measures, we may assume that all potentials are nonpositive. Pass to a subsequence along which $s_j \rightarrow s$ and $g_j \rightarrow g$ almost everywhere, and set

$$a_j = \inf_{\ell \geq j} g_\ell, \quad w_j = \left(\sup_{\ell \geq j} s_\ell \right)^*.$$

Then $0 \leq a_j \uparrow g$ almost everywhere, and $w_j \in \text{PSH}(X, h)$ decreases to s .

Step 1: $\text{MA}_h^{\text{ext}}(w_j) \geq a_j \, dV$. Fix j . For $N \geq j$, the finite maximum $m_N = \max_{j \leq \ell \leq N} s_\ell$ satisfies $\text{MA}_h^{\text{ext}}(m_N) \geq a_j \, dV$: on the set $\{m_N = s_\ell\}$, **Proposition 6.2.1** gives $\text{MA}_h^{\text{ext}}(m_N) \geq \text{MA}_h^{\text{ext}}(s_\ell) \geq g_\ell \, dV \geq a_j \, dV$, and these sets cover X . As $N \rightarrow \infty$, the functions m_N increase, are bounded above by zero, and have regularized limit w_j . By **Lemma 1.8.6**, $m_N \rightarrow w_j$ in capacity, so the damped measures $e^{m_N} \text{MA}_h^{\text{ext}}(m_N)$ converge weakly to $e^{w_j} \text{MA}_h^{\text{ext}}(w_j)$. Since $m_N \rightarrow w_j$ almost everywhere and $a_j \leq g$, dominated convergence gives $e^{m_N} a_j \rightarrow e^{w_j} a_j$ in $L^1(dV)$. Passing to the limit in $e^{m_N} \text{MA}_h^{\text{ext}}(m_N) \geq e^{m_N} a_j \, dV$ gives

$$e^{w_j} \text{MA}_h^{\text{ext}}(w_j) \geq e^{w_j} a_j \, dV.$$

The pole set of w_j has zero volume and is not charged by $\text{MA}_h^{\text{ext}}(w_j)$. Dividing by the positive weight off this set gives $\text{MA}_h^{\text{ext}}(w_j) \geq a_j \, dV$.

Step 2: passage to s . Since w_j decreases to $s \in \text{PSH}(X, h)$, **Lemma 1.8.6** gives $w_j \rightarrow s$ in capacity, and the damped measures of w_j converge weakly to $e^s \text{MA}_h^{\text{ext}}(s)$. Moreover $0 \leq e^{w_j} a_j \leq g$ and $e^{w_j} a_j \rightarrow e^s g$ almost everywhere, so dominated convergence and Step 1 give

$$e^s \text{MA}_h^{\text{ext}}(s) \geq e^s g \, dV.$$

Dividing by e^s on $\{s > -N\}$ and letting $N \rightarrow \infty$ gives $\text{MA}_h^{\text{ext}}(s) \geq g \, dV$ off the pole set of s . Both measures give zero mass to the pole set, which proves the lemma. $\square$

Theorem 13.25.1 *For every nonnegative $f \in L^1(dV)$ with positive integral,*

$$b_h(f) = \max\{a \geq 0 : \text{there exists } u \in \text{PSH}(X, h) \text{ with } \text{MA}_h^{\text{ext}}(u) \geq a f \, dV\}.$$

In particular, $f \, dV$ admits a positive scaled subsolution if and only if $b_h(f) > 0$.

Proof If $\text{MA}_h^{\text{ext}}(u) \geq a f \, dV$ with $a > 0$, then also $\text{MA}_h^{\text{ext}}(u) \geq a f_k \, dV$ for every k , and **Lemma 13.24.1** gives $a \leq c_h(f_k)$. Letting $k \rightarrow \infty$ gives $a \leq b_h(f)$. If $b_h(f) = 0$, the coefficient zero is attained by the zero potential.

Suppose now that $b = b_h(f) > 0$, and let u_k be continuous solutions of

$$\text{MA}_h(u_k) = c_h(f_k) f_k \, dV, \quad \sup_X u_k = 0.$$

By **Theorem 1.4.1**, a subsequence u_{k_j} converges in L^1 to some $u \in \text{PSH}(X, h)$ with $\sup_X u = 0$. The densities $c_h(f_{k_j}) f_{k_j}$ are dominated by $c_h(f_1) f$ and converge to $b f$ almost everywhere, hence in L^1 . **Lemma 13.25.1** now gives $\text{MA}_h^{\text{ext}}(u) \geq b f \, dV$, so the maximum is attained at $a = b$. $\square$

When $b_h(f) > 0$, a function $u \in \text{PSH}(X, h)$ with $\text{MA}_h^{\text{ext}}(u) \geq b_h(f) f \, dV$ is called a *threshold subsolution* for f , and a threshold subsolution with $\text{MA}_h^{\text{ext}}(u) = b_h(f) f \, dV$ is called a *threshold solution*; the theorem shows that threshold subsolutions exist. Its proof preserves only a lower bound for the density. It shows neither that the normalized solutions u_k converge in capacity, nor that their limit has

finite mass, nor that equality holds in the limit; these are the additional difficulties of the exact equation for an individual density. The threshold does not depend on the choice of truncations. If (q_k) is any increasing sequence of nonzero bounded densities converging to f almost everywhere, then $c_h(q_k) \geq b_h(f)$ by (13.80); conversely, the second half of the proof, applied to normalized solutions for q_k , gives a subsolution with coefficient $\lim_k c_h(q_k)$, which is therefore at most $b_h(f)$. Hence $\lim_k c_h(q_k) = b_h(f)$.

13.25.1 The greatest normalized threshold subsolution

Suppose $b_h(f) > 0$. The threshold subsolutions with supremum zero form a family that is stable under finite maxima and under L^1 limits. Its upper envelope is therefore again a normalized threshold subsolution, and it dominates all the others.

Proposition 13.25.1 *Suppose $b = b_h(f) > 0$. The family*

$$\mathcal{S}_f = \{s \in \text{PSH}(X, h) : \sup_X s = 0, \text{MA}_h^{\text{ext}}(s) \geq bf \, dV\}$$

is nonempty and compact in $L^1(X)$. Its upper envelope

$$\Phi_f = \left(\sup_{s \in \mathcal{S}_f} s \right)^*$$

belongs to $\mathcal{S}_f$ and is therefore its greatest member. Moreover, let u_λ be the greatest exponential solutions of Corollary 13.30.1 and $v_\lambda = u_\lambda - \sup_X u_\lambda$. Every L^1 limit of a sequence v_{λ_j} with $\lambda_j \downarrow 0$ belongs to $\mathcal{S}_f$, and hence lies below Φ_f .

Proof The family is nonempty by Theorem 13.25.1. By Theorem 1.4.1, an L^1 limit of members of $\mathcal{S}_f$ is h -plurisubharmonic with supremum zero, and Lemma 13.25.1, with $g_j = g = bf$, shows that it satisfies the measure inequality. Thus $\mathcal{S}_f$ is a closed subset of the compact set of normalized h -plurisubharmonic functions, hence compact. It is also stable under finite maxima: if $s_1, s_2 \in \mathcal{S}_f$, then $\max(s_1, s_2)$ has supremum zero, and Proposition 6.2.1, applied on the sets where the maximum equals s_1 or s_2 , gives $\text{MA}_h^{\text{ext}}(\max(s_1, s_2)) \geq bf \, dV$.

By Choquet's lemma there is a sequence $(s_i)_{i \geq 1}$ in $\mathcal{S}_f$ with $(\sup_i s_i)^* = \Phi_f$. Fix $s_0 \in \mathcal{S}_f$. The finite maxima $t_N = \max(s_0, s_1, \dots, s_N)$ belong to $\mathcal{S}_f$, increase with N , and satisfy $s_0 \leq t_N \leq 0$; their regularized limit is Φ_f . Hence $t_N \rightarrow \Phi_f$ almost everywhere and, by dominated convergence, in L^1 . Lemma 13.25.1 gives $\text{MA}_h^{\text{ext}}(\Phi_f) \geq bf \, dV$, and $s_0 \leq \Phi_f \leq 0$ forces $\sup_X \Phi_f = 0$. Thus $\Phi_f \in \mathcal{S}_f$, and by construction it dominates every member of $\mathcal{S}_f$.

Finally, suppose $v_{\lambda_j} \rightarrow v$ in L^1 with $\lambda_j \downarrow 0$. The measures $\text{MA}_h^{\text{ext}}(v_{\lambda_j}) = e^{\lambda_j u_{\lambda_j}} f \, dV$ have densities converging in L^1 to bf , by Corollary 13.30.1. Applying Lemma 13.25.1 to these densities and potentials shows that $v \in \mathcal{S}_f$. $\square$

The proposition gives a greatest normalized threshold subsolution, but not the equation $\text{MA}_h^{\text{ext}}(\Phi_f) = bf \, dV$; in particular, it does not show that Φ_f has finite mass.

Proposition 13.25.2 *Let $0 \leq f \in L^1(dV)$ have positive integral. If $f \in L^p(dV)$ for some $p > 1$, then $b_h(f) = c_h(f)$. In general,*

$$b_h(f) \geq \frac{v_-(h)}{\int_X f \, dV}.$$

If h is Kähler, then $b_h(f) = \int_X h^n / \int_X f \, dV$.

Proof Suppose that $f \in L^p$ with $p > 1$, and let v be a continuous solution of $\text{MA}_h(v) = c_h(f)f \, dV$. It is a subsolution with coefficient $c_h(f)$, so [Theorem 13.25.1](#) gives $c_h(f) \leq b_h(f)$. Conversely, [Lemma 13.24.1](#), applied to a threshold subsolution, gives $b_h(f) \leq c_h(f)$.

For general f , the continuous solution for f_k has total mass $c_h(f_k) \int_X f_k \, dV$, which is at least $v_-(h)$ by the definition of the lower mass. Letting $k \rightarrow \infty$ and using monotone convergence gives the lower bound for $b_h(f)$. If h is Kähler, Stokes' theorem for bounded potentials gives instead the identity $c_h(f_k) \int_X f_k \, dV = \int_X h^n$, and the same limit proves the last assertion. $\square$

13.25.2 Smooth comparison tests

The infimum [\(13.80\)](#) runs over bounded measurable densities below f . One may ask whether smooth densities suffice to compute the threshold. A smooth test g is in general not below f , so we compare it with f through the ratio $\|g/f\|_{L^\infty}$. Thus let f be a probability density bounded below by a positive constant, and define

$$C_h^{\text{sm}}(f) = \inf_g c_h(g) \|g/f\|_{L^\infty},$$

where g ranges over smooth strictly positive probability densities. For each such g , with $R = \|g/f\|_{L^\infty}$, a subsolution with coefficient a for $f \, dV$ is a subsolution with coefficient a/R for $g \, dV$, so $a \leq R c_h(g)$ by [Lemma 13.24.1](#). Hence $b_h(f) \leq C_h^{\text{sm}}(f)$, with equality if f is smooth (take $g = f$). When the lower mass vanishes, the two quantities can differ even in their positivity.

Theorem 13.25.2 *If $v_-(h) = 0$, there is a probability density $f \in L^1(dV)$ bounded below by a positive constant such that*

$$b_h(f) = 0 < C_h^{\text{sm}}(f).$$

Thus $f dV$ admits no positive scaled subsolution, although $c_h(g)\|g/f\|_{L^\infty}$ is bounded below by a positive constant for all smooth strictly positive probability densities g .

Proof We construct $f = (1 + Q)/M$, where $Q \geq 0$ concentrates on closed nowhere dense sets in such a way that it has essential infimum zero on every nonempty open set.

Step 1: the pieces. Let $(U_i)_{i \geq 1}$ be a countable basis of nonempty open subsets of X . We construct inductively numbers $\alpha_j > 0$, nonzero bounded densities q_j , and closed nowhere dense sets $K_j \subset X$ such that

$$\int_X q_j dV \leq 1, \quad q_j = 0 \text{ outside } K_j, \quad c_h(q_j) \leq \alpha_j 2^{-j}.$$

Start with $\alpha_1 = 1/4$. Once α_j has been chosen, **Theorems 25.1.1** and **25.13.1** and $v_-(h) = 0$ give a smooth strictly positive probability density g_j with $c_h(g_j) < \alpha_j 2^{-j}$. Removing from X an open dense set of small volume, we obtain a closed nowhere dense set K_j for which $q_j = g_j \mathbf{1}_{K_j}$ is nonzero and, since g_j is bounded, arbitrarily close to g_j in L^2 . By **Lemma 13.24.2** with $p = 2$, we can therefore choose K_j so that $c_h(q_j) \leq \alpha_j 2^{-j}$.

After $K_1, \dots, K_N$ have been chosen, put

$$m_N = \min_{1 \leq i \leq N} dV \left(U_i \setminus \bigcup_{j=1}^N K_j \right) > 0;$$

each set inside the minimum is open and nonempty, since a finite union of closed nowhere dense sets is closed and nowhere dense. Choose

$$0 < \alpha_{N+1} \leq \min\{\alpha_N/2, 2^{-N-2}m_N\},$$

and continue. In particular,

$$\sum_{j > N} \alpha_j \leq 2\alpha_{N+1} \leq 2^{-N-1}m_N.$$

Step 2: the concentrating part. The function $Q = \sum_j \alpha_j q_j$ is nonnegative and integrable. We claim that its essential infimum on every nonempty open set is zero. Since every nonempty open set contains some U_i , it suffices to consider U_i . Take $N \geq i$ and remove $K_1, \dots, K_N$ from U_i . On the remaining set, whose volume is at least m_N , the first N summands of Q vanish. By Markov's inequality, the set where the tail $\sum_{j > N} \alpha_j q_j$ exceeds 2^{-N} has volume at most

$$2^N \sum_{j>N} \alpha_j \int_X q_j dV \leq m_N/2.$$

Hence $Q \leq 2^{-N}$ on a subset of U_i of positive volume. Letting $N \rightarrow \infty$ proves the claim.

Step 3: $b_h(f) = 0$. Set $M = \int_X (1+Q) dV$ and $f = (1+Q)/M$, a probability density with $f \geq 1/M$. If $\text{MA}_h^{\text{ext}}(u) \geq af dV$ with $a > 0$, then $\text{MA}_h^{\text{ext}}(u) \geq (a\alpha_j/M)q_j dV$, and [Lemma 13.24.1](#) gives

$$\frac{a\alpha_j}{M} \leq c_h(q_j) \leq \alpha_j 2^{-j} \quad \text{for every } j.$$

This is impossible. Hence $b_h(f) = 0$ by [Theorem 13.25.1](#).

Step 4: $C_h^{\text{sm}}(f) > 0$. Let g be a smooth strictly positive probability density and put $R = \|g/f\|_{L^\infty}$. Then $g \leq R(1+Q)/M$ almost everywhere, and this forces $g \leq R/M$ everywhere. Otherwise, by continuity, $g > R(1+\varepsilon)/M$ on a nonempty open set for some $\varepsilon > 0$, while $Q < \varepsilon$ on a subset of positive volume of this set by Step 2, a contradiction. The order and homogeneity of the scalar in [Lemma 13.24.1](#) now give $c_h(g) \geq c_h(R/M) = (M/R)c_h(1)$, that is,

$$Rc_h(g) \geq Mc_h(1).$$

The constant density $g = 1$ attains this value, since $\text{ess inf}_X Q = 0$ gives $\|1/f\|_{L^\infty} = M$. Thus $C_h^{\text{sm}}(f) = Mc_h(1) > 0$, as required. $\square$

The point is that a smooth test g with $\|g/f\|_{L^\infty} \leq R$ is controlled by the essential infimum of f on open sets. It therefore cannot detect an increase of f that leaves this essential infimum unchanged on every open set, whereas bounded measurable tests below f do detect it. The theorem concerns only the existence of subsolutions. Exact solutions of $\text{MA}_h^{\text{ext}}(u) = b_h(f)f dV$, the singularity class in which they should be sought, and compactness of their normalized solutions are further problems; see [Problem 32.1.1](#).

13.26 Gauduchon tests for integrable densities

For a smooth strictly positive probability density, the normalization scalar is an infimum of Gauduchon quotients by [Theorem 25.1.1](#). We extend this dual formula to the threshold of an arbitrary integrable density. A uniform bound for all Gauduchon tests in a single L^r norm allows the passage from smooth to bounded densities, and monotone truncation then reaches all integrable densities, including those with zero threshold. The formula is most naturally written for the n th root of the density.

Recall that a Hermitian form γ is *Gauduchon* if $\text{dd}^c(\gamma^{n-1}) = 0$ ([Definition 4.1.1](#)); in dimension one every Hermitian form is Gauduchon. For a Gauduchon form γ and a nonnegative measurable function p , put

$$L_{h,\gamma}(p) = \frac{\int_X p(dV/\gamma^n)^{1/n} \gamma^n}{\int_X h \wedge \gamma^{n-1}} = \int_X p a_\gamma dV, \quad a_\gamma = \frac{(\gamma^n/dV)^{(n-1)/n}}{\int_X h \wedge \gamma^{n-1}}.$$

Since the coefficient a_γ is smooth and strictly positive, each individual test $L_{h,\gamma}$ is finite on L^n ; the supremum over γ may be infinite. In dimension one the test is $\int_X p dV / \int_X h$. For real or complex $p \in L^n(dV)$, define the *root functional*

$$\rho_h(p) = b_h(|p|^n)^{-1/n} \quad (p \neq 0), \quad \rho_h(0) = 0,$$

with the convention $0^{-1/n} = +\infty$.

Theorem 13.26.1 *For every real or complex $p \in L^n(dV)$,*

$$\rho_h(p) = \sup_{\gamma \text{ Gauduchon}} L_{h,\gamma}(|p|). \quad (13.81)$$

Equivalently, for every nonzero nonnegative $f \in L^1(dV)$,

$$b_h(f)^{1/n} = \inf_{\gamma \text{ Gauduchon}} \frac{\int_X h \wedge \gamma^{n-1}}{\int_X (f dV/\gamma^n)^{1/n} \gamma^n}. \quad (13.82)$$

Both sides of (13.81) may be $+\infty$, and both sides of (13.82) may vanish.

Proof It suffices to prove (13.81) for $p \geq 0$, since both sides depend only on $|p|$; the case $p = 0$ is immediate.

Step 1: smooth strictly positive p . Apply **Theorem 25.1.1**, with background h , to the probability measure $\mu = p^n dV/Z$, where $Z = \int_X p^n dV$. By homogeneity (**Lemma 13.24.1**) its scalar is $c_h(\mu) = Z c_h(p^n)$, while the denominator of each Gauduchon quotient is $Z^{-1/n} \int_X p(dV/\gamma^n)^{1/n} \gamma^n$. The factors of Z cancel, and the dual formula becomes

$$c_h(p^n)^{-1/n} = \sup_{\gamma} L_{h,\gamma}(p).$$

Since $b_h(p^n) = c_h(p^n)$ by **Proposition 13.25.2**, this proves (13.81) for such p .

Step 2: a uniform bound for the tests. The lower-density estimate of **Theorem 10.3.1**, with exponent two, gives a constant $m_h > 0$ such that

$$c_h(p^n) \|p^n\|_{L^2} \geq m_h$$

for smooth strictly positive p . By Step 1, therefore,

$$L_{h,\gamma}(p) \leq m_h^{-1/n} \|p\|_{L^{2n}} \quad \text{for every } \gamma. \quad (13.83)$$

Approximating nonnegative functions in L^{2n} by smooth strictly positive ones extends this bound to all nonnegative $p \in L^{2n}$. Since $a_\gamma > 0$, duality gives $\|a_\gamma\|_{L^{2n/(2n-1)}} \leq$

$m_h^{-1/n}$ for every γ . In particular, $p \mapsto \sup_\gamma L_{h,\gamma}(p)$ is Lipschitz on the cone of nonnegative functions in L^{2n} , with the same constant.

Step 3: bounded p . Let $p \geq 0$ be bounded and nonzero, and approximate it in L^{2n} by smooth strictly positive functions p_j . By Hölder's inequality, $p_j^n \rightarrow p^n$ in L^2 , so [Lemma 13.24.2](#) gives

$$c_h(p_j^n) \longrightarrow c_h(p^n) > 0.$$

By the Lipschitz bound derived from [\(13.83\)](#),

$$\sup_\gamma L_{h,\gamma}(p_j) \longrightarrow \sup_\gamma L_{h,\gamma}(p).$$

Passing to the limit in the identity of Step 1 for p_j , and using $b_h(p^n) = c_h(p^n)$ ([Proposition 13.25.2](#)), we obtain [\(13.81\)](#) for bounded p .

Step 4: general p . For nonnegative $p \in L^n$, put $p_k = \min(p, k)$. Then $p_k^n = \min(p^n, k^n)$ are truncations of p^n , so the definition of b_h and Step 3 give

$$\rho_h(p) = \lim_{k \rightarrow \infty} c_h(p_k^n)^{-1/n} = \sup_k \sup_\gamma L_{h,\gamma}(p_k).$$

For each fixed γ , monotone convergence gives $\sup_k L_{h,\gamma}(p_k) = L_{h,\gamma}(p)$. Interchanging the two suprema proves [\(13.81\)](#). Finally, every denominator in [\(13.82\)](#) is positive; taking reciprocals in [\(13.81\)](#) with $p = f^{1/n}$ proves [\(13.82\)](#), including the case $b_h(f) = 0$. $\square$

For a nonsmooth density we do not claim that the infimum in [\(13.82\)](#) is attained by a Gauduchon form; attainment by Gauduchon currents is studied in [Section 25.9](#).

For $n \geq 2$, the coefficient of the test has norm

$$\|a_\gamma\|_{L^{n/(n-1)}} = \frac{(\int_X \gamma^n)^{(n-1)/n}}{\int_X h \wedge \gamma^{n-1}}$$

in the exponent dual to n . By [\(25.54\)](#) in [Theorem 25.13.1](#), positive lower mass is therefore equivalent to a uniform bound for these norms, that is, for all tests on L^n simultaneously. Without positive lower mass, Step 2 of the proof still bounds the coefficients uniformly in the weaker norm of $L^{2n/(2n-1)}$, on every compact Hermitian manifold. This suffices to pass from smooth to bounded densities, and monotone truncation then treats all integrable densities.

Proposition 13.26.1 *Let f be a nonzero nonnegative function in $L^1(dV)$ and let $p \in L^n(dV)$ be real or complex. If h_1, h_2 are Hermitian forms on X and $mh_1 \leq h_2 \leq Mh_1$ for positive constants m, M , then*

$$m^n b_{h_1}(f) \leq b_{h_2}(f) \leq M^n b_{h_1}(f), \quad M^{-1} \rho_{h_1}(p) \leq \rho_{h_2}(p) \leq m^{-1} \rho_{h_1}(p).$$

If $h_2 - h_1 = dd^c a$ for a smooth real function a , then $b_{h_1}(f) = b_{h_2}(f)$ and $\rho_{h_1}(p) = \rho_{h_2}(p)$.

Proof For every Gauduchon form γ , the numerators in (13.82) satisfy

$$m \int_X h_1 \wedge \gamma^{n-1} \leq \int_X h_2 \wedge \gamma^{n-1} \leq M \int_X h_1 \wedge \gamma^{n-1},$$

while the denominators do not depend on the background. Taking the infimum over γ and then n th powers proves the bounds for the thresholds; taking reciprocal n th roots gives the bounds for ρ , with the stated conventions at zero and infinity. If $h_2 - h_1 = dd^c a$, the numerators agree by Stokes' theorem, since $dd^c(\gamma^{n-1}) = 0$. $\square$

Any two Hermitian metrics on the compact manifold X are comparable. Hence the positivity of $b_h(f)$, and the set of real or complex $p \in L^n$ with $\rho_h(p) < +\infty$, do not depend on the choice of h . The dependence on the reference volume is equally simple. If dV is replaced by $dV' = \sigma dV$ with a smooth function $\sigma > 0$, the measure $f dV$ has density $f' = f/\sigma$ with respect to dV' , and Theorem 13.25.1 shows that the threshold of f' relative to dV' equals $b_h(f)$. Correspondingly, the map $p \mapsto \sigma^{-1/n} p$ from $L^n(dV)$ to $L^n(dV')$ preserves both the L^n norm and the root functional.

13.27 Exact equations on products with zero lower mass

Positive lower mass guarantees solvability for all measures, but an individual density can have a positive threshold and an exact equation even when the lower mass vanishes. We construct explicit examples on products. Let (X_0, h_0) be a connected compact Hermitian manifold of dimension $m \geq 1$ with $v_-(h_0) = 0$. On its product with a projective space, a singular potential pulled back from the projective factor solves an explicit equation whose density has a sublogarithmic singularity. The coefficient is computed from the normalization scalars of bounded truncations, the equation itself follows from the product structure of the Monge–Ampère measure, and the product background again has zero lower mass.

Throughout this section, $Y = \mathbb{P}^k$ with $k \geq 1$, κ is the Fubini–Study form normalized by $\int_Y \kappa^k = 1$, and $X = X_0 \times Y$, a compact complex manifold of dimension $N = m + k$ with the Hermitian background $H = h_0 + \kappa$. Forms and functions on the factors are identified with their pullbacks to X . Put

$$V_0 = \int_{X_0} h_0^m, \quad C = \binom{N}{m}, \quad \mu = V_0^{-1} h_0^m \wedge \kappa^k, \quad R = \frac{\mu}{dV},$$

where dV is any smooth positive probability volume form on X . Then μ is a smooth positive probability volume form, and R is smooth and bounded above and below by positive constants. The normalization scalar c_H and the threshold b_H are those of [Sections 13.24](#) and [13.25](#), now on the N -dimensional manifold X with background H .

For $0 < \alpha < 1$ define, on Y ,

$$\psi([z_0 : \cdots : z_k]) = \log \frac{\sum_{i=1}^k |z_i|^2}{\sum_{i=0}^k |z_i|^2}, \quad u_\alpha = 1 - (1 - \psi)^\alpha.$$

The function ψ is smooth on $Y \setminus \{o\}$, where $o = [1 : 0 : \cdots : 0]$, and tends to $-\infty$ at o ; moreover $\psi \leq 0$, with equality exactly on the hyperplane $\{z_0 = 0\}$. Thus $u_\alpha \leq 0$, and u_α has a single pole at o , where $u_\alpha(o) = -\infty$.

Lemma 13.27.1 *The function u_α is κ -plurisubharmonic with supremum zero, and*

$$\text{MA}_\kappa^{\text{ext}}(u_\alpha) = q_\alpha \kappa^k, \quad \int_Y q_\alpha \kappa^k = 1.$$

The density q_α is smooth and strictly positive on $Y \setminus \{o\}$, belongs to $L^1(\kappa^k)$, and belongs to no $L^p(\kappa^k)$ with $p > 1$. If we set $q_\alpha(o) = +\infty$, then every truncation $\min(q_\alpha, s)$, $s > 0$, is strictly positive and continuous on Y .

Proof In homogeneous coordinates, $\kappa + \text{dd}^c \psi = \text{dd}^c \log \sum_{i=1}^k |z_i|^2 \geq 0$ on $Y \setminus \{o\}$. The function $\chi(t) = 1 - (1 - t)^\alpha$, $t \leq 0$, is increasing and convex, with $0 < \chi' \leq \alpha$. Hence, off o ,

$$\kappa + \text{dd}^c u_\alpha \geq (1 - \chi'(\psi))\kappa + \chi'(\psi)(\kappa + \text{dd}^c \psi) \geq (1 - \alpha)\kappa.$$

Since u_α is bounded above, it extends across o as a κ -plurisubharmonic function, with value $-\infty$ at o . On the hyperplane $\{z_0 = 0\}$ we have $\psi = 0$, hence $u_\alpha = 0$, so $\sup_Y u_\alpha = 0$.

To compute the measure, work in the affine chart $z_0 = 1$ and put $r = \sum_{i=1}^k |z_i|^2$. On this chart $\kappa = \text{dd}^c \log(1 + r)$ and $\kappa + \text{dd}^c u_\alpha = \text{dd}^c F$, where $s(r) = 1 - \log(r/(1 + r))$ and

$$F(r) = \log(1 + r) + 1 - s(r)^\alpha, \quad Q(r) = rF'(r) = \frac{r + \alpha s(r)^{\alpha-1}}{1 + r}.$$

For a radial function, the Levi form has the tangential eigenvalue $F'(r) = Q(r)/r$, with multiplicity $k - 1$, and the radial eigenvalue

$$Q'(r) = \frac{1 - \alpha s(r)^{\alpha-1} + \alpha(1 - \alpha)r^{-1}s(r)^{\alpha-2}}{(1 + r)^2} > 0.$$

Integrating in the radial variable gives $\int_{\{a < r < b\}} (\text{dd}^c F)^k = Q(b)^k - Q(a)^k$; the constant of proportionality is fixed by the case $F = \log(1 + r)$, for which $(\text{dd}^c F)^k = \kappa^k$

has mass one on the chart and $Q(r) = r/(1+r)$. Since again $Q(0) = 0$ and $Q(\infty) = 1$, the punctured chart has mass one. The complement of the chart is a hyperplane, which has zero volume, and the non-pluripolar measure does not charge o . Hence $\int_Y q_\alpha \kappa^k = 1$.

Relative to κ^k , whose tangential and radial eigenvalues are $1/(1+r)$ and $1/(1+r)^2$, the density on this chart is

$$q_\alpha(r) = (1+r)^{k+1} (Q(r)/r)^{k-1} Q'(r) \asymp r^{-k} (1 - \log r)^{-1-k(1-\alpha)} \quad (r \downarrow 0).$$

Near $r = 0$ the smooth volume is comparable to $r^{k-1} dr$ in the radial variable, so q_α is integrable. For $p > 1$, the substitution $L = 1 - \log r$ turns the integral of q_α^p into the integral of $e^{k(p-1)L}$ times a power of L , which diverges. The same asymptotics show that $q_\alpha(r) \rightarrow +\infty$ uniformly as $r \downarrow 0$, so every truncation $\min(q_\alpha, s)$ is continuous at o . Finally, $q_\alpha \geq (1-\alpha)^k > 0$ by the lower bound $\kappa + \text{dd}^c u_\alpha \geq (1-\alpha)\kappa$. $\square$

Lemma 13.27.2 *Let g be a strictly positive continuous function on Y , and put $M_g = \int_Y g \kappa^k$. Then*

$$c_H(Rg) = \frac{CV_0}{M_g}.$$

Proof Suppose first that g is smooth. Since κ is Kähler, [Theorem 9.1.1](#) on Y gives a smooth ϕ_g with $A_g = \kappa + \text{dd}^c \phi_g > 0$ and $A_g^k = (g/M_g)\kappa^k$; the scalar is determined by integration, since both sides have mass one. On X , since $h_0^{m+1} = 0$ and $A_g^{k+1} = 0$ for dimensional reasons,

$$(H + \text{dd}^c \phi_g)^N = C h_0^m \wedge A_g^k = (CV_0/M_g) Rg \, dV.$$

Uniqueness of the scalar gives $c_H(Rg) = CV_0/M_g$. For continuous $g > 0$, choose smooth $g_l > 0$ converging uniformly to g . Since g has a positive minimum, $(1-\varepsilon_l)g \leq g_l \leq (1+\varepsilon_l)g$ for some $\varepsilon_l \in (0, 1)$ tending to zero. The order and homogeneity of the scalar in [Lemma 13.24.1](#) give

$$(1-\varepsilon_l)c_H(Rg_l) \leq c_H(Rg) \leq (1+\varepsilon_l)c_H(Rg_l).$$

Since $M_{g_l} \rightarrow M_g$, the smooth case proves the formula. $\square$

Theorem 13.27.1 *The Hermitian form H is not closed and satisfies $v_-(H) = 0$. For every $0 < \alpha < 1$, the function $f = Rq_\alpha$ is a probability density in $L^1(dV)$, belonging to no $L^p(dV)$ with $p > 1$, and*

$$b_H(f) = CV_0 > 0, \quad \text{MA}_H^{\text{ext}}(u_\alpha) = b_H(f)f \, dV.$$

The potential u_α , pulled back to X , has supremum zero and finite mass CV_0 . It belongs to $\mathcal{E}_{\text{env}}(X, H, 0)$, and $P_{\delta H}(u_\alpha) \not\equiv -\infty$ for every $0 < \delta < 1$.

Proof Step 1: the threshold. Write $a = \min_X R > 0$, $A = \max_X R$, and $M_s = \int_Y \min(q_\alpha, s) \kappa^k$ for $s > 0$. By [Lemma 13.27.1](#), the truncations $\min(q_\alpha, s)$ are continuous and strictly positive, and $M_s \uparrow 1$ as $s \rightarrow \infty$. The truncations of f satisfy

$$R \min(q_\alpha, j/A) \leq \min(Rq_\alpha, j) \leq R \min(q_\alpha, j/a).$$

Hence [Lemma 13.27.2](#) and the monotonicity of the scalar give

$$\frac{CV_0}{M_{j/a}} \leq c_H(\min(f, j)) \leq \frac{CV_0}{M_{j/A}}.$$

Both bounds tend to CV_0 as $j \rightarrow \infty$, so $b_H(f) = CV_0$, whatever the reference volume dV .

Step 2: the equation. For $u_{\alpha,j} = \max(u_\alpha, -j)$, the binomial expansion of bounded local products, with factor forms of degrees m and k , gives

$$\text{MA}_H(u_{\alpha,j}) = Ch_0^m \wedge \text{MA}_\kappa(u_{\alpha,j}).$$

Multiplying by $\mathbf{1}_{\{u_\alpha > -j\}}$ and letting $j \rightarrow \infty$, as in the definition [\(6.1\)](#) of the extended measure, we obtain

$$\text{MA}_H^{\text{ext}}(u_\alpha) = Ch_0^m \wedge q_\alpha \kappa^k = CV_0 q_\alpha \mu = CV_0 f \, dV,$$

a measure of mass CV_0 . The bounds $a \leq R \leq A$ transfer the integrability properties of q_α to f .

Step 3: lower mass and nonclosedness. Pull back bounded h_0 -plurisubharmonic functions whose masses on X_0 tend to zero. The same expansion shows that their H -masses are C times their masses on X_0 , so $v_-(H) = 0$. If h_0 were closed, Stokes' theorem would give every bounded h_0 -plurisubharmonic function the mass $V_0 > 0$, contradicting $v_-(h_0) = 0$. Hence h_0 , and therefore H , is not closed.

Step 4: the envelopes. Choose $\alpha < \beta < 1$. For $b \geq 1$ and $\varepsilon > 0$ with $\varepsilon\beta \leq 1$, the number

$$K_b = \sup_{s \geq 1} \{bs^\alpha - \varepsilon s^\beta\} - b$$

is finite, since $\beta > \alpha$. The function $g_b = -\varepsilon(1 - \psi)^\beta - K_b$ on Y satisfies $\kappa + \text{dd}^c g_b \geq (1 - \varepsilon\beta)\kappa \geq 0$, by the chain-rule computation in the proof of [Lemma 13.27.1](#), applied to the increasing convex function $t \mapsto -\varepsilon(1 - t)^\beta$, whose derivative is at most $\varepsilon\beta$ for $t \leq 0$. With $L = 1 - \psi \geq 1$, the inequality $g_b \leq bu_\alpha$ reads $bL^\alpha - \varepsilon L^\beta - b \leq K_b$, so it holds on $Y \setminus \{o\}$, and also at o , where both sides are $-\infty$. Thus the pullback of g_b belongs to $\text{PSH}(X, H)$ and lies below bu_α . Since $b \geq 1$ is arbitrary, $u_\alpha \in \mathcal{E}_{\text{env}}(X, H, 0)$ by [Definition 12.4.1](#). For $0 < \delta < 1$, take $b = 1$ and $\varepsilon\beta \leq \delta$. Then g_1 is δH -plurisubharmonic and lies below u_α , so $P_{\delta H}(u_\alpha) \geq g_1$ is not identically $-\infty$. $\square$

Corollary 13.27.1 *Let X_0 be the elliptic threefold of [Theorem 25.17.1](#), with the balanced metric ω of [Proposition 25.17.1](#). On $X_0 \times \mathbb{P}^2$, with background $H = \omega + \kappa$, the densities $f = Rq_\alpha$ of the preceding theorem satisfy*

$$v_-(H) = 0, \quad b_H(f) = 240\pi, \quad \text{MA}_H^{\text{ext}}(u_\alpha) = 240\pi f \, dV.$$

Proof [Theorem 25.17.1](#) gives $v_-(\omega) = 0$, and [Proposition 25.17.1](#) gives $V_0 = 24\pi$. The product theorem applies with $m = 3$, $k = 2$ and $C = \binom{5}{3} = 10$. $\square$

These examples show that an individual density can have a positive threshold and an exact equation even though the background has zero lower mass. The exactness comes from the product structure. For $k \geq 2$, the radial flux also identifies the normalized exponential limit in [Theorem 13.31.1](#); the first moment determines whether scalar centering has a finite limit. [Problem 32.1.1](#) asks for an exact equation for every integrable density with positive threshold.

13.27.1 Closed factors and arbitrary integrable densities

The preceding examples use an explicit potential on projective space. On a closed factor, the mass bound from Stokes' theorem instead makes every threshold subsolution exact. This gives equations for arbitrary integrable densities on that factor, with no assumption that they are bounded below.

For this subsection let (X_0, h_0) be any connected compact Hermitian manifold of dimension $m \geq 1$, and let (Y, κ) be connected compact Kähler of dimension $k \geq 2$, normalized by $\int_Y \kappa^k = 1$. On $X = X_0 \times Y$ put

$$N = m + k, \quad H = h_0 + \kappa, \quad C = \binom{N}{m}, \quad V_0 = \int_{X_0} h_0^m, \quad c_0 = CV_0.$$

Forms and functions on the factors are pulled back when used on X . For any smooth positive probability volume form dV on X , put

$$\mu = V_0^{-1} h_0^m \wedge \kappa^k, \quad R = \frac{\mu}{dV}, \quad a = \min_X R > 0, \quad A = \max_X R.$$

Theorem 13.27.2 *For every nonzero nonnegative $g \in L^1(Y, \kappa^k)$, with $M_g = \int_Y g \kappa^k$, one has*

$$b_H(Rg) = \frac{c_0}{M_g}.$$

There is $v \in \text{PSH}(Y, \kappa)$ with $\sup_Y v = 0$ and $\int_Y \text{MA}_\kappa^{\text{ext}}(v) = 1$ whose pullback u satisfies

$$\text{MA}_H^{\text{ext}}(u) = \frac{c_0}{M_g} Rg \, dV, \quad \int_X \text{MA}_H^{\text{ext}}(u) = c_0.$$

If $v_-(h_0) = 0$, then $v_-(H) = 0$ and H is not closed.

Proof We first compute the scalars of bounded densities, then use the closed factor's mass bound to identify the equation for an unbounded density.

Step 1: bounded densities. If g is bounded and nonzero, **Theorem 10.1.1** on Y gives a bounded continuous v with $\text{MA}_\kappa(v) = c_\kappa(g)g\kappa^k$. Closed Stokes gives $c_\kappa(g) = 1/M_g$. The bounded product expansion gives

$$\text{MA}_H(v) = Ch_0^m \wedge \text{MA}_\kappa(v) = \frac{c_0}{M_g} Rg \, dV.$$

Uniqueness of the bounded normalization scalar therefore gives $c_H(Rg) = c_0/M_g$, including densities with zeros.

Step 2: the threshold. For general $g \in L^1$, the original truncations on X satisfy

$$R \min(g, j/A) \leq \min(Rg, j) \leq R \min(g, j/a).$$

By Step 1 and **Lemma 13.24.1**,

$$\frac{c_0}{\int_Y \min(g, j/a) \kappa^k} \leq c_H(\min(Rg, j)) \leq \frac{c_0}{\int_Y \min(g, j/A) \kappa^k}.$$

Both bounds tend to c_0/M_g .

Step 3: the exact equation. By **Proposition 13.25.2**, $b_\kappa(g) = 1/M_g$. Thus **Theorem 13.25.1** on Y gives $v \in \text{PSH}(Y, \kappa)$ with supremum zero and

$$\text{MA}_\kappa^{\text{ext}}(v) \geq (g/M_g)\kappa^k.$$

For $v_j = \max(v, -j)$, closed Stokes gives $\int_Y \text{MA}_\kappa(v_j) = 1$. The defining non-pluripolar truncations consequently give $\int_Y \text{MA}_\kappa^{\text{ext}}(v) \leq 1$. The prescribed lower measure has mass one, so equality holds both in mass and in the measure inequality.

The pullback u is H -plurisubharmonic, and $\max(u, -j)$ is the pullback of v_j . Multiplying the bounded product expansion by the pullback of $\mathbf{1}_{\{v > -j\}}$ and passing to the defining non-pluripolar limit gives

$$\text{MA}_H^{\text{ext}}(u) = Ch_0^m \wedge \text{MA}_\kappa^{\text{ext}}(v) = \frac{c_0}{M_g} Rg \, dV.$$

Its mass is c_0 . Finally, when $v_-(h_0) = 0$, pulling back bounded potentials from X_0 whose masses tend to zero proves $v_-(H) = 0$ by the same expansion. Closedness of h_0 would contradict that vanishing by Stokes' theorem, so H is not closed. $\square$

On the elliptic threefold of [Theorem 25.17.1](#), with the balanced metric of [Proposition 25.17.1](#), the product with $\mathbb{P}^2$ has $c_0 = 240\pi$. Thus every probability density from the projective factor has this threshold and a finite-mass threshold solution. The theorem concerns factor densities; it does not give an exact equation for an arbitrary density on X or identify limits of normalized exponential solutions.

13.28 Stability of the subsolution threshold

We now study how the threshold $b_h(f)$ depends on f . By [\(13.82\)](#), $b_h^{1/n}$ is an infimum of functions that are continuous on L^1 , and is therefore upper semicontinuous. It is not continuous in general: when $v_-(h) = 0$, every density with positive threshold is an L^1 limit of densities with zero threshold. For density roots, [\(13.81\)](#) expresses ρ_h as a supremum of positive linear functionals. Hence ρ_h is a norm on the space where it is finite, this space is complete for a suitable norm, and the threshold depends continuously on the root in that norm.

Theorem 13.28.1 *Suppose f_j, f are nonzero nonnegative L^1 densities and $f_j \rightarrow f$ in $L^1(dV)$. Then*

$$\limsup_{j \rightarrow \infty} b_h(f_j) \leq b_h(f).$$

Moreover,

$$b_h(f) = \limsup_{\delta \downarrow 0} \{c_h(q) : q \in L^\infty, q \geq 0, q \not\equiv 0, \|q - f\|_{L^1} < \delta\}, \quad (13.84)$$

and the suprema are finite for sufficiently small δ .

Proof For a Gauduchon form γ on X , write $A_\gamma(f) = \int_X (f dV / \gamma^n)^{1/n} \gamma^n$. Since $|s^{1/n} - t^{1/n}| \leq |s - t|^{1/n}$ for $s, t \geq 0$, Hölder's inequality shows that A_γ is continuous on L^1 ; it is positive at every nonzero nonnegative density. By [Theorem 13.26.1](#), $b_h^{1/n}$ is the infimum over γ of the continuous positive functions $f \mapsto \int_X h \wedge \gamma^{n-1} / A_\gamma(f)$. It is therefore upper semicontinuous, and testing a single γ bounds it above on an L^1 neighborhood of f .

For the second assertion, recall that $b_h(q) = c_h(q)$ for bounded q ([Proposition 13.25.2](#)). By the first assertion, $\limsup_j c_h(q_j) \leq b_h(f)$ for every sequence of nonzero nonnegative bounded densities $q_j \rightarrow f$ in L^1 . Hence the limit in [\(13.84\)](#) is at most $b_h(f)$, and the local upper bound makes the suprema finite for small δ . Conversely, the truncations f_k converge to f in L^1 and satisfy $c_h(f_k) \geq b_h(f)$, so every supremum in [\(13.84\)](#) is at least $b_h(f)$. $\square$

Since $b_h \geq 0$, upper semicontinuity makes b_h continuous at every density where it vanishes. If $v_-(h) = 0$, these are its only points of continuity. Indeed, let $b_h(f) > 0$ and $g = f / \int_X f dV$. By [Corollary 13.24.2](#) and [Theorem 13.25.1](#), the densities $(1-t)g + tf_0$, where f_0 is the density of [Theorem 13.24.1](#), have zero threshold and converge to g in L^1 as $t \downarrow 0$; multiplying them by $\int_X f dV$ gives densities with zero threshold converging to f . These statements concern only the scalar b_h ; they say nothing about capacity convergence of the corresponding potentials or about the limits of their Monge–Ampère measures.

13.28.1 Finite sums of densities

Since [\(13.81\)](#) expresses $\rho_h(p)$ as a supremum of positive linear functionals evaluated at $|p|$, the root functional is homogeneous, monotone and subadditive. Subadditivity shows that the sum of two densities with positive threshold again has positive threshold. In the statements below, f and g are nonzero nonnegative L^1 densities, and p and q are real or complex functions in L^n .

Proposition 13.28.1 *The functional ρ_h satisfies $\rho_h(tp) = |t|\rho_h(p)$ for scalars $t \neq 0$, $\rho_h(p) \leq \rho_h(q)$ whenever $|p| \leq |q|$, and*

$$\rho_h(p + q) \leq \rho_h(p) + \rho_h(q).$$

In particular, if $b_h(f), b_h(g) > 0$, then

$$b_h(f + g) \geq (b_h(f)^{-1/n} + b_h(g)^{-1/n})^{-n} > 0.$$

Proof By [\(13.81\)](#), $\rho_h(p) = \sup_{\gamma} L_{h,\gamma}(|p|)$ is a supremum of positive linear functionals evaluated at $|p|$. This gives homogeneity and monotonicity, and, together with $|p + q| \leq |p| + |q|$, the triangle inequality. Finally, $(f + g)^{1/n} \leq f^{1/n} + g^{1/n}$ gives

$$b_h(f + g)^{-1/n} = \rho_h((f + g)^{1/n}) \leq \rho_h(f^{1/n}) + \rho_h(g^{1/n}) = b_h(f)^{-1/n} + b_h(g)^{-1/n},$$

which is equivalent to the asserted lower bound for $b_h(f + g)$. $\square$

Proposition 13.28.2 *The real or complex vector space*

$$\mathcal{D}_h = \{p \in L^n(dV) : \rho_h(p) < +\infty\}$$

is complete for the norm $\|p\|_{\mathcal{D}_h} = \|p\|_{L^n} + \rho_h(p)$. It is an order ideal in L^n : if $q \in \mathcal{D}_h$ and $|p| \leq |q|$, then $p \in \mathcal{D}_h$. It contains L^∞ and is therefore dense in L^n for the L^n norm.

Moreover, $\mathcal{D}_h = L^n$ if and only if $v_-(h) > 0$, and in that case the norm $\|\cdot\|_{\mathcal{D}_h}$ is equivalent to the L^n norm. If h is Kähler, then

$$\rho_h(p) = \left(\int_X h^n \right)^{-1/n} \|p\|_{L^n}.$$

Proof By [Proposition 13.28.1](#), $\mathcal{D}_h$ is a vector space and an order ideal, and $\|\cdot\|_{\mathcal{D}_h}$ is a norm on it. Bounded functions belong to $\mathcal{D}_h$, because $b_h(|p|^n) = c_h(|p|^n) > 0$ for bounded nonzero p .

We next show that ρ_h is lower semicontinuous on L^n . If $p_j \rightarrow p$ in L^n , then $|p_j|^n \rightarrow |p|^n$ in L^1 , and the upper semicontinuity of b_h in [Theorem 13.28.1](#) gives

$$\rho_h(p) \leq \liminf_j \rho_h(p_j).$$

This includes the case $b_h(|p|^n) = 0$, in which the right side must be infinite; for $p = 0$ the inequality is trivial. Now let (p_j) be a Cauchy sequence in $\mathcal{D}_h$. It converges in L^n to some p , and lower semicontinuity gives $\rho_h(p) \leq \liminf_j \rho_h(p_j) < +\infty$, so $p \in \mathcal{D}_h$. Applied to $p_j - p_k$ as $k \rightarrow \infty$, lower semicontinuity also gives

$$\rho_h(p_j - p) \leq \liminf_{k \rightarrow \infty} \rho_h(p_j - p_k),$$

which tends to zero as $j \rightarrow \infty$. Together with L^n convergence, this proves completeness.

If $v_-(h) > 0$, [Proposition 13.25.2](#) gives $\rho_h(p) \leq v_-(h)^{-1/n} \|p\|_{L^n}$, so $\mathcal{D}_h = L^n$ with an equivalent norm. If $v_-(h) = 0$, the density f of [Theorem 13.24.1](#) has $b_h(f) = 0$ by [Theorem 13.25.1](#); thus $f^{1/n}$ belongs to L^n but not to $\mathcal{D}_h$. The Kähler formula follows from the same proposition. $\square$

Thus, when the lower mass vanishes, $\mathcal{D}_h$ is a proper dense subspace of L^n , complete for the stronger norm $\|\cdot\|_{\mathcal{D}_h}$; its nonnegative elements are the n th roots of the densities admitting a positive scaled subsolution. A finite sum of such densities again admits a positive scaled subsolution, but a convergent infinite sum need not: the smooth summands in [Theorem 13.24.1](#) give an example. By [Proposition 13.26.1](#), the space $\mathcal{D}_h$ does not depend on the Hermitian form h , and the norms $\|\cdot\|_{\mathcal{D}_h}$ for different Hermitian forms are equivalent. The closure of the bounded functions for this norm is studied in [Section 13.28.2](#).

The restriction of ρ_h to $\mathcal{D}_h$ is itself a norm: if $p \neq 0$, then $\rho_h(p) \geq L_{h,\gamma}(|p|) > 0$ for any Gauduchon form γ . Whether this weaker norm is complete depends on the upper mass.

Proposition 13.28.3 *The norm ρ_h is complete on $\mathcal{D}_h$ if and only if $v_+(h) < +\infty$. When the upper mass is finite,*

$$\|p\|_{L^n} \leq v_+(h)^{1/n} \rho_h(p) \quad (p \in \mathcal{D}_h),$$

so ρ_h and $\|\cdot\|_{\mathcal{D}_h}$ are equivalent norms.

Proof Suppose $v_+(h) < +\infty$. A continuous solution for a bounded density q has mass $c_h(q) \int_X q \, dV \leq v_+(h)$. Applying this to the truncations of $|p|^n$ and letting the truncation level increase gives $b_h(|p|^n) \|p\|_{L^n}^n \leq v_+(h)$, which is the asserted inequality. Hence ρ_h and $\|\cdot\|_{\mathcal{D}_h}$ are equivalent, and completeness follows from Proposition 13.28.2.

Suppose instead that $v_+(h) = +\infty$. By Theorems 25.1.1 and 25.13.1, the normalization scalars of smooth strictly positive probability densities are unbounded above. For each j , choose such a density f_j with

$$c_h(f_j) \geq (j2^j)^n, \quad \text{and put} \quad p_j = j f_j^{1/n}.$$

Then $\|p_j\|_{L^n} = j$ and $\rho_h(p_j) = j c_h(f_j)^{-1/n} \leq 2^{-j}$, so the partial sums $P_N = \sum_{j \leq N} p_j$ form a Cauchy sequence for ρ_h .

Fix a Gauduchon form γ . Its coefficient a_γ is bounded below by a positive constant, so (13.81) gives $\rho_h(p) \geq c \|p\|_{L^1}$ with a constant $c > 0$. Hence $\sum_j p_j$ converges in L^1 to a nonnegative function P . If P_N converged for ρ_h to an element of $\mathcal{D}_h$, that element would also be the L^1 limit, hence equal to P almost everywhere. But $P \geq p_j$ gives $\|P\|_{L^n} \geq j$ for every j , so $P \notin L^n$. Therefore ρ_h is not complete. $\square$

The two mass properties play separate roles: positive lower mass makes every L^n function admissible, whereas finite upper mass makes the root norm control the L^n norm. The norm $\|\cdot\|_{\mathcal{D}_h}$ is complete without either assumption.

All four combinations occur. On a compact Kähler manifold both mass properties hold. The Hopf threefold has positive lower mass and infinite upper mass (Corollary 8.6.1). The elliptic threefold of Theorem 25.17.1 has zero lower mass, and finite upper mass for its balanced metric (Proposition 25.17.1). The product manifolds of Corollary 25.17.2 have zero lower mass and infinite upper mass. Since neither $\mathcal{D}_h$ nor the completeness of ρ_h depends on the choice of h (Propositions 6.5.1 and 13.26.1), we obtain the following table.

Manifold	Domain $\mathcal{D}_h$	Is ρ_h complete?
Kähler manifold	L^n	Yes
Hopf threefold	L^n	No
Elliptic threefold	$\mathcal{D}_h \subsetneq L^n$	Yes
Product example	$\mathcal{D}_h \subsetneq L^n$	No

13.28.2 Approximation by bounded density roots

Bounded functions are dense in $\mathcal{D}_h$ for the L^n norm, but not obviously for the norm $\|\cdot\|_{\mathcal{D}_h}$. Let $\mathcal{D}_h^0$ denote the closure of L^∞ in $\mathcal{D}_h$ for this norm. We show that a function belongs to $\mathcal{D}_h^0$ exactly when its tails are small uniformly over all Gauduchon tests. The basic tool is a subcritical estimate. For every $r > n$,

$$\rho_h(p) \leq C_r \|p\|_{L^r} \quad (p \in L^r), \quad (13.85)$$

where the constant C_r depends on h , the reference volume and r , but not on p . Indeed, for nonzero $p \in L^r$ the density $|p|^n$ belongs to $L^{r/n}$, so $b_h(|p|^n) = c_h(|p|^n)$ by [Proposition 13.25.2](#), and the lower-density estimate of [Theorem 10.3.1](#), with exponent r/n , gives $c_h(|p|^n) \| |p|^n \|_{L^{r/n}} \geq c_{r/n} > 0$.

Proposition 13.28.4 *For $p \in \mathcal{D}_h$, the following conditions are equivalent:*

- (1) $p \in \mathcal{D}_h^0$;
- (2) $\rho_h(|p| \mathbf{1}_{\{|p|>K\}}) \rightarrow 0$ as $K \rightarrow \infty$;
- (3) whenever $|q_j| \leq |p|$ and $q_j \rightarrow 0$ in measure, one has $\|q_j\|_{\mathcal{D}_h} \rightarrow 0$.

By [\(13.81\)](#), the second condition can be written as

$$\sup_{\gamma \text{ Gauduchon}} L_{h,\gamma}(|p| \mathbf{1}_{\{|p|>K\}}) \rightarrow 0 \quad (K \rightarrow \infty).$$

The space $\mathcal{D}_h^0$ is a closed order ideal in $\mathcal{D}_h$. It contains L^r for every $r > n$, and smooth functions are dense in it. If $v_-(h) > 0$, then $\mathcal{D}_h^0 = \mathcal{D}_h = L^n$.

Proof For $K > 0$, set $p_K = p \min(1, K/|p|)$ where $p \neq 0$, and $p_K = 0$ where $p = 0$. Then $|p - p_K| = (|p| - K)_+$ and

$$(|p| - K)_+ \leq |p| \mathbf{1}_{\{|p|>K\}}, \quad |p| \mathbf{1}_{\{|p|>2K\}} \leq 2(|p| - K)_+.$$

Since the L^n norms of the tails tend to zero, these inequalities and the monotonicity of ρ_h show that the second condition is equivalent to $p_K \rightarrow p$ in $\mathcal{D}_h$; in particular, it implies the first. Conversely, if a is bounded and $K \geq \|a\|_{L^\infty}$, then $(|p| - K)_+ \leq |p - a|$, so $\|p - p_K\|_{\mathcal{D}_h} \leq \|p - a\|_{\mathcal{D}_h}$. Approximating p by bounded functions a shows that the first condition implies $p_K \rightarrow p$, hence the second.

Assume the second condition, and let q_j be as in the third. Fix K . On $\{|p| \leq K\}$, the functions q_j are bounded by K and tend to zero in measure, hence in L^{2n} ; by [\(13.85\)](#) with $r = 2n$, the root functional of $q_j \mathbf{1}_{\{|p| \leq K\}}$ tends to zero. On the complementary set, $\rho_h(q_j \mathbf{1}_{\{|p|>K\}}) \leq \rho_h(|p| \mathbf{1}_{\{|p|>K\}})$. Letting first j and then K tend to infinity gives $\rho_h(q_j) \rightarrow 0$, and dominated convergence gives $\|q_j\|_{L^n} \rightarrow 0$. Conversely, the third condition applied to $q_j = |p| \mathbf{1}_{\{|p|>j\}}$ gives the second.

Since the second condition passes from p to every function dominated by $|p|$, the space $\mathcal{D}_h^0$ is an order ideal; it is closed by definition. For $p \in L^r$ with $r > n$, the truncations p_K converge to p in L^r , hence in $\mathcal{D}_h$ by [\(13.85\)](#). Bounded functions can be approximated in L^{2n} by smooth functions, which then converge in $\mathcal{D}_h$ by the

same estimate; hence smooth functions are dense in $\mathcal{D}_h^0$. Under positive lower mass, **Proposition 13.28.2** shows that $\mathcal{D}_h = L^n$ with an equivalent norm, and bounded functions are dense in L^n ; hence $\mathcal{D}_h^0 = \mathcal{D}_h = L^n$. $\square$

By **Proposition 13.26.1**, the space $\mathcal{D}_h^0$ does not depend on the choice of the Hermitian form h . Convergence in $\mathcal{D}_h$ controls the threshold: if $p_j \rightarrow p \neq 0$ in $\mathcal{D}_h$, then

$$|\rho_h(p_j) - \rho_h(p)| \leq \rho_h(p_j - p) \rightarrow 0, \quad b_h(|p_j|^n) \rightarrow b_h(|p|^n) > 0.$$

For $p \in \mathcal{D}_h^0$, the uniform tail condition also gives a uniform modulus for exponential damping and error bounds for the scalars of the exponential equations; see **Proposition 13.30.1**. It does not by itself give capacity convergence of the solutions. We do not know whether $\mathcal{D}_h^0 = \mathcal{D}_h$ when $v_-(h) = 0$.

13.28.3 Density roots from a closed factor

The product formula of **Theorem 13.27.2** identifies a complete subspace of density roots with uniformly vanishing tails even when the ambient lower mass is zero. Use the product data $X_0, Y, N, H, c_0, \mu, R$ of **Section 13.27.1**. The spaces $\mathcal{D}_H$ and $\mathcal{D}_H^0$ are now taken on the N -dimensional product with reference volume dV .

Proposition 13.28.5 *For real or complex $\xi \in L^N(Y, \kappa^k)$, put $J\xi = R^{1/N} \pi_Y^* \xi$. Then*

$$\|J\xi\|_{L^N(dV)} = \|\xi\|_{L^N(\kappa^k)}, \quad \rho_H(J\xi) = c_0^{-1/N} \|\xi\|_{L^N(\kappa^k)}.$$

The image of J is a closed linear subspace of $\mathcal{D}_H^0$. If $g = |\xi|^N$ and $A = \max_X R$, then

$$\rho_H(J\xi \mathbf{1}_{\{|J\xi| > K\}}) \leq \left(\frac{1}{c_0} \int_{\{g > K^N/A\}} g \kappa^k \right)^{1/N} \rightarrow 0.$$

For $dV = \mu$, so that $R = 1$, the exact tail formula is

$$\rho_H(\pi_Y^* \xi \mathbf{1}_{\{|\xi| > K\}}) = \left(\frac{1}{c_0} \int_{\{|\xi| > K\}} |\xi|^N \kappa^k \right)^{1/N}.$$

Proof Since $|J\xi|^N = R|\xi|^N$, integration against dV gives the first norm identity. For nonzero ξ , **Theorem 13.27.2** applied to $g = |\xi|^N$ gives the root-functional identity; for $\xi = 0$ it holds by definition. Applying the two identities to differences yields

$$\|J\xi - J\eta\|_{\mathcal{D}_H} = (1 + c_0^{-1/N}) \|\xi - \eta\|_{L^N(\kappa^k)}.$$

Bounded approximations of ξ in L^N have bounded images because R is bounded, so $J\xi \in \mathcal{D}_H^0$. Completeness of $L^N(Y, \kappa^k)$ and the displayed identity make the image closed.

On $\{|J\xi| > K\}$ one has $g > K^N/A$, and hence

$$|J\xi|\mathbf{1}_{\{|J\xi|>K\}} \leq (Rg\mathbf{1}_{\{g>K^N/A\}})^{1/N}.$$

Monotonicity of the root functional and its identity for factor roots give the estimate, with the value zero when the tail vanishes. Integrability of g makes the bound tend to zero; the L^N tails also vanish. When $R = 1$, the amplitude cutoff itself is pulled back from Y , so the same norm identity gives equality. $\square$

For $Y = \mathbb{P}^k$ and $dV = \mu$, take $p_\alpha = \pi_Y^*(q_\alpha^{1/N})$ with q_α from [Lemma 13.27.1](#). Then $p_\alpha \in \mathcal{D}_H^0$ but $p_\alpha \notin L^r(dV)$ for every $r > N$. Moreover,

$$\rho_H(p_\alpha \mathbf{1}_{\{p_\alpha > K\}}) \asymp (\log K)^{-k(1-\alpha)/N} \quad (K \rightarrow +\infty).$$

Indeed, the radial estimate of that lemma gives $q_\alpha \asymp r^{-k}(1 - \log r)^{-1-k(1-\alpha)}$. With $L = 1 - \log r$, the density level set $\{q_\alpha > K^N\}$ lies between two sets $\{L > c \log K\}$ for fixed positive constants c , once K is large. Integrating the radial density $L^{-1-k(1-\alpha)} dL$ and taking its N th root gives the claimed tail. The integrability exclusion follows from $q_\alpha \notin L^s$ for $s > 1$.

These roots enlarge the examples in $\mathcal{D}_H^0$ beyond the subcritical L^r classes. They give neither $\mathcal{D}_H^0 = \mathcal{D}_H$ nor a general criterion for an exact equation at zero lower mass.

13.29 Limits of exponential equations

In this section θ is an arbitrary smooth real $(1, 1)$ -form and μ a finite non-pluripolar measure. We consider solutions $u_\lambda \in \text{PSH}(X, \theta)$ of

$$\text{MA}_\theta(u_\lambda) = e^{\lambda u_\lambda} \mu \quad (\lambda > 0).$$

As $\lambda \downarrow 0$, one expects suitably normalized solutions to converge to a solution of $\text{MA}_\theta(u) = c\mu$ with a scalar $c > 0$. For an L^p density with $p > 1$ and a Hermitian background, the continuous solutions satisfy $\lambda u_\lambda \rightarrow \log c$ uniformly ([Proposition 10.5.1](#)). For solutions in a fixed unbounded ordinary type, no such uniform convergence is possible: by [Proposition 1.23.1](#), the L^∞ distance from λu_λ to every finite constant is infinite for each $\lambda > 0$. The limit must instead be formulated through normalized potentials and their measures. Write

$$v_\lambda = u_\lambda - \sup_X u_\lambda, \quad c_\lambda = e^{\lambda \sup_X u_\lambda},$$

so that $\text{MA}_\theta(v_\lambda) = c_\lambda e^{\lambda v_\lambda} \mu$. By [Lemma 1.23.2](#), $e^{\lambda v_\lambda} \rightarrow 1$ in $L^1(\mu)$ as $\lambda \downarrow 0$; hence, if $c_\lambda \rightarrow c < +\infty$, the right-hand sides converge in total variation to $c\mu$. If $\mu = f dV$ with $f \in L^p$ for some $p > 1$, [Lemma 1.23.2](#) gives an error linear in λ .

To identify the Monge–Ampère measure of an L^1 limit of the v_λ , one needs in addition a continuity theorem for the Monge–Ampère operator. For potentials of a fixed ordinary type, [Corollary 13.8.1](#) identifies the limiting measure under a common barrier and a domination hypothesis. In a relative envelope class, [Theorem 30.3.1](#) instead constructs a common lower envelope under positive lower mass: for a semipositive big θ and a reference satisfying (12.20), an L^1 -convergent sequence in the class whose measures are dominated by one finite non-pluripolar measure converges in capacity, and its measures converge weakly. That argument, with its mass hypothesis, is developed in [Chapter 30](#).

13.29.1 A positive limiting exponent

When the exponents converge to a positive limit, the factor $e^{\lambda u}$ makes the Monge–Ampère mass of deep sublevels uniformly small. If the potentials converge in capacity, the tail criterion of [Theorem 7.4.1](#) then identifies the limit of their Monge–Ampère measures, and convergence of the right-hand sides identifies the equation.

Theorem 13.29.1 *Let θ be any smooth real $(1, 1)$ -form and μ a finite non-pluripolar measure. Suppose $f_j \geq 0$, $f_j \rightarrow f$ in $L^1(\mu)$, and $\lambda_j > 0$ with $\lambda_j \rightarrow \lambda > 0$. Let $u_j, u \in \text{PSH}(X, \theta)$ be nonpositive, suppose $u_j \rightarrow u$ in capacity, and assume*

$$\text{MA}_\theta^{\text{ext}}(u_j) = e^{\lambda_j u_j} f_j \mu.$$

Then $\text{MA}_\theta^{\text{ext}}(u)$ is finite and

$$\text{MA}_\theta^{\text{ext}}(u) = e^{\lambda u} f \mu.$$

Moreover, $\text{MA}_\theta^{\text{ext}}(u_j) \rightarrow \text{MA}_\theta^{\text{ext}}(u)$ weakly, and the right-hand sides converge in total variation.

Proof Discarding finitely many indices, we may assume that $\lambda_j \geq \lambda/2$. The measures $\text{MA}_\theta^{\text{ext}}(u_j)$ have masses at most $\|f_j\|_{L^1(\mu)}$, which are uniformly bounded, and since $u_j \leq 0$, their deep sublevels satisfy

$$\text{MA}_\theta^{\text{ext}}(u_j)(\{u_j < -T\}) \leq e^{-\lambda T/2} \|f_j\|_{L^1(\mu)}.$$

The tail criterion [Theorem 7.4.1](#), which holds for an arbitrary smooth background by [Theorem 7.6.1](#), therefore shows that $\text{MA}_\theta^{\text{ext}}(u)$ is finite and that $\text{MA}_\theta^{\text{ext}}(u_j) \rightarrow \text{MA}_\theta^{\text{ext}}(u)$.

It remains to identify this limit with $e^{\lambda u} f \mu$. By [Lemma 1.8.5](#), $u_j \rightarrow u$ in μ -measure. Since $t \mapsto e^{\lambda t}$ is λ -Lipschitz for $t \leq 0$, the functions $e^{\lambda u_j}$, which are bounded by one, converge in μ -measure to $e^{\lambda u}$. The change of exponent is uniform for nonpositive arguments, because the mean value theorem gives

$$\sup_{t \leq 0} |e^{\lambda_j t} - e^{\lambda t}| \leq |\lambda_j - \lambda| \sup_{s \geq 0} s e^{-(\lambda/2)s} \rightarrow 0.$$

Thus $e^{\lambda_j u_j} \rightarrow e^{\lambda u}$ in μ -measure, and hence in $f\mu$ -measure, since the finite measure $f\mu$ is absolutely continuous with respect to μ . As these functions are bounded by one, the convergence also holds in $L^1(f\mu)$. Therefore

$$\begin{aligned} \int_X |e^{\lambda_j u_j} f_j - e^{\lambda u} f| d\mu &\leq \|f_j - f\|_{L^1(\mu)} \\ &+ \int_X |e^{\lambda_j u_j} - e^{\lambda u}| f d\mu \rightarrow 0. \end{aligned}$$

This proves the total-variation convergence of the right-hand sides, and comparing the two limits gives the equation for u . $\square$

Additive normalizations of the potentials can be absorbed into the densities: translating each u_j by a constant multiplies f_j by an exponential factor, and the theorem applies as long as the modified densities still converge in $L^1(\mu)$. Convergence in capacity is a hypothesis; the theorem says nothing about sequences that converge only in L^1 , and it does not keep the limit in a prescribed envelope class.

The proof also shows where the difficulty lies as $\lambda_j \downarrow 0$: the tail bound $e^{-\lambda_j T} \|f_j\|_{L^1(\mu)}$ no longer tends to zero uniformly in j as $T \rightarrow \infty$. A zero-exponent limit therefore needs another source of uniform tail control, such as the integrability condition of [Corollary 7.4.1](#); a uniform bound on the total masses does not by itself control these tails.

13.30 Exponential equations for an individual density

We return to the Hermitian background h and a fixed nonzero density $0 \leq f \in L^1(dV)$, and consider, for $\lambda > 0$, the exponential equation

$$\text{MA}_h^{\text{ext}}(u) = e^{\lambda u} f dV, \quad u \in \text{PSH}(X, h). \quad (13.86)$$

A *solution* is a function $u \in \text{PSH}(X, h)$ satisfying (13.86), and an *exponential subsolution* at exponent λ is a function $s \in \text{PSH}(X, h)$ with $\text{MA}_h^{\text{ext}}(s) \geq e^{\lambda s} f dV$. For the truncations $f_k = \min(f, k)$, [Theorem 10.1.2](#) gives continuous solutions u_k of the truncated equations, and these decrease as k increases. Strict domination shows that every exponential subsolution is a common lower bound for the u_k . Hence, as soon as one subsolution exists, the decreasing limit is not identically $-\infty$, and [Theorem 13.29.1](#) shows that it solves (13.86); it is the greatest subsolution. A positive threshold $b_h(f)$ provides exponential subsolutions for every exponent, and the normalized greatest solutions then recover $b_h(f)$ as $\lambda \downarrow 0$.

Theorem 13.30.1 *Fix $\lambda > 0$, and suppose that (13.86) has an exponential subsolution $s \in \text{PSH}(X, h)$. For $k \geq 1$, let u_k be the continuous solution of*

$$\text{MA}_h(u_k) = e^{\lambda u_k} f_k dV, \quad f_k = \min(f, k),$$

given by [Theorem 10.1.2](#). Then u_k decreases to a solution u_λ of (13.86), and $\text{MA}_h^{\text{ext}}(u_\lambda)$ has finite mass. Moreover, u_λ is the greatest exponential subsolution: every exponential subsolution v at exponent λ satisfies $v \leq u_\lambda$. In particular, u_λ is the greatest solution of (13.86).

Proof Since $f_k \leq f_{k+1}$, [Lemma 10.4.2](#) gives $u_{k+1} \leq u_k$.

We first show that every exponential subsolution v lies below each u_k . Let $t > 0$. On the set $\{u_k < v - t\}$,

$$\text{MA}_h(u_k) = e^{\lambda u_k} f_k \, dV \leq e^{-\lambda t} e^{\lambda v} f \, dV \leq e^{-\lambda t} \text{MA}_h^{\text{ext}}(v - t).$$

Since u_k is bounded, $P_{h/2}(u_k) \geq \inf_X u_k$ is not identically $-\infty$, and $v - t \leq u_k$. Strict domination, [Theorem 13.1.1](#), therefore gives $u_k \geq v - t$. Letting $t \downarrow 0$ gives $u_k \geq v$.

In particular $s \leq u_k \leq u_1$ for every k , so the decreasing limit $u_\lambda \geq s$ is not identically $-\infty$ and belongs to $\text{PSH}(X, h)$. By [Lemma 1.8.6](#), $u_k \rightarrow u_\lambda$ in capacity. Choose a constant $A \geq \sup_X u_1$. The nonpositive functions $u_k - A$ satisfy

$$\text{MA}_h^{\text{ext}}(u_k - A) = e^{\lambda(u_k - A)} e^{\lambda A} f_k \, dV,$$

and $e^{\lambda A} f_k \rightarrow e^{\lambda A} f$ in $L^1(dV)$. [Theorem 13.29.1](#), applied with $\mu = dV$ and constant exponents, shows that $\text{MA}_h^{\text{ext}}(u_\lambda)$ is finite and that u_λ solves (13.86). Finally, every exponential subsolution lies below all u_k , hence below u_λ , which is itself a subsolution. $\square$

Being the greatest subsolution, u_λ does not depend on the approximation used to construct it. The equation may have other, smaller solutions with different singularities. If $f \in L^p$ for some $p > 1$, the continuous solution of [Theorem 10.1.2](#) is a subsolution and therefore lies below u_λ . Thus u_λ is bounded, and bounded exponential comparison ([Corollary 10.2.2](#)) shows that it coincides with the continuous solution.

Corollary 13.30.1 *Suppose $b = b_h(f) > 0$. Then (13.86) has a greatest solution u_λ for every $\lambda > 0$. If $v \in \text{PSH}(X, h)$ satisfies $\sup_X v = 0$ and $\text{MA}_h^{\text{ext}}(v) \geq b f \, dV$, then*

$$u_\lambda \geq v + \lambda^{-1} \log b.$$

Put

$$M_\lambda = \sup_X u_\lambda, \quad v_\lambda = u_\lambda - M_\lambda, \quad c_\lambda = e^{\lambda M_\lambda}.$$

Then, as $\lambda \downarrow 0$,

$$c_\lambda \longrightarrow b_h(f), \quad e^{\lambda u_\lambda} f \longrightarrow b_h(f) f \quad \text{in } L^1(dV).$$

Proof By Theorem 13.25.1, a function v as in the statement exists. Since $v \leq 0$, the function $s = v + \lambda^{-1} \log b$ satisfies

$$\text{MA}_h^{\text{ext}}(s) \geq b f \, dV \geq e^{\lambda s} f \, dV,$$

so it is an exponential subsolution. Theorem 13.30.1 gives the greatest solution u_λ and the bound $u_\lambda \geq s$; in particular, $c_\lambda \geq b$.

Set $g_\lambda = e^{\lambda v_\lambda} f$. By Lemma 1.23.2, applied to the finite measure $f \, dV$, we have $g_\lambda \rightarrow f$ in L^1 as $\lambda \downarrow 0$. Each g_λ is nonzero, since v_λ is finite almost everywhere. The equation for u_λ reads $\text{MA}_h^{\text{ext}}(v_\lambda) = c_\lambda g_\lambda \, dV$, so Theorem 13.25.1, applied to the density g_λ , gives

$$c_\lambda \leq b_h(g_\lambda).$$

The upper semicontinuity of the threshold (Theorem 13.28.1) therefore gives

$$b \leq \liminf_{\lambda \downarrow 0} c_\lambda \leq \limsup_{\lambda \downarrow 0} c_\lambda \leq b_h(f) = b.$$

This proves $c_\lambda \rightarrow b$. Since $e^{\lambda u_\lambda} f = c_\lambda g_\lambda$ and $g_\lambda \rightarrow f$ in L^1 , it also proves $e^{\lambda u_\lambda} f \rightarrow b f$ in L^1 . $\square$

Since $\text{MA}_h^{\text{ext}}(v_\lambda) = e^{\lambda u_\lambda} f \, dV$, the Monge–Ampère measures of the normalized greatest solutions converge in total variation to $b_h(f) f \, dV$. This answers the questions about the scalar and the measure raised in Section 13.29; the potentials v_λ themselves are harder to control. Under positive lower mass, Corollary 30.7.1 shows that every L^1 -convergent sequence v_{λ_j} with $\lambda_j \downarrow 0$ converges in capacity to a solution of $\text{MA}_h^{\text{ext}}(v) = b_h(f) f \, dV$. For L^p data with $p > 1$, Proposition 13.19.1 gives uniform precompactness. In both cases, convergence of the whole family (v_λ) requires that all its cluster limits coincide. This holds when the dual problem for $f^{1/n}$ over Gauduchon currents, studied in Section 25.9, has a smooth strictly positive maximizer: the whole family then converges uniformly (Corollary 25.9.2). If the maximizer is smooth and semipositive, and strictly positive outside a proper analytic set, Proposition 25.9.5 gives L^1 convergence of the whole family and a fixed lower barrier, and Corollary 25.9.5 strengthens this to uniform convergence for L^p data with $p > 1$.

For a general positive threshold, the corollary gives the lower bound

$$v_\lambda \geq v - \lambda^{-1} \log(c_\lambda/b_h(f))$$

for every normalized threshold subsolution v . The next subsection estimates the scalar error $\log(c_\lambda/b_h(f))$ when $f^{1/n}$ can be approximated by bounded functions in the norm of $\mathcal{D}_h$. When $b_h(f) = 0$, [Theorem 13.30.1](#) still applies whenever an exponential subsolution exists; examples are constructed in [Section 13.30.2](#).

13.30.1 An error bound for the scalar limit

Suppose that $f^{1/n}$ belongs to the space $\mathcal{D}_h^0$ of [Section 13.28.2](#). The uniform tail condition of [Proposition 13.28.4](#) then gives a rate for the convergence $c_\lambda \rightarrow b_h(f)$ in [Corollary 13.30.1](#). Split the root $p = f^{1/n}$ at a height K . On $\{p \leq K\}$, the error $p(1 - e^{\lambda v/n})$ of the damped root has norm $O(K\lambda)$ in $\mathcal{D}_h$, uniformly over normalized potentials v , while on $\{p > K\}$ it is bounded by the tail of p , which is small in that norm. Optimizing over K gives a modulus valid for every normalized potential.

Proposition 13.30.1 *Let $0 \leq p \in \mathcal{D}_h^0$ be nonzero, and put $f = p^n$, $R = \rho_h(p)$ and $b = R^{-n} = b_h(f)$. There is a constant C_h , depending only on h and dV , such that the function*

$$\eta_p(\lambda) = \inf_{K>0} (\|p \mathbf{1}_{\{p>K\}}\|_{\mathcal{D}_h} + C_h K \lambda)$$

tends to zero as $\lambda \downarrow 0$ and satisfies

$$\|p(1 - e^{\lambda v/n})\|_{\mathcal{D}_h} \leq \eta_p(\lambda) \quad (v \in \text{PSH}(X, h), \sup_X v = 0). \quad (13.87)$$

Let u_λ , v_λ and c_λ be the greatest exponential solutions and their normalizations from [Corollary 13.30.1](#). If $\eta_p(\lambda) < R$, then

$$b \leq c_\lambda \leq (R - \eta_p(\lambda))^{-n}$$

and

$$\|\text{MA}_h^{\text{ext}}(v_\lambda) - b f dV\|_{\text{TV}} \leq (c_\lambda - b) \|p\|_{L^n}^n + nb \|p\|_{L^n}^{n-1} \eta_p(\lambda).$$

If $p \in L^r$ for some finite $r > n$, the same bounds hold with $\eta_p(\lambda)$ replaced by $C_{h,r} \|p\|_{L^r} \lambda$, where $C_{h,r}$ depends only on h , dV and r . In particular, for each such p the scalar and total-variation errors are $O(\lambda)$.

Proof By [Lemma 1.5.1](#), normalized h -plurisubharmonic functions are uniformly bounded in every L^s with $s < +\infty$. By [\(13.85\)](#) with $r = 2n$, their norms $\|v\|_{\mathcal{D}_h}$ are therefore uniformly bounded; let C_h be $1/n$ times this bound. Let v be normalized and $K > 0$. On $\{p \leq K\}$ we have

$$0 \leq p(1 - e^{\lambda v/n}) \leq K\lambda(-v)/n,$$

since $1 - e^{-x} \leq x$ for $x \geq 0$, while on $\{p > K\}$ we use the bound $p(1 - e^{\lambda v/n}) \leq p$. The monotonicity of $\|\cdot\|_{\mathcal{D}_h}$ and the triangle inequality give

$$\|p(1 - e^{\lambda v/n})\|_{\mathcal{D}_h} \leq \|p\mathbf{1}_{\{p > K\}}\|_{\mathcal{D}_h} + C_h K\lambda,$$

and taking the infimum over K proves [\(13.87\)](#). By [Proposition 13.28.4](#), and since the L^n tails of p tend to zero, $\|p\mathbf{1}_{\{p > K\}}\|_{\mathcal{D}_h} \rightarrow 0$ as $K \rightarrow \infty$. Choosing K first and then letting $\lambda \downarrow 0$ shows that $\eta_p(\lambda) \rightarrow 0$.

Now set $q_\lambda = p e^{\lambda v_\lambda/n}$, so that $q_\lambda^n = g_\lambda = e^{\lambda v_\lambda} f$, with g_λ as in the proof of [Corollary 13.30.1](#). Since $0 \leq q_\lambda \leq p$ and $\rho_h(p - q_\lambda) \leq \eta_p(\lambda)$ by [\(13.87\)](#), the triangle inequality and monotonicity give

$$R - \eta_p(\lambda) \leq \rho_h(q_\lambda) \leq R.$$

The same proof gives $b \leq c_\lambda \leq b_h(g_\lambda) = \rho_h(q_\lambda)^{-n}$, which yields the scalar bound. For the measures, the factorization of $p^n - q_\lambda^n$ gives $0 \leq p^n - q_\lambda^n \leq n p^{n-1}(p - q_\lambda)$, and Hölder's inequality implies

$$\|f - g_\lambda\|_{L^1} \leq n \|p\|_{L^n}^{n-1} \|p - q_\lambda\|_{L^n} \leq n \|p\|_{L^n}^{n-1} \eta_p(\lambda).$$

Since $\text{MA}_h^{\text{ext}}(v_\lambda) = c_\lambda g_\lambda dV$, the identity $c_\lambda g_\lambda - b f = (c_\lambda - b)g_\lambda - b(f - g_\lambda)$, together with $\|g_\lambda\|_{L^1} \leq \|f\|_{L^1} = \|p\|_{L^n}^n$, proves the total-variation bound.

Finally, suppose $p \in L^r$ with $n < r < +\infty$, and choose $n < s < r$. By [\(13.85\)](#) with exponent s , and since $\|\cdot\|_{L^n} \leq \|\cdot\|_{L^s}$, we have $\|\cdot\|_{\mathcal{D}_h} \leq (1 + C_s)\|\cdot\|_{L^s}$. Hölder's inequality and [Lemma 1.5.1](#) then give, for every normalized v ,

$$\|p(-v)\|_{\mathcal{D}_h} \leq (1 + C_s)\|p(-v)\|_{L^s} \leq (1 + C_s)\|p\|_{L^r}\|v\|_{L^{rs/(r-s)}} \leq n C_{h,r} \|p\|_{L^r}.$$

Since $0 \leq 1 - e^{\lambda v/n} \leq \lambda(-v)/n$, the left side of [\(13.87\)](#) is therefore at most $C_{h,r} \|p\|_{L^r} \lambda$, and the two estimates above can be repeated with this bound in place of $\eta_p(\lambda)$. For λ so small that $C_{h,r} \|p\|_{L^r} \lambda \leq R/2$, the function $t \mapsto (R - t)^{-n}$ has bounded derivative on $[0, R/2]$, so the scalar error $c_\lambda - b$, and hence the total-variation error, is $O(\lambda)$. $\square$

For a general $p \in \mathcal{D}_h^0$ the modulus $\eta_p(\lambda)$ tends to zero, but we do not know whether it is $O(\lambda)$. Combined with the lower bound $v_\lambda \geq v - \lambda^{-1} \log(c_\lambda/b)$ for normalized threshold subsolutions v , the proposition gives

$$0 \leq \lambda^{-1} \log(c_\lambda/b) \leq -\frac{n}{\lambda} \log(1 - \eta_p(\lambda)/R),$$

which stays bounded as $\lambda \downarrow 0$ when $\eta_p(\lambda) = O(\lambda)$, in particular for $p \in L^r$ with $r > n$; root tails alone do not give such a bound. Even when a uniform lower barrier for v_λ is available, passing to the limit in capacity requires the singularity-type or lower-mass hypotheses of a continuity theorem. The proposition estimates only scalars and measures; when the lower mass vanishes, it does not give an exact equation at the threshold.

13.30.2 Exponential equations at zero threshold

When $b_h(f) = 0$, no positive multiple of $f \, dV$ is dominated by a Monge–Ampère measure. An exponential subsolution s only needs $\text{MA}_h^{\text{ext}}(s) \geq e^{\lambda s} f \, dV$, however, and the factor $e^{\lambda s}$ is small where s is very negative. A density concentrating near the pole of a singular potential can therefore admit exponential subsolutions although its threshold vanishes. We construct such densities on the products of [Section 13.27](#).

We keep the notation of that section: $X = X_0 \times Y$ with $Y = \mathbb{P}^k$, the background $H = h_0 + \kappa$, the constants N, C and V_0 , the probability volume form $\mu = V_0^{-1} h_0^m \wedge \kappa^k$ with density $R = \mu/dV$, and the potential u_α with density q_α from [Lemma 13.27.1](#), for a fixed $0 < \alpha < 1$. On $Y \setminus \{o\}$ put $L = 1 - \psi \geq 1$, so that $u_\alpha = 1 - L^\alpha$, and $t = e^{1-L}$. As functions of L , define

$$a = \alpha L^{\alpha-1}, \quad Q = t + (1-t)a, \quad D = t(1-a) + (1-t)\alpha(1-\alpha)L^{\alpha-2},$$

$$W = kQ^{k-1}D, \quad B_\tau = q_\alpha e^{\tau(L^\alpha-1)} \quad (\tau > 0), \quad b_0 = (1-\alpha)^k.$$

Here Q is the function $Q(r)$ of [Lemma 13.27.1](#), written in terms of L , and $D = -dQ/dL$. The weight B_τ is chosen so that $e^{\tau u_\alpha} B_\tau = q_\alpha$ off o .

Lemma 13.30.1 *As functions of L ,*

$$q_\alpha = Q^{k-1} D e^{k(L-1)}, \quad q_\alpha \geq b_0,$$

and $W(L) \sim k\alpha^k(1-\alpha)L^{-1-k(1-\alpha)}$ as $L \rightarrow +\infty$. For every $\tau > 0$, $e^{\tau(L^\alpha-1)}W(L) \rightarrow +\infty$ as $L \rightarrow +\infty$. In particular, $B_\tau \kappa^k$ has infinite mass on every punctured neighborhood of o .

Proof In the notation of the proof of [Lemma 13.27.1](#), $t = r/(1+r)$ and $s(r) = L$. Since the mass of $q_\alpha \kappa^k$ on $\{r_1 < r < r_2\}$ is $Q(r_2)^k - Q(r_1)^k$, this measure has radial distribution $-d(Q^k)/dL = W(L) \, dL$. The Fubini–Study measure κ^k corresponds to $Q = t$, so its radial distribution is $ke^{-k(L-1)}dL$. Both measures are invariant under the unitary group of the chart, so q_α is the ratio of the two distributions, which is the stated formula. The lower bound $q_\alpha \geq b_0$ follows from $\kappa + dd^c u_\alpha \geq (1-\alpha)\kappa$ off o . As $L \rightarrow +\infty$, t tends to zero exponentially, so $Q \sim \alpha L^{\alpha-1}$ and $D \sim \alpha(1-\alpha)L^{\alpha-2}$; this gives the asymptotics of W . Consequently,

$$\log(e^{\tau(L^\alpha-1)}W(L)) = \tau L^\alpha - [1 + k(1-\alpha)] \log L + O(1) \rightarrow +\infty,$$

and the mass of $B_\tau \kappa^k$ on $\{L > T\}$, which equals $\int_T^\infty e^{\tau(L^\alpha - 1)} W(L) dL$, is infinite for every T . $\square$

Theorem 13.30.2 *Let $f \geq 0$ be a nonzero integrable function on X , and put $F = f/R$.*

(1) *If $\lambda > 0$ and $F \leq AB_\lambda$ almost everywhere for a constant $A > 0$, then*

$$s_\lambda = u_\alpha + \lambda^{-1} \log(CV_0/A)$$

is an exponential subsolution at exponent λ , of mass CV_0 , and the equation

$\text{MA}_H^{\text{ext}}(u) = e^{\lambda u} f dV$ has a greatest solution, whose mass is finite and positive.

(2) *Suppose that F is locally essentially bounded on $X \setminus (X_0 \times \{o\})$ and*

$$\lim_{T \rightarrow +\infty} \text{ess sup}_{x \in X_0, L(y) > T} \frac{\log^+(F(x, y)/q_\alpha(y))}{L(y)^\alpha} = 0,$$

where $\log^+ r = \log \max(1, r)$ for $r \geq 0$. Then the hypothesis of (1), and hence its conclusion, holds for every $\lambda > 0$.

Proof (1) By **Theorem 13.27.1**, $\text{MA}_H^{\text{ext}}(u_\alpha) = CV_0 q_\alpha \mu$. Off the pole fiber $X_0 \times \{o\}$ we have $e^{\lambda u_\alpha} B_\lambda = q_\alpha$ and $f dV = F\mu \leq AB_\lambda \mu$, hence

$$e^{\lambda s_\lambda} f dV \leq (CV_0/A) e^{\lambda u_\alpha} AB_\lambda \mu = CV_0 q_\alpha \mu = \text{MA}_H^{\text{ext}}(s_\lambda),$$

and both measures vanish on the pole fiber. Thus s_λ is an exponential subsolution, and its mass is CV_0 , since adding a constant does not change the Monge–Ampère measure. **Theorem 13.30.1** now gives the greatest solution u and the finiteness of its mass. The mass $\int_X e^{\lambda u} f dV$ is positive because u is finite almost everywhere and f has positive integral.

(2) Fix $\lambda > 0$. By hypothesis, there is T such that $F/q_\alpha \leq e^{(\lambda/2)L^\alpha}$ almost everywhere on $\{L > T\}$. Since $e^{(\lambda/2)L^\alpha} \leq e^\lambda e^{\lambda(L^\alpha - 1)}$ for $L \geq 1$, we have $F \leq e^\lambda B_\lambda$ there. On the complement $\{L \leq T\}$, which is compact and disjoint from the pole fiber, F is essentially bounded, while $B_\lambda \geq q_\alpha \geq b_0 > 0$. Increasing the constant, we obtain $F \leq AB_\lambda$ almost everywhere on X . $\square$

Theorem 13.30.3 *Let F_j , $j \geq 1$, be smooth strictly positive probability densities on X_0 with respect to $dV_0 = V_0^{-1} h_0^m$, whose normalization scalars on X_0 , relative to h_0 and dV_0 , satisfy $c_{h_0}(F_j) \leq 2^{-2j}/C$. There are smooth strictly positive probability densities g_j on Y with respect to κ^k such that the probability densities*

$$f_j = RF_j g_j, \quad f = \sum_{j \geq 1} 2^{-j} f_j$$

on X satisfy $c_H(f_j) \leq 2^{-2j}$ and $b_H(f) = 0$. The function f is finite everywhere, smooth off the pole fiber $X_0 \times \{o\}$, has integral one and is bounded below by a positive constant. For every $\lambda > 0$, the equation $\text{MA}_H^{\text{ext}}(u) = e^{\lambda u} f dV$ has an exponential subsolution and a greatest solution, of finite mass, and every solution is unbounded.

Proof Put $w_j = 2^{-j}$ and $M_j = \max_{X_0} F_j$.

Step 1: a smooth baseline. Fix C^j norms $\|\cdot\|_{C^j}$ on X_0 , computed in a fixed finite atlas, so that they increase with j . Choose $0 < \varepsilon_j \leq 1/2$ with

$$w_j \varepsilon_j M_j \leq b_0 2^{-j-2}, \quad w_j \varepsilon_j \|F_j\|_{C^j} \leq 2^{-j}.$$

Then $E = \sum_j w_j \varepsilon_j F_j$ converges in every C^l norm, so E is smooth on X_0 , and $0 < E \leq b_0/4$.

Step 2: bumps escaping to the pole. Choose a smooth function $\chi : \mathbb{R} \rightarrow [0, 1]$, supported in $[0, 1]$, positive on $(0, 1)$ and flat at 0 and 1. Starting with $T_0 = 0$, choose inductively $T_j \geq 2$ with $T_j > T_{j-1} + 2$ and

$$Z_j = \int_{T_j}^{T_j+1} \chi(L - T_j) e^{(L^\alpha - 1)/j} W(L) dL \geq 2w_j M_j.$$

This is possible because, by [Lemma 13.30.1](#) with $\tau = 1/j$, the factor $e^{(L^\alpha - 1)/j} W(L)$ is uniformly large on sufficiently distant intervals. On the annulus $\{T_j \leq L \leq T_j + 1\}$ put $\beta_j = \chi(L - T_j) B_{1/j} / Z_j$, extend β_j by zero, and set $g_j = \varepsilon_j + (1 - \varepsilon_j) \beta_j$. Since χ is flat at the endpoints, β_j is smooth; it vanishes near o and near the hyperplane $\{L = 1\}$. Its integral against κ^k is one, so g_j is a smooth strictly positive probability density with respect to κ^k . Moreover,

$$w_j M_j (1 - \varepsilon_j) \beta_j \leq B_{1/j} / 2.$$

Step 3: the scalars $c_H(f_j)$. By [Theorem 9.1.1](#) on Y , there is a smooth ϕ_j with $\kappa + \text{dd}^c \phi_j > 0$ and $(\kappa + \text{dd}^c \phi_j)^k = g_j \kappa^k$; the scalar is one because both sides have mass one. On X_0 , the same theorem gives a smooth v_j with $h_0 + \text{dd}^c v_j > 0$ and $(h_0 + \text{dd}^c v_j)^m = c_{h_0}(F_j) F_j dV_0$. Since only one term of the binomial expansion survives for dimensional reasons,

$$(H + \text{dd}^c(v_j + \phi_j))^N = C c_{h_0}(F_j) F_j g_j \mu = C c_{h_0}(F_j) f_j dV.$$

Uniqueness of the scalar gives $c_H(f_j) = C c_{h_0}(F_j) \leq 2^{-2j}$.

Step 4: properties of f . By Tonelli's theorem, $\int_X f dV = \sum_j w_j = 1$. The density of $f dV$ with respect to μ is

$$F = f/R = \sum_j w_j F_j g_j = E + \sum_j w_j (1 - \varepsilon_j) F_j \beta_j.$$

The annuli are disjoint and escape to the pole, so only finitely many bumps meet any compact subset of $Y \setminus \{o\}$; hence F , and therefore f , is smooth off the pole fiber. On the pole fiber all bumps vanish and $F = E$, so f is finite everywhere. Also $f \geq w_1 f_1 \geq \frac{1}{2} \min_X f_1 > 0$. If $\text{MA}_H^{\text{ext}}(u) \geq a f dV$ with $a > 0$, then $\text{MA}_H^{\text{ext}}(u) \geq a w_j f_j dV$, and [Lemma 13.24.1](#) gives

$$a w_j \leq c_H(f_j) \leq 2^{-2j}, \quad \text{that is, } a \leq 2^{-j}, \quad \text{for every } j.$$

This is impossible, so $b_H(f) = 0$ by [Theorem 13.25.1](#).

Step 5: exponential subsolutions. Fix $\lambda > 0$, and choose J with $1/j \leq \lambda$ for $j \geq J$. Since $L^\alpha - 1 \geq 0$, we have $B_{1/j} \leq B_\lambda$ for these j . As the bumps have disjoint supports, Step 2 bounds their total contribution $\sum_{j \geq J} w_j(1 - \varepsilon_j)F_j\beta_j$ by $B_\lambda/2$. The baseline satisfies $E \leq b_0/4 \leq B_\lambda/4$, because $B_\lambda \geq q_\alpha \geq b_0$. The remaining finitely many bumps are bounded by the constant

$$K_\lambda = \max_Y \sum_{j < J} w_j(1 - \varepsilon_j)M_j\beta_j,$$

and $K_\lambda \leq (K_\lambda/b_0)B_\lambda$. Hence $F \leq A_\lambda B_\lambda$ with $A_\lambda = 3/4 + K_\lambda/b_0$, and [Theorem 13.30.2](#) gives the exponential subsolution $u_\alpha + \lambda^{-1} \log(CV_0/A_\lambda)$ and the greatest solution. Finally, a bounded solution u would satisfy $\text{MA}_H^{\text{ext}}(u) \geq e^{\lambda \inf_X u} f \, dV$, a positive scaled subsolution, contradicting $b_H(f) = 0$. Hence every solution is unbounded. $\square$

The density just constructed also satisfies the criterion in part (2) of [Theorem 13.30.2](#): on the j th annulus, $F/q_\alpha \leq 1/4 + \frac{1}{2}e^{(L^\alpha-1)/j}$, and away from all annuli the ratio is at most $1/4$. Approaching the pole through the annuli forces $j \rightarrow \infty$, so the required limit is zero. Since $b_H(f) = 0$, [Proposition 13.25.2](#) also shows that f belongs to no L^p with $p > 1$.

Densities F_j as in the theorem exist whenever $v_-(h_0) = 0$, by [Theorems 25.1.1](#) and [25.13.1](#). For instance, on the elliptic threefold, [Theorem 25.17.1](#) gives smooth functions v_ℓ with $h_0 + \text{dd}^c v_\ell > 0$ and masses $\delta_\ell = \int_{X_0} (h_0 + \text{dd}^c v_\ell)^3 \rightarrow 0$. The probability densities $F_\ell = (h_0 + \text{dd}^c v_\ell)^3 / (\delta_\ell \, dV_0)$ satisfy $c_{h_0}(F_\ell) = \delta_\ell$ by uniqueness of the scalar, and a subsequence with $\delta_{\ell_j} \leq 2^{-2j}/C$ gives the required densities. Thus the construction applies to this threefold times $\mathbb{P}^k$ for every $k \geq 1$. With the balanced metric of [Proposition 25.17.1](#), $V_0 = 24\pi$, so the explicit subsolutions have mass CV_0 , equal to 96π on the fourfold ($k = 1$) and 240π on the fivefold ($k = 2$). These values concern the subsolutions; the greatest solutions have their own finite positive masses.

In this construction the projective components g_j are chosen after the densities F_j , to fit them. We do not know whether the exponential equation is solvable for every prescribed concentration family of this kind, and we have no necessary criterion for solvability at zero threshold.

13.30.3 Solvable exponents and collapse at zero threshold

We return to a general Hermitian form h on X and a nonzero density $0 \leq f \in L^1(dV)$. Let $\Lambda_h(f)$ be the set of exponents $\lambda > 0$ for which (13.86) has a solution. By [Theorem 13.30.1](#), $\lambda \in \Lambda_h(f)$ if and only if the equation has an exponential subsolution at exponent λ .

Proposition 13.30.2 *If $\lambda_0 \in \Lambda_h(f)$, then $[\lambda_0, +\infty) \subset \Lambda_h(f)$. Consequently, $\Lambda_h(f)$ is empty, or equals $(a, +\infty)$ for some $a \geq 0$, or equals $[a, +\infty)$ for some $a > 0$. If $b_h(f) > 0$, then $\Lambda_h(f) = (0, +\infty)$.*

Proof Let u be a solution at λ_0 , and put $s = u - \max(0, \sup_X u)$. Then $s \leq \min(u, 0)$, so for $\lambda \geq \lambda_0$,

$$\begin{aligned} \text{MA}_h^{\text{ext}}(s) &= e^{\lambda_0 u} f \, dV \\ &\geq e^{\lambda_0 s} f \, dV \geq e^{\lambda s} f \, dV. \end{aligned}$$

Thus s is an exponential subsolution at every $\lambda \geq \lambda_0$, and [Theorem 13.30.1](#) gives a solution. Hence $\Lambda_h(f)$ contains $[\lambda_0, +\infty)$ together with each of its points λ_0 . A nonempty subset of $(0, +\infty)$ with this property is determined by its infimum a and by whether a belongs to it, which gives the stated forms. If $b_h(f) > 0$, [Corollary 13.30.1](#) gives $\Lambda_h(f) = (0, +\infty)$. $\square$

Proposition 13.30.3 *Suppose $b_h(f) = 0$. Let $\lambda_j > 0$ decrease to zero, and let u_j be any solution of (13.86) at exponent λ_j . Put*

$$M_j = \sup_X u_j, \quad v_j = u_j - M_j, \quad c_j = e^{\lambda_j M_j}.$$

Then

$$\begin{aligned} c_j &\longrightarrow 0, \quad \lambda_j M_j \longrightarrow -\infty, \\ \|\text{MA}_h^{\text{ext}}(u_j)\|_{\text{TV}} &= \|\text{MA}_h^{\text{ext}}(v_j)\|_{\text{TV}} \longrightarrow 0. \end{aligned}$$

Moreover, $e^{\lambda_j u_j} \rightarrow 0$ uniformly on X , where the exponential is zero on the pole set, and $u_j \rightarrow -\infty$ uniformly, that is, $\sup_X u_j \rightarrow -\infty$.

Proof Set $g_j = e^{\lambda_j v_j} f$. By [Lemma 1.23.2](#), applied to the finite non-pluripolar measure $f \, dV$, $g_j \rightarrow f$ in L^1 ; each g_j is nonzero, since v_j is finite almost everywhere. Since the Monge–Ampère measure is unchanged by adding constants,

$$\text{MA}_h^{\text{ext}}(v_j) = c_j g_j \, dV, \quad \text{hence} \quad 0 < c_j \leq b_h(g_j)$$

by [Theorem 13.25.1](#). The upper semicontinuity of the threshold, [Theorem 13.28.1](#), gives $\limsup_j c_j \leq b_h(f) = 0$. Since $0 \leq g_j \leq f$, the total masses are at most $c_j \|f\|_{L^1}$ and tend to zero. Moreover $\lambda_j M_j = \log c_j \rightarrow -\infty$, and $0 \leq e^{\lambda_j u_j} \leq e^{\lambda_j M_j} = c_j$. Finally, once $\lambda_j < 1$ and $\log c_j < 0$, we have $M_j = \lambda_j^{-1} \log c_j \leq \log c_j$, so $M_j \rightarrow -\infty$. $\square$

For the density of **Theorem 13.30.3**, solutions exist for every positive exponent, so the collapse applies as $\lambda \downarrow 0$ to every choice of solutions, in particular to the greatest ones. By contrast, the subsolutions of **Theorem 13.30.2** keep the mass CV_0 for every exponent, while the masses of the solutions above them tend to zero: on a nonclosed background, the order of two potentials does not give an order of their total Monge–Ampère masses. Whether the normalized potentials converge in capacity, and which equation a normalized cluster limit satisfies at exponent zero, are not decided by this argument. Positive endpoints of $\Lambda_h(f)$ are governed instead by the compactness criterion below.

13.30.4 Positive endpoints and one-sided limits

For $\lambda \in \Lambda_h(f)$, write U_λ for the greatest solution given by **Theorem 13.30.1**. When the exponents stay above a fixed $\tau > 0$, the solution of a bounded truncated equation at exponent τ is a common upper barrier for all subsolutions. Together with the maximality of greatest solutions, this barrier gives an order estimate between U_{λ_1} and U_{λ_2} , which controls the positive endpoint of $\Lambda_h(f)$ and the limits of U_λ from the right.

Lemma 13.30.2 *For every $\tau > 0$, there is a nonnegative $t_\tau \in \text{PSH}(X, h) \cap C(X)$ such that every exponential subsolution at an exponent $\lambda \geq \tau$ lies below t_τ . Put $K_\tau = \sup_X t_\tau$. If $\tau \leq \lambda_1 \leq \lambda_2$ belong to $\Lambda_h(f)$, then*

$$U_{\lambda_2} \geq U_{\lambda_1} - K_\tau \frac{\lambda_2 - \lambda_1}{\lambda_2}.$$

Consequently, $\lambda \mapsto U_\lambda + K_\tau \log(\lambda/\tau)$ is nondecreasing on $\Lambda_h(f) \cap [\tau, +\infty)$.

Proof Set $q = \min(f, 1)$, a nonzero bounded density. By **Theorem 10.1.2**, there is a continuous $w \in \text{PSH}(X, h)$ with $\text{MA}_h(w) = e^{\tau w} q \, dV$. Put $t_\tau = w + \max(0, -\inf_X w)$. Then $t_\tau \geq 0$ and $t_\tau \geq w$, so for $\lambda \geq \tau$,

$$\text{MA}_h(t_\tau) = e^{\tau w} q \, dV \leq e^{\lambda t_\tau} f \, dV.$$

Let u be an exponential subsolution at an exponent $\lambda \geq \tau$, and let $\epsilon > 0$. On $\{t_\tau < u - \epsilon\}$,

$$\text{MA}_h(t_\tau) \leq e^{\lambda(u-\epsilon)} f \, dV \leq e^{-\lambda\epsilon} \text{MA}_h^{\text{ext}}(u - \epsilon).$$

The bounded function t_τ satisfies $P_{h/2}(t_\tau) \not\equiv -\infty$, and $u - \epsilon \preceq t_\tau$. Thus **Theorem 13.1.1** gives $t_\tau \geq u - \epsilon$, and letting $\epsilon \downarrow 0$ gives $t_\tau \geq u$.

For the order estimate, put $\delta = K_\tau(\lambda_2 - \lambda_1)/\lambda_2$. By the first part, $U_{\lambda_1} \leq t_\tau \leq K_\tau$, so $(\lambda_2 - \lambda_1)U_{\lambda_1} \leq \lambda_2\delta$, that is, $\lambda_1 U_{\lambda_1} \geq \lambda_2(U_{\lambda_1} - \delta)$. Since the Monge–Ampère measure is unchanged by adding constants,

$$\begin{aligned} \mathrm{MA}_h^{\mathrm{ext}}(U_{\lambda_1} - \delta) &= e^{\lambda_1 U_{\lambda_1}} f \, dV \\ &\geq e^{\lambda_2 (U_{\lambda_1} - \delta)} f \, dV. \end{aligned}$$

Thus $U_{\lambda_1} - \delta$ is an exponential subsolution at λ_2 , and the maximality of U_{λ_2} gives $U_{\lambda_2} \geq U_{\lambda_1} - \delta$. Finally, $1 - x^{-1} \leq \log x$ for $x \geq 1$; with $x = \lambda_2/\lambda_1$ this gives $\delta \leq K_\tau \log(\lambda_2/\lambda_1)$, which proves the monotonicity. $\square$

Proposition 13.30.4 *Suppose $\Lambda_h(f) \neq \emptyset$ and $a = \inf \Lambda_h(f) > 0$. Then $a \in \Lambda_h(f)$ if and only if there are exponents $\lambda_j > a$ decreasing to a and solutions u_j at exponent λ_j with $\inf_j \sup_X u_j > -\infty$.*

If $a \notin \Lambda_h(f)$, then every sequence of solutions u_j at exponents $\lambda_j > a$ decreasing to a satisfies

$$\begin{aligned} \sup_X u_j &\longrightarrow -\infty, & e^{\lambda_j u_j} &\longrightarrow 0 \text{ uniformly on } X, \\ \|\mathrm{MA}_h^{\mathrm{ext}}(u_j)\|_{\mathrm{TV}} &\longrightarrow 0, \end{aligned}$$

where the exponential is zero on the pole sets.

Proof Suppose first that $a \in \Lambda_h(f)$, let u_a be a solution at a , and put $s = u_a - \max(0, \sup_X u_a)$. As in the proof of [Proposition 13.30.2](#), s is an exponential subsolution at every $\lambda \geq a$, so $U_\lambda \geq s$. Hence the greatest solutions at any exponents $\lambda_j \downarrow a$ have suprema at least $\sup_X s > -\infty$.

Conversely, let λ_j and u_j be as in the statement. The lemma with $\tau = a$ gives the common upper bound $u_j \leq K_a$. Write $M_j = \sup_X u_j$. After extraction, $M_j \rightarrow M \in \mathbb{R}$ and, by [Theorem 1.4.1](#), $u_j - M_j \rightarrow v$ in L^1 for some $v \in \mathrm{PSH}(X, h)$. Then $u_j \rightarrow u = v + M$ in L^1 and, after a further extraction, almost everywhere. Since $a \leq \lambda_j \leq \lambda_1$, $u_j \leq K_a$ and $K_a \geq 0$, the densities $e^{\lambda_j u_j} f$ are bounded by $e^{\lambda_1 K_a} f$, and dominated convergence gives

$$e^{\lambda_j u_j} f \longrightarrow e^{au} f \quad \text{in } L^1(dV).$$

[Lemma 13.25.1](#) now gives $\mathrm{MA}_h^{\mathrm{ext}}(u) \geq e^{au} f \, dV$. Thus u is an exponential subsolution at a , and [Theorem 13.30.1](#) gives a solution at a .

Finally, suppose $a \notin \Lambda_h(f)$, and let u_j be solutions at exponents $\lambda_j \downarrow a$. If $\sup_X u_j$ did not tend to $-\infty$, a subsequence would satisfy the condition just shown to imply $a \in \Lambda_h(f)$. Hence $M_j \rightarrow -\infty$. Once $M_j < 0$, since $\lambda_j \geq a > 0$,

$$0 \leq e^{\lambda_j u_j} \leq e^{\lambda_j M_j} \leq e^{a M_j} \longrightarrow 0,$$

and the total mass $\int_X e^{\lambda_j u_j} f \, dV$ is at most $e^{a M_j} \|f\|_{L^1}$. $\square$

Proposition 13.30.5 *For every $a \in \Lambda_h(f)$, the greatest solutions satisfy*

$$U_\lambda \longrightarrow U_a \quad \text{in } L^1 \text{ and in capacity} \quad (\lambda \downarrow a),$$

and their Monge–Ampère measures converge in total variation to $e^{aU_a} f \, dV$.

Proof Let $K = K_a$ be the constant of the lemma with $\tau = a$, and let $\lambda_j > a$ decrease to a . By the lemma, the functions

$$V_j = U_{\lambda_j} + K \log(\lambda_j/a)$$

decrease and satisfy $V_j \geq U_a$. Their limit V therefore belongs to $\text{PSH}(X, h)$ and satisfies $V \geq U_a$. Dominated convergence between the integrable bounds U_a and V_1 gives $V_j \rightarrow V$ in L^1 , and **Lemma 1.8.6** gives convergence in capacity. Since the added constants tend to zero, $U_{\lambda_j} \rightarrow V$ in both senses.

The nonpositive functions $U_{\lambda_j} - K$ satisfy

$$\text{MA}_h^{\text{ext}}(U_{\lambda_j} - K) = e^{\lambda_j(U_{\lambda_j} - K)} e^{\lambda_j K} f \, dV,$$

and $e^{\lambda_j K} f \rightarrow e^{aK} f$ in L^1 . **Theorem 13.29.1** therefore gives $\text{MA}_h^{\text{ext}}(V) = e^{aV} f \, dV$, together with total-variation convergence of the measures $\text{MA}_h^{\text{ext}}(U_{\lambda_j})$. Hence V is a solution at a , so $V \leq U_a$ by maximality, while $V \geq U_a$ by construction. Thus $V = U_a$. Since every sequence of exponents converging to a from above has a decreasing subsequence, this proves the assertions. $\square$

The corrected order also controls approach from the left. The limit solves the equation at the limiting exponent; maximality gives an inequality with the greatest solution there, but does not force equality.

Proposition 13.30.6 *Suppose $\Lambda_h(f) \neq \emptyset$, and put $a_0 = \inf \Lambda_h(f)$. For every $a > a_0$, there is $L_a \in \text{PSH}(X, h)$ such that*

$$U_\lambda \longrightarrow L_a \quad \text{in } L^1 \text{ and in capacity} \quad (\lambda \uparrow a).$$

It satisfies

$$L_a \leq U_a, \quad \text{MA}_h^{\text{ext}}(L_a) = e^{aL_a} f \, dV.$$

The equation measures converge in total variation to this finite measure. The left limit is independent of the auxiliary exponent and of the cofinal sequence used to construct it.

Proof Choose $\tau \in \Lambda_h(f)$ with $0 < \tau < a$; the upper-interval property gives such a choice. Put $K = K_\tau$ from **Lemma 13.30.2** and

$$V_\lambda = U_\lambda + K \log(\lambda/\tau) \quad (\lambda \in \Lambda_h(f), \lambda \geq \tau).$$

This family is increasing. For a sequence $\lambda_j \uparrow a$ with $\tau \leq \lambda_j < a$, its members lie between the integrable potentials V_τ and V_a . The upper-envelope construction in **Section 1.19** gives

$$V_a^- = \left(\sup_{\tau \leq \lambda < a} V_\lambda \right)^* = \left(\lim_j V_{\lambda_j} \right)^* \in \text{PSH}(X, h).$$

Indeed cofinality and the order give the same pointwise supremum for every such sequence. Regularization changes it only on a pluripolar set. Dominated convergence between the integrable bounds gives L^1 convergence to V_a^- , and [Lemma 1.8.6](#) gives convergence in capacity. Since the added constants converge, set

$$L_a = V_a^- - K \log(a/\tau).$$

Then $U_{\lambda_j} \rightarrow L_a$ in both topologies and $L_a \leq U_a$; the latter inequality survives regularization because V_a is upper semicontinuous.

The potentials $U_{\lambda_j} - K$ and their limit $L_a - K$ are nonpositive. Apply [Theorem 13.29.1](#) with exponents tending to $a > 0$ and densities $e^{\lambda_j K} f \rightarrow e^{aK} f$ in L^1 . It proves the exact equation and total-variation convergence.

Every sequence approaching a from the left has a cofinal increasing subsequence. If potential convergence in either topology, or total-variation convergence of the equation measures, failed, a sequence staying outside a fixed neighbourhood of the proposed limit would therefore have an increasing subsequence, contrary to the preceding argument. This proves the full left limit and measure convergence. Repeating the construction with another τ gives the same L^1 limit; canonical plurisubharmonic representatives that agree almost everywhere agree everywhere. Thus the auxiliary choice does not change L_a . $\square$

Proposition 13.30.7 *Suppose $\Lambda_h(f) \neq \emptyset$, put $a_0 = \inf \Lambda_h(f)$, and let L_a be the left limit of [Proposition 13.30.6](#). The set*

$$D = \{a > a_0 : L_a \neq U_a\}$$

is at most countable. At every $a \notin D$, the greatest solutions are continuous in L^1 and in capacity as $\lambda \rightarrow a$, and their equation measures converge in total variation to $e^{aU_a} f \, dV$.

Proof Fix $a_0 < \alpha < \beta$, choose an admitted $0 < \tau < \alpha$, and use the corrected family V_λ from the preceding proof on $[\alpha, \beta]$. Its integrals

$$I(\lambda) = \int_X V_\lambda \, dV$$

form a finite bounded increasing real function. For $a \in (\alpha, \beta]$, the left-limit proposition gives

$$I(a) - I(a-) = \int_X (U_a - L_a) \, dV.$$

If $L_a \neq U_a$, this quantity is positive: the integrable nonnegative difference cannot vanish almost everywhere without equality of the canonical potentials. For any finite ordered collection of such points, the sum of their jumps is at most $I(\beta) - I(\alpha)$.

Consequently there are only finitely many jumps at least $1/m$ for each positive integer m , and at most countably many positive jumps. A countable cover by intervals with rational endpoints inside $(a_0, +\infty)$ proves the assertion about D .

If $a \notin D$, the left limit is U_a , and **Proposition 13.30.5** supplies the same right limit in both topologies and for the equation measures. Splitting an arbitrary approaching sequence into its two sides proves the stated two-sided convergence. $\square$

Whether an actual jump occurs, or all left limits equal the greatest solution, remains undecided. An intrinsic criterion on f and the existence or nonexistence of a positive excluded endpoint remain separate questions. These one-sided limits concern greatest solutions at positive exponents; they do not identify limits of arbitrary solutions with other singularities or supply a zero-exponent limit.

13.31 Radial selection for integrable densities

The scalar and measure limits in **Corollary 13.30.1** do not by themselves determine a limit potential. For the sublogarithmic densities of **Lemma 13.27.1**, the radial flux supplies the missing information. It also distinguishes convergence after subtracting the supremum from convergence after subtracting $\lambda^{-1} \log b$, where b is the critical scalar: the latter depends on a first moment of the limiting measure.

Use the product $X = X_0 \times Y$, $Y = \mathbb{P}^k$, $H = h_0 + \kappa$, and the probability volume $\mu = V_0^{-1} h_0^m \wedge \kappa^k$ of **Section 13.27**, with $\dim X_0 = m$, $v_-(h_0) = 0$ and $k \geq 2$. Put $b = \binom{N}{m} V_0$, where $N = m + k$. For $0 < \alpha < 1$, let $U_{\lambda, \alpha}$ be the greatest solution of

$$\text{MA}_H^{\text{ext}}(U_{\lambda, \alpha}) = e^{\lambda U_{\lambda, \alpha}} q_\alpha \mu, \quad \lambda > 0.$$

The threshold of this forcing measure is $b > 0$, by **Theorem 13.27.1**, so the solutions exist by **Corollary 13.30.1**.

13.31.1 Separation and the radial flux

Lemma 13.31.1 *There is a κ -plurisubharmonic function $w_{\lambda, \alpha}$ on Y such that*

$$U_{\lambda, \alpha} = \lambda^{-1} \log b + w_{\lambda, \alpha}, \quad w_{\lambda, \alpha} \geq u_\alpha, \quad \text{MA}_\kappa^{\text{ext}}(w_{\lambda, \alpha}) = e^{\lambda w_{\lambda, \alpha}} q_\alpha \kappa^k.$$

The last measure has mass one. On the affine chart centered at o , set $s = \log |z|^2$, $\rho(s) = \log(1 + e^s)$ and $m(s) = \rho'(s)$. The function $w = w_{\lambda, \alpha}$ is radial and satisfies

$$\begin{aligned} Q_{\lambda, \alpha}(s) &= \int_{-\infty}^s e^{\lambda w(r)} q_\alpha(r) d(m(r)^k), \\ w'(s) &= Q_{\lambda, \alpha}(s)^{1/k} - m(s), \quad Q_{\lambda, \alpha}(-\infty) = 0, \quad Q_{\lambda, \alpha}(+\infty) = 1. \end{aligned} \tag{13.88}$$

Proof Choose a smooth nondecreasing concave function χ on $[0, +\infty)$, equal to the identity on $[0, 1]$ and constant on $[2, +\infty)$, and put $q_j = j\chi(q_\alpha/j)$. Concavity gives $q_j \uparrow q_\alpha$ and

$$\min(q_\alpha, j) \leq q_j \leq \min(q_\alpha, 2j).$$

The functions q_j are smooth and positive on Y : near o they are constant, and elsewhere the density is smooth. Let w_j be the continuous solution of $\text{MA}_\kappa(w_j) = e^{\lambda w_j} q_j \kappa^k$ from [Theorem 10.1.2](#). It is the greatest subsolution by [Theorem 13.30.1](#) and bounded uniqueness. Since $u_\alpha \leq 0$ and $\text{MA}_\kappa^{\text{ext}}(u_\alpha) = q_\alpha \kappa^k$, it is a subsolution for every q_j , whence $u_\alpha \leq w_j$. Density comparison gives $w_j \downarrow w$.

The pullback $W_j = \lambda^{-1} \log b + w_j$ is a bounded solution on X , by the product expansion in [Theorem 13.27.1](#). For the smooth density $q_j \mu$ it is therefore also the greatest subsolution. Every subsolution for $q_\alpha \mu$ is a subsolution for $q_j \mu$, so $U_{\lambda, \alpha} \leq W_j$.

Monotone convergence in capacity and [Theorem 13.29.1](#) on Y identify the equation for $w \geq u_\alpha$. Moreover, Stokes gives $\int_Y e^{\lambda w_j} q_j \kappa^k = 1$. The integrands are dominated by $e^{\lambda \sup_Y w_1} q_\alpha$, so dominated convergence gives the same identity for w . Its pullback is a product solution, hence lies below the greatest solution on X . Together with $U_{\lambda, \alpha} \leq \lim_j W_j$, this proves separation and all measure assertions.

Uniqueness makes each w_j invariant under the unitary action on the affine coordinates $z \in \mathbb{C}^k$, and the limit has the same invariance. A radial κ -plurisubharmonic function has a convex nondecreasing profile $\rho + w$. Symmetric convolution of this convex profile on compact s intervals, decreasing as the scale decreases, and bounded-product continuity give its radial measure $d((\rho + w)'^k)$, as in [Lemma 13.27.1](#). The bound $w \geq u_\alpha$, whose growth is $o(|s|)$ at $-\infty$, forces the initial derivative to vanish. The positive density makes the flux continuous and positive at finite s , yielding [\(13.88\)](#). Its final value is the mass one already proved. The profile is consequently smooth on finite s intervals. $\square$

13.31.2 The normalized limit

Set

$$a_{\lambda, \alpha} = \sup_Y w_{\lambda, \alpha}, \quad v_{\lambda, \alpha} = w_{\lambda, \alpha} - a_{\lambda, \alpha}, \quad c_{\lambda, \alpha} = e^{\lambda \sup_X U_{\lambda, \alpha}} = b e^{\lambda a_{\lambda, \alpha}}.$$

In particular $a_{\lambda, \alpha} \geq 0$.

Theorem 13.31.1 *Let $\alpha_j \rightarrow \alpha \in (0, 1)$ and $\lambda_j \rightarrow 0$ with $\lambda_j > 0$, at arbitrary relative rates. Then*

$$v_{\lambda_j, \alpha_j} \longrightarrow u_\alpha \quad \text{in } L^1(Y), \text{ in capacity, and locally uniformly on } Y \setminus \{o\}.$$

Their pullbacks converge in $L^1(X)$, in capacity on X , and locally uniformly off $X_0 \times \{o\}$. Furthermore $q_{\alpha_j} \rightarrow q_\alpha$ in $L^1(\kappa^k)$, $c_{\lambda_j, \alpha_j} \rightarrow b$, and the equation measures converge in total variation to $bq_\alpha\mu$. The limiting pullback has finite mass b and belongs to $\mathcal{E}_{\text{env}}(X, H, 0)$.

Proof Choose $[\alpha_-, \alpha_+] \Subset (0, 1)$ containing all late parameters. The density formula in [Lemma 13.27.1](#) gives, uniformly for δ in this interval and $t = -s$ large,

$$q_\delta(s) \leq Ce^{kt}(1+t)^{-1-k(1-\alpha_+)}.$$

Away from o the densities are jointly smooth, including on the hyperplane at infinity. Thus one integrable density g dominates all q_δ , and dominated convergence gives $q_{\alpha_j} \rightarrow q_\alpha$ in L^1 .

For every normalized κ -plurisubharmonic v , [Theorem 1.4.1](#) gives $\int_Y (-v)\kappa^k \leq C_k$. Absolute continuity of the integral of g therefore implies

$$\sup_{\sup_Y v=0} \int_{\{v < -T\}} g\kappa^k \longrightarrow 0 \quad (T \rightarrow \infty).$$

Taking $T = \lambda^{-1/2}$ shows that

$$\int_Y (1 - e^{\lambda v}) q_\delta \kappa^k \leq \lambda T + \int_{\{v < -T\}} g\kappa^k \longrightarrow 0$$

uniformly in δ and v . Write $v_j = v_{\lambda_j, \alpha_j}$ and $a_j = a_{\lambda_j, \alpha_j}$. The exact mass identity of the lemma is

$$1 = e^{\lambda_j a_j} \int_Y e^{\lambda_j v_j} q_{\alpha_j} \kappa^k. \quad (13.89)$$

It gives $e^{\lambda_j a_j} \rightarrow 1$, hence $\lambda_j a_j \rightarrow 0$. The actual densities $e^{\lambda_j a_j} e^{\lambda_j v_j} q_{\alpha_j}$ converge in L^1 to q_α and are bounded by $2g$ for all late j .

Their cumulative radial fluxes Q_j consequently converge uniformly to the flux Q_α of u_α . By [\(13.88\)](#), $v'_j \rightarrow u'_\alpha$ uniformly on compact s intervals. The normalized L^1 bound controls one value of each profile on a fixed annulus; thus every sequence has a subsequence converging uniformly on compact s intervals to $u_\alpha + d$ for some finite constant d .

Near infinity the common bound for the densities is smooth and bounded. Hence $1 - Q_j(s) \leq Ce^{-s}$ and $|v'_j(s)| \leq Ce^{-s}$ for large s . Integrating gives uniform convergence up to the hyperplane at infinity. At the other end, monotonicity of $\rho + v_j$ gives, for $s < s_0$,

$$v_j(s) \leq v_j(s_0) + \rho(s_0).$$

Choose s_0 so negative that the right side is negative for all late members of the subsequence. The supremum zero is then attained outside this inner ball. Uniform convergence on its compact complement gives $\sup_Y(u_\alpha + d) = 0$, so $d = 0$. Normalized compactness identifies every L^1 cluster limit with u_α ; this proves convergence of the entire family and its local uniform convergence off o .

For capacity convergence, fix $T > 0$. The sublevel $\{u_\alpha < -T\}$ is a neighborhood of o , and its complement is a compact set on which convergence is uniform. Its capacity is at most C/T by (1.15). Let $j \rightarrow \infty$ and then $T \rightarrow \infty$. The same argument on X uses the normalized pullback of u_α and proves convergence in Hermitian capacity there; comparison sets omit pole sets. Pullback also preserves the L^1 and local uniform limits. The product expansion proves total-variation convergence of the measures, and Theorem 13.27.1 supplies the exact limiting mass and envelope class. $\square$

13.31.3 Scalar centering and its moment boundary

Proposition 13.31.1 *The first moment*

$$M_\alpha = \int_Y u_\alpha q_\alpha \kappa^k$$

is finite exactly when $\alpha < k/(k+1)$. In this range,

$$-M_\alpha = \alpha \int_1^\infty x^{\alpha-1} [\alpha x^{\alpha-1} + (1 - \alpha x^{\alpha-1})e^{1-x}]^k dx. \quad (13.90)$$

For the joint limits of Theorem 13.31.1, if $\alpha < k/(k+1)$, then

$$a_{\lambda_j, \alpha_j} \rightarrow -M_\alpha, \quad U_{\lambda_j, \alpha_j} - \lambda_j^{-1} \log b \rightarrow u_\alpha - M_\alpha$$

in L^1 , in capacity, and locally uniformly away from the pole fiber. If $\alpha \geq k/(k+1)$, then $a_{\lambda_j, \alpha_j} \rightarrow +\infty$ and the latter translated potentials tend to $+\infty$ locally uniformly off the pole fiber, although $\lambda_j a_{\lambda_j, \alpha_j} \rightarrow 0$. In both cases the exact scalar error is

$$\lambda_j^{-1} \log(c_{\lambda_j, \alpha_j}/b) = a_{\lambda_j, \alpha_j}.$$

Proof As $t = -s \rightarrow \infty$, the radial profile of Lemma 13.27.1 satisfies

$$u_\alpha \sim -t^\alpha, \quad Q'_\alpha(s) \sim k(1-\alpha)\alpha^k t^{-1-k(1-\alpha)}.$$

Thus the first moment is finite precisely when $(k+1)\alpha < k$. In that case, write $x = 1 - \psi$. Its cumulative flux is

$$Q_\alpha = [\alpha x^{\alpha-1} + (1 - \alpha x^{\alpha-1})e^{1-x}]^k.$$

Integration by parts gives (13.90); the pole boundary term vanishes since $(k+1)\alpha - k < 0$.

Suppose $\alpha < k/(k+1)$ and choose the parameter interval in the preceding proof with $\alpha_+ < k/(k+1)$. Its dominating density g satisfies $(-u_{\alpha_+})g \in L^1$. Write $w_j = w_{\lambda_j, \alpha_j} = v_j + a_j$. Since $w_j \geq u_{\alpha_j} \geq u_{\alpha_+}$, the mass identity and $e^r \geq 1+r$ give $\int_Y w_j q_{\alpha_j} \kappa^k \leq 0$. On a fixed annulus A away from o , the normalized smooth-volume L^1 bound gives

$$\int_A w_j q_{\alpha_j} \kappa^k \geq a_j \int_A q_{\alpha_j} \kappa^k - C.$$

On the complement, use $w_j \geq u_{\alpha_+}$ and the integrable lower bound. The annulus has uniformly positive measure, so $0 \leq a_j \leq C_*$. Along any subsequence with $a_j \rightarrow a$, local uniform convergence gives $w_j \rightarrow u_{\alpha} + a$ off o . In the exact identity

$$\int_Y \frac{e^{\lambda_j w_j} - 1}{\lambda_j} q_{\alpha_j} \kappa^k = 0,$$

the negative part is dominated by $(-u_{\alpha_+})g$ and the positive part by $C_* e^{C_*} g$. Dominated convergence gives $M_{\alpha} + a = 0$. Every subsequence therefore has the asserted scalar limit. Adding these convergent constants to the normalized potentials gives all three claimed topologies.

If $\alpha \geq k/(k+1)$, use instead

$$\int_Y \frac{1 - e^{\lambda_j v_j}}{\lambda_j} q_{\alpha_j} \kappa^k = \frac{1 - e^{-\lambda_j a_j}}{\lambda_j} \leq a_j.$$

The integrands are nonnegative and tend off o to $(-u_{\alpha})q_{\alpha}$. Fatou's lemma forces $a_j \rightarrow +\infty$. The preceding theorem gives $\lambda_j a_j \rightarrow 0$; local uniform convergence of v_j gives the stated divergence of w_j . This includes sequences approaching the moment boundary from below. $\square$

For the elliptic fivefold of Corollary 13.27.1, $b = 240\pi$ and the moment boundary is $\alpha = 2/3$. The choice $\alpha = 1/2$ has a finite centering constant. For $2/3 \leq \alpha < 1$, the supremum-normalized family still converges to the exact threshold solution, while its scalar-centered version diverges off the pole fiber. Thus convergence of the normalization scalars alone does not give a bounded first-order scalar error.

13.31.4 Order in the separated class

We use here the closed-class uniqueness theorem: on a compact connected Kähler manifold, two potentials whose non-pluripolar measures have full mass and are equal differ by a constant. This is an external input; its source is identified in [Section 33.10](#).

Corollary 13.31.1 *Every separated threshold subsolution $r = r(y)$ with $r \in \text{PSH}(Y, \kappa)$ and $\text{MA}_H^{\text{ext}}(r) \geq bq_\alpha \mu$ equals $u_\alpha + d$ for some constant d . In particular u_α is its unique supremum-zero member. If $\alpha < k/(k+1)$, then $u_\alpha - M_\alpha$ is the greatest such subsolution whose q_α -mean on Y is nonpositive.*

Proof The product formula reduces the inequality to $\text{MA}_\kappa^{\text{ext}}(r) \geq q_\alpha \kappa^k$. Closed Stokes gives each bounded truncation mass one, so the extended measure of r has mass at most one. The inequality therefore gives equality and full mass. Closed-class uniqueness yields $r = u_\alpha + d$. In the finite-moment range its mean is $M_\alpha + d$, which is nonpositive exactly when $d \leq -M_\alpha$. $\square$

At and beyond the moment boundary every constant translate has mean $-\infty$, so that mean condition no longer chooses a greatest translate. The order assertion concerns separated potentials. Selection for arbitrary integrable densities and uniqueness of arbitrary critical potentials on the nonclosed product remain the questions of [Problem 32.1.1](#) and [Section 13.29](#).

Chapter 14

Normalization and weak adjoint measures

Let X be a connected compact complex manifold of dimension $n \geq 1$ with a smooth positive volume form dV . Function spaces are real, and Lebesgue norms are taken with respect to dV . Until [Section 14.8](#), θ is a smooth semipositive big real $(1, 1)$ -form and $\varphi \in \text{PSH}(X, \theta)$ is a model reference in the sense of [\(12.20\)](#): it is a fixed point of the ordinary singularity envelope $P_\theta[\cdot]$ of [Definition 1.19.1](#), and its envelope $P_{\varepsilon\theta}(\varphi)$ in a smaller background is not identically $-\infty$ for some $0 < \varepsilon < 1$. We write $u \sim \varphi$ when u has the ordinary singularity type of φ ([Definition 1.12.1](#)), and $\text{MA}_\theta^{\text{ext}}$ for the extended non-pluripolar Monge–Ampère measure of [Theorem 6.1.1](#); when its total mass is finite, it is the usual non-pluripolar measure, which we also denote by MA_θ .

In the ordinary type of φ , the equation $\text{MA}_\theta^{\text{ext}}(u) = c e^F dV$ determines the constant $c > 0$ uniquely, even when it has several normalized solutions. As a function of the logarithmic density F , the logarithm of this constant is concave. Its supporting functionals are probability measures that describe the first-order response of the constant to a change of density; for smooth Hermitian equations they are the Gauduchon adjoint probabilities of the linearized operator. The convex dual of the functional controls the concentration of these measures through entropy, and this gives compactness when the density, the reference or the positive background varies. The same measures provide the integral normalizations that single out the limit of the exponential equations as the exponent tends to zero. The scalar functional does not, however, determine the singularities of the solutions: examples with moving divisors have identical functionals but different limiting potentials. On closed projective backgrounds, convex geometry gives quantitative criteria for varying references, including references with nonanalytic poles or degenerate residuals.

14.1 The scalar functional

The domination principle makes the constant decrease as the density increases, and mixed Monge–Ampère products strengthen this monotonicity to concavity in

the logarithmic density. Compactness of the solutions then gives continuity under uniformly bounded L^1 perturbations.

For a bounded real measurable function F , part (2) of [Theorem 13.11.1](#), applied to the bounded density e^F , gives $u \in \text{PSH}(X, \theta)$ with $u \sim \varphi$ and a unique constant $c_\varphi(F) > 0$ such that

$$\text{MA}_\theta^{\text{ext}}(u) = c_\varphi(F) e^F dV. \quad (14.1)$$

The *normalization scalar* is

$$B_\varphi(F) = \log c_\varphi(F).$$

Since the constant is unique, B_φ is well defined; it depends on φ only through its ordinary singularity type.

Proposition 14.1.1 *Let $F, G \in L^\infty(dV)$ be real. The functional B_φ is decreasing, and for every constant $a \in \mathbb{R}$,*

$$B_\varphi(F + a) = B_\varphi(F) - a.$$

Consequently

$$-\text{ess sup}_X(G - F) \leq B_\varphi(G) - B_\varphi(F) \leq -\text{ess inf}_X(G - F), \quad (14.2)$$

and $|B_\varphi(G) - B_\varphi(F)| \leq \|G - F\|_\infty$.

Proof Suppose that $F \leq G$ almost everywhere and, to reach a contradiction, that $c_\varphi(F) < c_\varphi(G)$. Let $u, v \sim \varphi$ solve the two equations. Since $F \leq G$ and the extended measure is unchanged by adding constants, for every constant a ,

$$\text{MA}_\theta^{\text{ext}}(u) \leq \frac{c_\varphi(F)}{c_\varphi(G)} \text{MA}_\theta^{\text{ext}}(v + a),$$

and the ratio is strictly less than one. As $u \sim \varphi$, the envelope $P_{\varepsilon\theta}(u)$ dominates a translate of $P_{\varepsilon\theta}(\varphi)$ and is therefore not identically $-\infty$; moreover $v + a \preceq u$. The singular strict domination principle, [Theorem 13.1.1](#), gives $u \geq v + a$ for every a , which is impossible at any point where both potentials are finite. Thus $B_\varphi(F) \geq B_\varphi(G)$.

Replacing F by $F + a$ and the constant by $e^{-a} c_\varphi(F)$ leaves the right-hand side of (14.1) unchanged, so uniqueness of the constant proves the translation rule. Finally, G lies between the constant translates $F + \text{ess inf}_X(G - F)$ and $F + \text{ess sup}_X(G - F)$; monotonicity and the translation rule give (14.2). $\square$

The scalar does not depend on the smooth representative of the background: for a smooth real h , replacing θ by $\theta + \text{dd}^c h$ and each potential u , including φ , by $u - h$ preserves the currents and the prescribed ordinary type, and hence leaves the equation and its constant unchanged.

Concavity comes from mixed products. A convex combination of two solutions stays in the prescribed ordinary type, and [Lemma 6.4.1](#) bounds its measure below by the corresponding mixed density.

Theorem 14.1.1 *The functional B_φ is concave on the real space $L^\infty(dV)$: for F, G in that space,*

$$B_\varphi(tF + (1-t)G) \geq tB_\varphi(F) + (1-t)B_\varphi(G), \quad 0 \leq t \leq 1.$$

Proof Let $u, v \sim \varphi$ solve the equations for F and G , and set $H = tF + (1-t)G$ and $D = c_\varphi(F)^t c_\varphi(G)^{1-t}$. [Lemma 6.4.1](#) and the arithmetic–geometric mean inequality give

$$\begin{aligned} \text{MA}_\theta^{\text{ext}}(tu + (1-t)v) &\geq (t(c_\varphi(F)e^F)^{1/n} + (1-t)(c_\varphi(G)e^G)^{1/n})^n dV \\ &\geq D e^H dV. \end{aligned}$$

The averaged potential $tu + (1-t)v$ has the ordinary type of φ . If $c_\varphi(H) < D$, its measure dominates the measure of a solution $w \sim \varphi$ for H by the factor $D/c_\varphi(H) > 1$. Applying the singular strict domination principle to w and to every constant translate of the averaged potential, as in the proof of [Proposition 14.1.1](#), leads to the same contradiction. Hence $c_\varphi(H) \geq D$, and taking logarithms proves concavity. $\square$

For smooth Hermitian data, this concavity agrees with the second-variation formula of [Theorem 9.7.1](#).

Uniformly bounded logarithmic densities give the solutions a common lower barrier, and compactness of the solutions identifies the limiting scalar even when the densities converge only in L^1 .

Theorem 14.1.2 *If F_j, F are uniformly bounded real measurable functions and $F_j \rightarrow F$ in $L^1(dV)$, then*

$$B_\varphi(F_j) \longrightarrow B_\varphi(F).$$

Proof Choose solutions $u_j \sim \varphi$ normalized by $\sup_X u_j = 0$, and write $c_j = c_\varphi(F_j)$. If $|F_j| \leq M$, monotonicity and the translation rule of [Proposition 14.1.1](#) give

$$e^{-M} c_\varphi(0) \leq c_j \leq e^M c_\varphi(0).$$

In particular, the Monge–Ampère measures of the u_j are dominated by a fixed multiple of dV , and [Theorem 13.11.2](#) gives a constant C such that

$$\varphi - C \leq u_j \leq \varphi.$$

From any subsequence, extract a further subsequence with $c_j \rightarrow c > 0$ and $u_j \rightarrow u$ in $L^1(X)$. By [Corollary 13.8.1](#), the convergence also holds in capacity, $u \sim \varphi$, and the measures converge weakly. On the other hand, the exponential function is Lipschitz on the common range of the F_j , so $c_j e^{F_j} \rightarrow c e^F$ in $L^1(dV)$. Therefore

$$\text{MA}_\theta^{\text{ext}}(u) = c e^F dV,$$

and uniqueness of the constant gives $c = c_\varphi(F)$. Since every subsequence has a further subsequence along which $c_j \rightarrow c_\varphi(F)$, the whole sequence converges, and so do the logarithms. $\square$

14.2 Supporting probability measures

A supporting functional of the concave function B_φ describes the first-order response of the scalar to a change of logarithmic density. Monotonicity and the translation rule force such a functional to be minus the integral against a probability measure. We work first on the space $C(X)$ of continuous real functions, with the uniform norm. For $F \in C(X)$, let $\mathcal{A}_\varphi(F)$ be the set of Borel probability measures ν on X satisfying

$$B_\varphi(G) \leq B_\varphi(F) - \int_X (G - F) d\nu \quad \text{for every } G \in C(X). \quad (14.3)$$

Thus $G \mapsto -\int_X G d\nu$ is a supergradient of B_φ at F . We call the members of $\mathcal{A}_\varphi(F)$ the *supporting probabilities* at F .

Theorem 14.2.1 *For every $F \in C(X)$, the set $\mathcal{A}_\varphi(F)$ is nonempty, convex and weakly compact. Every one of its measures is absolutely continuous with respect to dV .*

Proof The function $C_\varphi = -B_\varphi$ is convex and Lipschitz. Fix $F \in C(X)$. For a direction $h \in C(X)$, the limit

$$p(h) = \lim_{t \downarrow 0} \frac{C_\varphi(F + th) - C_\varphi(F)}{t}$$

exists and is finite: convexity makes the difference quotients monotone in $t > 0$, and their absolute values are at most $\|h\|_\infty$. Clearly p is positively homogeneous. Given another direction $k \in C(X)$, apply convexity at the midpoint of $F + 2th$ and $F + 2tk$ and let $t \downarrow 0$; this gives $p(h + k) \leq p(h) + p(k)$. Thus p is sublinear.

By the Hahn–Banach theorem, the zero functional on $\{0\}$ extends to a linear functional $\ell \leq p$. Since $p(h) \leq \|h\|_\infty$, applying this bound to h and $-h$ shows that ℓ is continuous. Monotonicity of the convex difference quotients gives

$$C_\varphi(F + h) \geq C_\varphi(F) + \ell(h),$$

which is (14.3) once ℓ is represented by a probability. Testing the translation rule with positive and negative constants gives $\ell(1) = 1$. If $h \geq 0$, monotonicity of B_φ gives $C_\varphi(F - th) \leq C_\varphi(F)$ for $t > 0$, whereas the inequality just proved gives the lower bound $C_\varphi(F) - t\ell(h)$. Hence $\ell(h) \geq 0$. By the Riesz representation theorem, $\ell(h) = \int_X h d\nu$ for a probability measure ν , and $\nu \in \mathcal{A}_\varphi(F)$. Each inequality in (14.3) defines a weakly closed half-space in the compact space of probability measures, so their intersection is closed and convex, hence weakly compact.

It remains to prove absolute continuity. Let K be compact with $dV(K) = 0$, and choose continuous functions $0 \leq \chi_j \leq 1$, equal to one on K , whose supports have volumes tending to zero. For any $\nu \in \mathcal{A}_\varphi(F)$, the supporting inequality with $G = F + \chi_j$ gives

$$0 \leq \nu(K) \leq \int_X \chi_j d\nu \leq B_\varphi(F) - B_\varphi(F + \chi_j).$$

The right-hand side tends to zero by [Theorem 14.1.2](#), so $\nu(K) = 0$. By inner regularity of finite Borel measures on X , the same holds for every Borel set of zero volume. The Radon–Nikodym theorem now gives $d\nu = h_\nu dV$ with $h_\nu \geq 0$ and $\int_X h_\nu dV = 1$. $\square$

Proposition 14.2.1 *Let $F_j, F \in C(X)$ with $F_j \rightarrow F$ uniformly, and let $\nu_j \in \mathcal{A}_\varphi(F_j)$. Then every weak cluster point of (ν_j) belongs to $\mathcal{A}_\varphi(F)$. In particular, if the latter set consists of a single measure, ν_j converges weakly to it.*

Proof Take a weakly convergent subsequence and fix $G \in C(X)$. In the inequality

$$B_\varphi(G) \leq B_\varphi(F_j) - \int_X (G - F_j) d\nu_j,$$

the Lipschitz continuity of B_φ , the uniform convergence of F_j and the weak convergence of the probabilities allow passage to the limit. The limiting inequality holds for every G , so the limit measure belongs to $\mathcal{A}_\varphi(F)$. If that set is a singleton, every convergent subsequence has the same limit, and compactness of the space of probability measures proves the final assertion. $\square$

14.2.1 Directional derivatives

As ν runs through the supporting probabilities at F , the integral $-\int_X G d\nu$ ranges exactly between the two one-sided derivatives of B_φ at F in the direction G . Consequently, differentiability is equivalent to uniqueness of the supporting probability. For $F, G \in C(X)$, write $D^+ B_\varphi(F)[G]$ and $D^- B_\varphi(F)[G]$ for the limits of the difference quotient $(B_\varphi(F + tG) - B_\varphi(F))/t$ as $t \downarrow 0$ and $t \uparrow 0$, respectively.

Proposition 14.2.2 *For $F, G \in C(X)$, the one-sided derivatives exist, and*

$$D^+ B_\varphi(F)[G] = - \max_{\nu \in \mathcal{A}_\varphi(F)} \int_X G d\nu,$$

$$D^- B_\varphi(F)[G] = - \min_{\nu \in \mathcal{A}_\varphi(F)} \int_X G d\nu.$$

Consequently B_φ is Gâteaux differentiable at F if and only if $\mathcal{A}_\varphi(F)$ is a singleton. Its derivative is then $G \mapsto -\int_X G d\nu$.

Proof The one-sided limits exist and are finite by concavity and the Lipschitz bound. For $t > 0$, every supporting probability ν at F gives

$$\frac{B_\varphi(F + tG) - B_\varphi(F)}{t} \leq - \int_X G \, d\nu.$$

Conversely, choose $\nu_t \in \mathcal{A}_\varphi(F + tG)$ and apply its supporting inequality with the test function F ; this bounds the same quotient below by $-\int_X G \, d\nu_t$. Along a sequence $t \downarrow 0$, the measures ν_t have a weak limit point, which belongs to $\mathcal{A}_\varphi(F)$ by [Proposition 14.2.1](#). The two bounds identify the right derivative with minus the maximum. Applying this identity to $-G$ gives the formula for the left derivative.

If $\mathcal{A}_\varphi(F)$ is a singleton $\{\nu\}$, the two derivatives coincide for every G and equal $-\int_X G \, d\nu$, a continuous linear functional of G . Conversely, if the two one-sided derivatives agree for every G , all supporting probabilities have the same integral against every continuous function, and the Riesz representation theorem shows that they coincide. $\square$

14.2.2 Generic uniqueness

On every affine line in $C(X)$, the concave function B_φ is differentiable outside a countable set, so the gap between its two directional derivatives along the line vanishes on a dense subset. Upper semicontinuity of this gap and separability of $C(X)$ turn the one-dimensional fact into uniqueness of the supporting probability on a dense G_δ subset of $C(X)$.

Theorem 14.2.2 *The set*

$$\mathcal{U}_\varphi = \{F \in C(X, \mathbb{R}) : \mathcal{A}_\varphi(F) \text{ is a singleton}\}$$

is a dense G_δ subset of $C(X)$ with the uniform norm. At every $F \in \mathcal{U}_\varphi$, the functional B_φ is Gâteaux differentiable, and its derivative is minus the integral against the unique supporting probability. If $F_j \rightarrow F$ uniformly and $\nu_j \in \mathcal{A}_\varphi(F_j)$, then ν_j converges weakly to that probability.

Proof For $h \in C(X, \mathbb{R})$ define the width

$$w_h(F) = \max_{\nu \in \mathcal{A}_\varphi(F)} \int_X h \, d\nu - \min_{\nu \in \mathcal{A}_\varphi(F)} \int_X h \, d\nu \geq 0.$$

The extrema exist by weak compactness. We claim that the width is upper semicontinuous in F . Indeed, let $F_j \rightarrow F$ and choose maximizing and minimizing probabilities at each F_j . Along a subsequence realizing the upper limit of the widths, compactness of the space of probability measures gives weak limits of both choices. By [Proposition 14.2.1](#), both limits belong to $\mathcal{A}_\varphi(F)$, so the difference of their integrals against h is at most $w_h(F)$.

Consequently, for every $\epsilon > 0$ the set $\{F : w_h(F) < \epsilon\}$ is open. It is also dense. If $h = 0$ there is nothing to prove. Otherwise fix F and an open ball about it. The function

$$b(t) = B_\varphi(F + th)$$

is finite and concave on the real line, so it is differentiable outside an at most countable set: its one-sided derivatives are finite and monotone, and the nonempty open intervals between unequal one-sided derivatives at distinct points are disjoint, so each contains a different rational number. Choose a point of differentiability t so close to zero that $F + th$ lies in the given ball. The derivative formulas of [Proposition 14.2.2](#) give $w_h(F + th) = 0$, which proves density.

The compact manifold X is metrizable, so $C(X)$ is separable. Choose a countable uniformly dense family (h_j) in $C(X)$. By the Baire category theorem in the complete metric space $C(X)$, the set

$$\bigcap_{j,k \geq 1} \{F : w_{h_j}(F) < 1/k\}$$

is a dense G_δ . At every point of this intersection, all supporting probabilities have the same integral against every h_j . Since they have unit mass, uniform approximation gives equal integrals against every continuous function, and the Riesz representation theorem shows that the probabilities coincide. Conversely, a singleton has zero width in every direction, so the intersection is exactly $\mathcal{U}_\varphi$. The formula for the derivative follows from [Proposition 14.2.2](#), and the approximation assertion from [Proposition 14.2.1](#). $\square$

14.2.3 Gauduchon adjoints

For a smooth Hermitian equation, differentiating the scalar identifies the supporting probability with the adjoint probability of the linearized operator.

Theorem 14.2.3 *Let $\theta = \omega$ be a Hermitian form, let $\varphi = 0$, and let F be a smooth real function. Let u be the smooth solution of (14.1), unique up to an additive constant by [Corollary 11.4.1](#), and let μ_u be its Gauduchon adjoint probability from [Proposition 4.7.1](#); for $n = 1$, this is $\mu_u = (\omega + dd^c u) / \int_X \omega$. Then*

$$\mathcal{A}_0(F) = \{\mu_u\}.$$

Proof Suppose first that $n \geq 2$. By uniqueness of the constant, the normalization scalar of the smooth equation in [Theorem 9.7.1](#) is B_0 , and that theorem gives, for every smooth real G ,

$$\left. \frac{d}{dt} \right|_{t=0} B_0(F + tG) = - \int_X G d\mu_u.$$

Let $\nu \in \mathcal{A}_0(F)$. Testing the supporting inequality at $F + tG$ for both signs of t and letting $t \rightarrow 0$ shows that G has the same integral against ν and μ_u . Since smooth functions are uniformly dense in $C(X)$, it follows that $\nu = \mu_u$, and the assertion follows from nonemptiness of $\mathcal{A}_0(F)$. In dimension one, Stokes' theorem gives $c_0(F) = \int_X \omega / \int_X e^F dV$; differentiating its logarithm in the same way yields the stated measure, since $\omega + dd^c u = c_0(F)e^F dV$. $\square$

Consequently, in the Hermitian case the supporting probabilities at a continuous F can be approached through smooth data. If smooth F_j converge uniformly to F , then by [Proposition 14.2.1](#) every weak cluster point of the Gauduchon adjoint probabilities of the solutions for F_j belongs to $\mathcal{A}_0(F)$, and is therefore absolutely continuous. If $\mathcal{A}_0(F)$ is a singleton, which holds in particular for every $F \in \mathcal{U}_0$, these probabilities converge to its unique member, independently of the approximation. We do not know whether $\mathcal{A}_0(F)$ is a singleton for every continuous F , even in this Hermitian setting; the same question is open for the singular references considered above.

For $n \geq 2$, the Hermitian zero-reference case admits a quantitative strengthening: [Corollary 25.8.1](#) bounds the densities of all supporting probabilities uniformly in L^q , for $1 < q < n/(n-1)$, when $\|F\|_\infty$ is bounded, and also for $q = n/(n-1)$ when ω has positive lower mass $\nu_-(\omega) > 0$ in the sense of [Definition 6.5.1](#). The proof uses the Gauduchon-current formulation of [Chapter 25](#), and we do not claim such a bound for an arbitrary singular reference.

A weak linearized operator requires more than a supporting probability. In the same Hermitian zero-reference setting, [Theorem 25.7.1](#) represents each supporting probability by a determinant-weighted positive dd^c -closed current. Identifying that current with a scalar multiple of a weak power $(\omega + dd^c u)^{n-1}$ would require a well-defined product and its compatibility with approximation.

A similar representation holds for a functional defined by subsolutions rather than by an equation in a prescribed singularity type. Let $0 \leq f \in L^1(dV)$ be nonzero with $f^{1/n} \in \mathcal{D}_\omega^0$, the space of densities with uniformly vanishing Gauduchon tails from [Section 13.28.2](#). Then [Proposition 25.9.3](#) describes the supporting probabilities of $F \mapsto \log b_\omega(e^F f)$, where $b_\omega(\cdot)$ is the density threshold of [Theorem 13.25.1](#).

14.2.4 Divisorial smoothing

For a singular reference, the supporting probability can be unique while smoothings of the solution have different limiting adjoint probabilities. The reason is that the non-pluripolar product discards the mass on a divisor that the smoothings keep. On a product of two projective lines, explicit formulas exhibit both the lost mass and its dependence on the smoothing.

In this subsection, $X = \mathbb{P}^1 \times \mathbb{P}^1$. Let ω_1 and ω_2 be the pullbacks of the Fubini–Study forms of the two factors, normalized to have integral one on their factors, and put

$$\theta = 2\omega_1 + 2\omega_2, \quad \beta = \omega_1 + 2\omega_2, \quad \omega = \omega_1 + \omega_2, \quad dV = \omega_1 \wedge \omega_2.$$

Thus dV is a probability volume form, $\theta^2 = 8dV$ and $\beta^2 = 4dV$. Let z be the affine coordinate on the first factor, and put

$$r = \frac{|z|^2}{1 + |z|^2}, \quad \psi = \log r, \quad D = \{0\} \times \mathbb{P}^1.$$

The function r extends smoothly to the first factor, with value one at infinity, and ψ is quasi-plurisubharmonic with value $-\infty$ exactly on D . The Poincaré–Lelong formula gives $\text{dd}^c \psi = [D] - \omega_1$, so $\theta + \text{dd}^c \psi = \beta + [D]$.

For a smooth positive $(1, 1)$ -form Ω on the surface X , the linearization $v \mapsto 2\text{dd}^c v \wedge \Omega / \Omega^2$ of the logarithmic Monge–Ampère operator has the adjoint probability $\rho \Omega^2$, where the Gauduchon multiplier $\rho > 0$ satisfies $\text{dd}^c(\rho \Omega) = 0$ and $\int_X \rho \Omega^2 = 1$ (Proposition 4.7.1). We call $Q = \rho \Omega$ the *adjoint cofactor* of Ω : it is dd^c -closed, and $\Omega \wedge Q$ is the adjoint probability.

Lemma 14.2.1 *Write $x = \log |z|^2$ and $\chi(x) = \log(1 + e^x)$. The envelope $\varphi = P_\theta[\psi]$ is*

$$\varphi = W(x) - 2\chi(x), \quad W(x) = \begin{cases} x + 2 \log 2, & x \leq 0, \\ 2\chi(x), & x \geq 0. \end{cases} \quad (14.4)$$

It satisfies $\psi \leq \varphi \leq 0$, $0 \leq \varphi - \psi \leq 2 \log 2$, and the model condition (12.20) with $\varepsilon = 3/4$.

Proof The function W is convex: both one-sided derivatives at zero equal one, and the derivative of 2χ increases from one to two on $[0, \infty)$. Since $\omega_1 = \text{dd}^c \chi(x)$ on the affine chart, $W - 2\chi$ is $2\omega_1$ -plurisubharmonic there. Since W has slope one for $x \leq 0$ and agrees with 2χ for $x \geq 0$, the function $W - 2\chi$ extends to a global $2\omega_1$ -plurisubharmonic function, with a logarithmic pole along D and equal to zero where $|z| \geq 1$. The asserted bounds follow from $\psi = x - \chi$: the difference $\varphi - \psi$ equals $2 \log 2 - \chi$ for $x \leq 0$ and $\chi - x$ for $x \geq 0$.

For $C > 0$ write $v_C = P_\theta(\min\{\psi + C, 0\})$. Rotations of the first factor and the transitive unitary action on the second preserve the whole competitor class, so the envelope is radial and independent of the second factor. The function $V_C = 2\chi + v_C$ is then convex in x and satisfies $V_C \leq \chi + x + C$. This upper bound as $x \rightarrow -\infty$ forces the slope of V_C at $-\infty$ to be at least one, and by convexity all its slopes are at least one. For $x < 0$,

$$V_C(x) \leq V_C(0) + x \leq 2 \log 2 + x = W(x).$$

For $x \geq 0$, the zero obstacle gives $V_C \leq 2\chi = W$. Consequently $v_C \leq \varphi$. If $C \geq 2 \log 2$, the bounds already proved make φ a competitor, so $v_C = \varphi$. Letting $C \rightarrow \infty$ proves $P_\theta[\psi] = \varphi$. Since $\varphi \sim \psi$ and the ordinary envelope depends only on the singularity type, also $P_\theta[\varphi] = \varphi$.

Finally

$$\frac{3}{4}\theta + \text{dd}^c \psi = \frac{1}{2}\omega_1 + \frac{3}{2}\omega_2 + [D] \geq 0.$$

Since $\psi \leq \varphi$, the function ψ is a competitor for $P_{(3/4)\theta}(\varphi)$, which is therefore not identically $-\infty$. $\square$

Proposition 14.2.3 *Every $v \in \text{PSH}(X, \theta)$ with $v \sim \varphi$ is uniquely of the form $v = \psi + w$, where $w \in \text{PSH}(X, \beta)$ is bounded. Its non-pluripolar measure is*

$$\text{MA}_\theta(v) = (\beta + \text{dd}^c w)^2, \quad \int_X \text{MA}_\theta(v) = 4. \quad (14.5)$$

For every real continuous F ,

$$B_\varphi(F) = \log 4 - \log \int_X e^F dV, \quad \mathcal{A}_\varphi(F) = \left\{ \frac{e^F dV}{\int_X e^F dV} \right\}.$$

At $v = \psi$, the non-pluripolar part of $\theta + \text{dd}^c \psi$ is β , whose adjoint cofactor is $Q = \beta/4$, with adjoint probability $\beta \wedge Q = dV$.

Proof On $X \setminus D$, the function $w = v - \psi$ is bounded, because $v \sim \varphi \sim \psi$, and satisfies $\beta + \text{dd}^c w \geq 0$. After adding local potentials of the closed form β , [Lemma 1.3.7](#) extends w across D ; the extensions agree on overlaps and give a bounded β -plurisubharmonic function on X . Conversely, for every bounded $w \in \text{PSH}(X, \beta)$, the function $\psi + w$ is θ -plurisubharmonic with current $\beta + \text{dd}^c w + [D]$, and it has the ordinary type of φ . The decomposition is unique, since two such functions w agree off D and hence everywhere.

Put $T = \beta + \text{dd}^c w$. The bounded-product construction gives

$$T^2 - \beta^2 = \text{dd}^c(w(T + \beta)),$$

and Stokes' theorem against the constant function yields $\int_X T^2 = 4$. The product gives no mass to D by [Proposition 1.7.1](#); we also give a direct cutoff estimate, which will be used again below. Shift w so that $0 \leq w \leq M$, and set $f_t = \max\{\psi/t, -1\}$ for $t > 0$. Choose smooth convex functions σ_ϵ with derivative in $[0, 1]$, equal to -1 below $-1 - \epsilon$ and to the identity above $-1 + \epsilon$, converging uniformly to $\max\{\cdot, -1\}$. Then $f_{t,\epsilon} = \sigma_\epsilon(\psi/t)$ is globally smooth, constant near D , and

$$f_{t,\epsilon} \longrightarrow f_t \text{ uniformly,} \quad \text{dd}^c f_{t,\epsilon} \geq -\omega_1/t.$$

Testing the distributional identity against $f_{t,\epsilon}$, using positivity of $T + \beta$, and letting $\epsilon \rightarrow 0$, we obtain

$$\int_X (-f_t) T^2 \leq \int_X (-f_t) \beta^2 + \frac{M}{t} \int_X \omega_1 \wedge (T + \beta) = \int_X (-f_t) \beta^2 + \frac{4M}{t}. \quad (14.6)$$

Here the last integral equals four by Stokes' theorem. The right-hand side tends to zero as $t \rightarrow \infty$, since $f_t \rightarrow 0$ off D and $\beta^2(D) = 0$; as $-f_t = 1$ on D , this gives $T^2(D) = 0$. Off D the currents $\theta + \text{dd}^c v$ and T agree, so locality and the fact that the extended measure puts no mass on the pole set prove [\(14.5\)](#).

For the Hermitian background β , [Theorem 10.1.1](#) with density e^F gives a bounded solution w and a constant $c > 0$, and the correspondence above turns it into a solution $\psi + w$ in the ordinary type of φ . Every potential of that type has mass four, so

integration forces $c = 4/\int_X e^F dV$, which is the formula for B_φ . Jensen's inequality for the probability $\nu_F = e^F dV / \int_X e^F dV$ gives

$$B_\varphi(G) \leq B_\varphi(F) - \int_X (G - F) d\nu_F.$$

Thus ν_F is a supporting probability. For any supporting probability, testing its inequality at $G = F \pm th$ and differentiating at $t = 0$ shows that its integral against every $h \in C(X)$ equals that of ν_F .

For a smooth real h and sufficiently small $|t|$, we have $\beta + tdd^c h > 0$, so $\psi + th$ stays in the same ordinary type and its residual measure is $(\beta + tdd^c h)^2$, with derivative $2dd^c h \wedge \beta$ at $t = 0$. Since β is closed, the constant weight $\rho = 1/4$ annihilates this derivative after integration, and $Q = \rho\beta$ gives the asserted probability. This normalization uses the residual mass: since $\int_X \theta \wedge Q = 3/2$, the cofactor Q is not a normalized Gauduchon current for θ in the sense of [Section 4.4](#). $\square$

Theorem 14.2.4 *Let g be a smooth real function on the second factor with $\gamma = dd^c g \geq -\omega_2$, regarded as a function on X . For $0 < \delta \leq 1$ put*

$$u_{\delta,g} = \log(r + \delta e^g), \quad \Omega_{\delta,g} = \theta + dd^c u_{\delta,g}, \quad F_{\delta,g} = \log \frac{\Omega_{\delta,g}^2}{4dV}.$$

The forms satisfy $\Omega_{\delta,g} \geq \omega$ and $\int_X \Omega_{\delta,g}^2 = 8$. For each fixed g , as $\delta \downarrow 0$ the smooth potentials $u_{\delta,g}$ decrease pointwise to ψ , converge in L^1 and in the capacity Cap_ω , and converge smoothly off D . Moreover $F_{\delta,g} \rightarrow 0$ in $L^p(dV)$ for every $1 \leq p < \infty$. The adjoint cofactors and adjoint probabilities of the forms $\Omega_{\delta,g}$ are

$$Q_{\delta,g} = \Omega_{\delta,g}/8, \quad \nu_{\delta,g} = \Omega_{\delta,g}^2/8,$$

and they have the weak limits

$$\begin{aligned} Q_{\delta,g} &\longrightarrow (\beta + [D])/8, \\ \nu_{\delta,g} &\longrightarrow \frac{1}{2}dV + \frac{1}{2}[D] \wedge \omega_2 + \frac{1}{8}[D] \wedge dd^c g. \end{aligned} \tag{14.7}$$

The limiting probability has mass 1/2 on D and depends on g , although $\mathcal{A}_\varphi(0) = \{dV\}$. The cofactors do not approach $\beta/4$, and their limit is not $\rho\beta$ for any locally integrable scalar ρ .

Proof Smoothness and monotone convergence follow directly from the defining formula, also on D , where $\psi = -\infty$. Off D , set

$$\lambda = \frac{r}{r + \delta e^g}, \quad h = \psi - g - \log \delta.$$

The chain rule gives $\Omega_{\delta,g} = A_\delta + R_\delta$, where

$$A_\delta = (2 - \lambda)\omega_1 + 2\omega_2 + (1 - \lambda)\gamma, \quad R_\delta = \lambda(1 - \lambda)dh \wedge d^c h.$$

Thus $A_\delta \geq \omega_1 + \omega_2$ and $R_\delta \geq 0$, and the inequality $\Omega_{\delta,g} \geq \omega$ extends across D by continuity. Closedness of θ and Stokes' theorem give the mass eight. Since $\Omega_{\delta,g}$ is closed, the Gauduchon condition $\text{dd}^c(\rho\Omega_{\delta,g}) = 0$ reduces to the elliptic equation $\text{dd}^c \rho \wedge \Omega_{\delta,g} = 0$ on the connected surface, whose smooth solutions are constant by the maximum principle. Normalization against $\Omega_{\delta,g}^2$ gives $\rho = 1/8$ and the stated adjoint cofactors and probabilities.

The rank-one form R_δ has square zero, hence $\Omega_{\delta,g}^2 = A_\delta^2 + 2A_\delta \wedge R_\delta$. The bounded coefficients of A_δ converge off D to those of β , which gives $A_\delta^2 \rightarrow 4dV$. Write $N = d\psi \wedge d^c\psi$. In $A_\delta \wedge R_\delta$, the part in which R_δ contributes only derivatives along the first factor (the normal part) is

$$\lambda(1-\lambda)N \wedge (2\omega_2 + (1-\lambda)\gamma).$$

Terms mixing a derivative along the first factor with one along the second vanish for degree reasons. The remaining tangential term is $\lambda(1-\lambda)(2-\lambda)\omega_1 \wedge dg \wedge d^c g$, which tends to zero by dominated convergence.

The normal coefficients can be computed in polar coordinates. Put $s = \delta e^g$ and $t = |z|^2$. Then

$$\lambda = \frac{t}{s + (1+s)t}, \quad N = \frac{i dz \wedge d\bar{z}}{2\pi t(1+t)^2}.$$

After angular integration the radial measure of $\lambda(1-\lambda)N$ is

$$\frac{s dt}{(1+t)(s + (1+s)t)^2} = \frac{dy}{(1+sy)(1 + (1+s)y)^2}, \quad t = sy.$$

It is bounded by $dy/(1+y)^2$ and tends to that measure, whose integral is one. With an additional factor $1-\lambda$, the rescaled measure becomes $dy/(1 + (1+s)y)^3$, which is bounded by $dy/(1+y)^3$ and has limiting integral $1/2$. The mass of both measures outside every fixed tube around D tends to zero, uniformly in the point of the second factor because g is bounded. Testing against continuous functions therefore gives

$$\lambda(1-\lambda)N \longrightarrow [D], \quad \lambda(1-\lambda)^2N \longrightarrow \frac{1}{2}[D].$$

Combining the normal and the remaining terms proves

$$\Omega_{\delta,g}^2 \longrightarrow 4dV + [D] \wedge (4\omega_2 + \gamma). \quad (14.8)$$

Dividing by eight gives the second line of (14.7). The limit is positive since $4\omega_2 + \gamma \geq 3\omega_2$, and its mass on D is $4/8 = 1/2$ by Stokes' theorem on the second factor. Taking $g = 0$ and a small nonconstant smooth g gives different limits, since $\text{dd}^c g$ vanishes identically only for constant g .

The difference of the potentials satisfies

$$0 \leq u_{\delta,g} - \psi \leq \log(1 + \delta e^{\max g}/r)$$

off D . The right-hand side tends to zero and is dominated by an integrable logarithmic pole, which proves L^1 convergence. Continuity of distributional differentiation then gives the limit of the cofactors. A locally integrable function times the smooth form β has absolutely continuous coefficients, so it cannot produce the singular coefficients of $[D]$.

For convergence in capacity, use the capacity Cap_ω of [Section 1.8](#); after subtracting one, its test potentials range over $v \in \text{PSH}(X, \omega)$ with $-1 \leq v \leq 0$. For such v , apply the cutoff argument of [\(14.6\)](#) with β replaced by ω and $w = v + 1$. Stokes' theorem gives $\int_X \omega_1 \wedge (2\omega + \text{dd}^c v) = 2$, so

$$\text{Cap}_\omega \{\psi < -t\} \leq \int_X (-f_t) \omega^2 + 2/t \longrightarrow 0.$$

The same bound shows that D has capacity zero. For $\eta > 0$, the set of points off D where $u_{\delta,g} - \psi > \eta$ is contained in

$$\left\{ r < \frac{\delta e^{\max g}}{e^\eta - 1} \right\}.$$

This is a sublevel set of ψ whose level tends to $-\infty$ as $\delta \downarrow 0$. The capacity bound for such sublevel sets, together with $\text{Cap}_\omega(D) = 0$, proves convergence in capacity.

Finally, $\Omega_{\delta,g} \geq \omega$ gives $F_{\delta,g} \geq -\log 2$. In the affine chart $|\text{d}\psi|_\omega^2 \leq C/r$, while g and its first two derivatives are bounded. The decomposition above yields $\Omega_{\delta,g} \leq C_g(1 + r^{-1})\omega$, hence

$$|F_{\delta,g}| \leq C_g + 2|\log r|.$$

Every finite power of this logarithmic bound is integrable. Smooth convergence off D gives $F_{\delta,g} \rightarrow 0$ there, and dominated convergence proves convergence in L^p . $\square$

The exponential densities satisfy $\int_X e^{F_{\delta,g}} \text{d}V = 2$ for every δ , whereas their pointwise limit has integral one; they are therefore not uniformly integrable. The smoothings leave the ordinary type of φ and keep the mass eight of bounded potentials instead of the mass four of that type. The example thus shows which concentration a recovery theorem must exclude. The hypotheses of [Proposition 14.2.1](#) (uniform convergence) and of [Theorem 14.1.2](#) (uniformly bounded densities converging in L^1) are stronger than the convergence in every L^p obtained here. In the fixed divisorial type, a common bound on the residual potentials gives a direct recovery estimate instead.

Corollary 14.2.1 *Let $w_j, w \in \text{PSH}(X, \beta)$ satisfy $|w_j|, |w| \leq M$ for a fixed $M \geq 1$, and suppose that $w_j \rightarrow w$ in capacity. Put*

$$\begin{aligned} T_j &= \beta + \text{dd}^c w_j, & T &= \beta + \text{dd}^c w, \\ Q_j &= T_j/4, & Q &= T/4, & \nu_j &= T_j^2/4, & \nu &= T^2/4. \end{aligned}$$

Then $Q_j \rightarrow Q$ as currents and $\nu_j \rightarrow \nu$ as probability measures. More precisely, for real $f \in C^\infty(X)$ choose $C_f \geq 0$ with $-C_f \beta \leq \text{dd}^c f \leq C_f \beta$. For every $\eta > 0$, writing $E_{j,\eta} = \{|w_j - w| > \eta\}$, one has

$$\left| \int_X f (d\nu_j - d\nu) \right| \leq C_f (2\eta + 2M^2 \text{Cap}_\beta(E_{j,\eta})). \quad (14.9)$$

If T_j is smooth and strictly positive, then Q_j and ν_j are its adjoint cofactor and adjoint probability. If $\psi + w$ solves (14.1) for some $F \in C(X)$, the limit ν is the unique member of $\mathcal{A}_\varphi(F)$.

Proof The capacity is the one of Section 1.8, and $\beta \leq 2\omega$ gives $\text{Cap}_\beta \leq 4 \text{Cap}_\omega$. Set $a_j = (w_j + M)/(2M)$ and $S_j = \beta + \text{dd}^c a_j$. Then $0 \leq a_j \leq 1$ and

$$\begin{aligned} S_j &= \left(1 - \frac{1}{2M}\right) \beta + \frac{1}{2M} T_j, \\ S_j^2 &\geq \left(\frac{1}{M} - \frac{1}{2M^2}\right) \beta \wedge T_j \geq \frac{1}{2M} \beta \wedge T_j. \end{aligned}$$

Positivity of bounded mixed products justifies these inequalities. Thus $\int_E \beta \wedge T_j \leq 2M \text{Cap}_\beta(E)$ for every Borel set E , and the same bound holds for T . By closedness and Stokes' theorem, $\int_X \beta \wedge (T_j + T) = 8$. Now test the identity

$$T_j^2 - T^2 = \text{dd}^c((w_j - w)(T_j + T))$$

against f . On $X \setminus E_{j,\eta}$ the potential difference has absolute value at most η , and on $E_{j,\eta}$ at most $2M$. Consequently

$$\begin{aligned} \left| \int_X f (T_j^2 - T^2) \right| &\leq C_f \left(8\eta + 2M \int_{E_{j,\eta}} \beta \wedge (T_j + T) \right) \\ &\leq C_f (8\eta + 8M^2 \text{Cap}_\beta(E_{j,\eta})). \end{aligned}$$

Dividing by four proves (14.9). Letting first $j \rightarrow \infty$ with η fixed and then $\eta \downarrow 0$ shows that $\int_X f d\nu_j \rightarrow \int_X f d\nu$. All ν_j and ν have mass one by Proposition 14.2.3, and smooth functions are uniformly dense in $C(X)$, so $\nu_j \rightarrow \nu$.

The constant test potential in the definition of capacity gives $4dV(E) \leq \text{Cap}_\beta(E)$. Splitting the potential difference over the same sets yields

$$\|w_j - w\|_{L^1(d\nu)} \leq \eta + \frac{M}{2} \text{Cap}_\beta(E_{j,\eta}).$$

Taking the limits in the same order proves L^1 convergence, and hence convergence of the currents Q_j by continuity of distributional differentiation. The limiting cofactor satisfies $\text{dd}^c Q = 0$, $\int_X \beta \wedge Q = 1$, and $T \wedge Q = \nu$ as a bounded product. For smooth real h , the signed measure $2\text{dd}^c h \wedge T$ is the formal linearization of the residual operator at w in the direction h , and its integral against the constant $1/4$ vanishes by Stokes' theorem. It is the derivative of the residual measure along $w + th$ whenever these functions remain β -plurisubharmonic.

If T_j is smooth and strictly positive, the maximum principle on the connected surface makes its Gauduchon multiplier constant, and the mass four normalizes it to $1/4$. Finally, if $\psi + w$ solves the equation at F , then $\nu = T^2/4 = e^F dV / \int_X e^F dV$, which is the unique supporting probability by [Proposition 14.2.3](#). $\square$

In the corollary, the potentials $\psi + w_j$ keep their pole along D , and the adjoint objects refer to the smooth residual forms T_j . We do not know whether a similar recovery holds for more general singular references, for unbounded residual sequences, or when the Gauduchon multipliers are not constant.

14.3 A convex functional on probability measures

To pass to the limit in the supporting inequality, we need to control the mass that supporting probabilities can put on small sets. The convex dual of B_φ provides this control: the measures in each of its sublevel sets are uniformly absolutely continuous. This allows the logarithmic density and the supporting measure to vary simultaneously.

Let $\mathcal{P}(X)$ denote the set of Borel probability measures on X , with the weak topology. Define

$$H_\varphi(\nu) = \sup_{G \in C(X)} \left(B_\varphi(G) + \int_X G \, d\nu \right), \quad \nu \in \mathcal{P}(X). \quad (14.10)$$

The value $+\infty$ is allowed, while taking $G = 0$ shows that $H_\varphi \geq B_\varphi(0) > -\infty$.

Proposition 14.3.1 *The functional H_φ is convex and weakly lower semicontinuous. For every $F \in C(X)$,*

$$B_\varphi(F) = \min_{\nu \in \mathcal{P}(X)} \left(H_\varphi(\nu) - \int_X F \, d\nu \right). \quad (14.11)$$

The minimizers are exactly $\mathcal{A}_\varphi(F)$.

Proof Each function of ν in the supremum defining H_φ is affine and weakly continuous, so their supremum is convex and lower semicontinuous. By definition, $H_\varphi(\nu) - \int_X F \, d\nu \geq B_\varphi(F)$, with equality precisely when

$$B_\varphi(G) + \int_X G \, d\nu \leq B_\varphi(F) + \int_X F \, d\nu \quad \text{for every } G \in C(X).$$

This is the defining inequality of $\mathcal{A}_\varphi(F)$, and the minimum is attained because $\mathcal{A}_\varphi(F)$ is nonempty by [Theorem 14.2.1](#). $\square$

Theorem 14.3.1 *For every finite real L , the set*

$$\mathcal{K}_L = \{\nu \in \mathcal{P}(X) : H_\varphi(\nu) \leq L\}$$

is weakly compact. Its measures are uniformly absolutely continuous with respect to dV : for every $\epsilon > 0$ there is a $\delta > 0$ such that

$$dV(E) < \delta \implies \sup_{\nu \in \mathcal{K}_L} \nu(E) < \epsilon \quad (14.12)$$

for every Borel set E . In particular, writing $d\nu = h_\nu dV$, the densities in this set are uniformly integrable in $L^1(dV)$. On $\mathcal{K}_L$, weak convergence of measures also implies weak convergence of their densities in $L^1(dV)$.

Proof Weak compactness follows from lower semicontinuity and compactness of $\mathcal{P}(X)$. We may assume that the sublevel set is nonempty, so that $L \geq B_\varphi(0)$. Fix $t > 0$. By [Theorem 14.1.2](#), there is $\delta_t > 0$ such that

$$0 \leq \chi \leq 1, \quad \chi \in C(X), \quad \int_X \chi dV < \delta_t \implies B_\varphi(t\chi) > B_\varphi(0) - 1.$$

Indeed, otherwise there would be a sequence of such functions χ tending to zero in L^1 with $B_\varphi(t\chi) \leq B_\varphi(0) - 1$, contrary to that theorem. For $\nu \in \mathcal{K}_L$, the defining supremum gives

$$t \int_X \chi d\nu \leq L - B_\varphi(t\chi) < L - B_\varphi(0) + 1.$$

Choose t so large that $(L - B_\varphi(0) + 1)/t < \epsilon/2$. If $dV(E) < \delta_t/2$, outer regularity gives an open neighborhood O of E with $dV(O) < \delta_t$. For any compact $K \subset E$, choose a continuous cutoff $0 \leq \chi \leq 1$ equal to one on K and supported in O . The last inequality gives $\nu(K) < \epsilon/2$, uniformly in $\nu \in \mathcal{K}_L$, and inner regularity yields $\nu(E) \leq \epsilon/2 < \epsilon$. This proves [\(14.12\)](#).

In particular, every measure in the sublevel set is absolutely continuous, with a density of integral one. Together with the uniform small-set estimate, this is exactly uniform integrability on the finite measure space (X, dV) .

Finally, suppose that $\nu_j \rightarrow \nu$ weakly within the sublevel set. For a bounded measurable G , choose continuous G_k with $|G_k| \leq \|G\|_\infty$ and $G_k \rightarrow G$ in dV -measure; such approximations exist by Lusin's theorem. Uniform absolute continuity gives

$$\sup_{\sigma \in \mathcal{K}_L} \int_X |G_k - G| d\sigma \longrightarrow 0.$$

To see this, split X into $\{|G_k - G| \leq a\}$ and its complement; the integral over the first set is at most a , and the integral over the second is at most $2\|G\|_\infty$ times a uniformly

small measure. For fixed k , weak convergence applies to G_k . Letting first $j \rightarrow \infty$ and then $k \rightarrow \infty$ proves convergence of the integrals against G , which is exactly weak $L^1(dV)$ convergence of the densities. In particular, every sequence in the sublevel set has a subsequence whose densities converge weakly in L^1 . $\square$

14.4 Bounded measurable densities and stability

The supporting probabilities of continuous approximations of a bounded measurable logarithmic density lie in one sublevel set of H_φ . Uniform integrability then allows both the density and the supporting measure to vary when we pass to the limit in the supporting inequality.

Theorem 14.4.1 *For every $F \in L^\infty(dV)$ there is a nonempty set of absolutely continuous probability measures, again denoted $\mathcal{A}_\varphi(F)$, characterized by*

$$B_\varphi(G) \leq B_\varphi(F) - \int_X (G - F) d\nu \quad \text{for every } G \in L^\infty(dV). \quad (14.13)$$

For continuous F , this set agrees with the one defined by (14.3). Formula (14.11) also holds for bounded measurable F , with these measures as its minimizers; there the objective is interpreted as $+\infty$ whenever $H_\varphi(\nu) = +\infty$, and otherwise ν is absolutely continuous, so that the integral of the L^∞ class F is well defined.

Suppose that $F_j, F \in L^\infty(dV)$ are uniformly bounded and $F_j \rightarrow F$ in $L^1(dV)$, and let $\nu_j \in \mathcal{A}_\varphi(F_j)$. Then the densities of the ν_j are uniformly integrable, and every weak L^1 cluster point belongs to $\mathcal{A}_\varphi(F)$. If the latter is a singleton, the whole sequence converges to it weakly in $L^1(dV)$.

Proof First, if $H_\varphi(\nu) < \infty$, the measure ν is absolutely continuous by Theorem 14.3.1. A bounded measurable G admits uniformly bounded continuous approximations $G_k \rightarrow G$ in $L^1(dV)$, and absolute continuity together with the common bound gives $\int_X G_k d\nu \rightarrow \int_X G d\nu$. Combined with Theorem 14.1.2, this proves

$$H_\varphi(\nu) = \sup_{G \in L^\infty(dV)} \left(B_\varphi(G) + \int_X G d\nu \right) \quad (14.14)$$

for such ν .

To construct supporting probabilities at F , choose continuous F_j with $|F_j| \leq M = \|F\|_\infty$ and $F_j \rightarrow F$ in $L^1(dV)$, and choose $\nu_j \in \mathcal{A}_\varphi(F_j)$. The minimum formula of Proposition 14.3.1 and the Lipschitz bound give

$$H_\varphi(\nu_j) = B_\varphi(F_j) + \int_X F_j d\nu_j \leq B_\varphi(0) + 2M.$$

By Theorem 14.3.1, a subsequence converges weakly in L^1 to a probability measure ν . Uniform absolute continuity gives

$$\int_X |F_j - F| d\nu_j \longrightarrow 0,$$

by splitting again at a fixed small positive threshold: the sets where $|F_j - F|$ exceeds it have dV -measure tending to zero. Since F is bounded and measurable, weak L^1 convergence applies to its integral. Lower semicontinuity of H_φ and continuity of B_φ yield

$$H_\varphi(\nu) \leq \liminf_j H_\varphi(\nu_j) = B_\varphi(F) + \int_X F d\nu.$$

The reverse inequality follows from (14.14) with $G = F$. Equality, combined with the same supremum formula, proves (14.13) for ν and the minimum formula.

For continuous F , every measure satisfying (14.3) has finite dual value by Proposition 14.3.1, so (14.14) extends its supporting inequality to all bounded measurable tests; the converse inclusion is trivial. Thus the two definitions agree. Finally, an absolutely continuous probability satisfying (14.13) has finite dual value and attains the minimum, so the characterization is exact.

For the stability assertion, we start from the given F_j and ν_j instead of an approximating construction. The common uniform bound again places all ν_j in a single finite sublevel set of H_φ , and the same compactness and limiting argument shows that every weak L^1 cluster point attains the minimum for F . If the set of minimizers is a singleton, compactness forces the whole sequence to converge to its member. $\square$

14.5 Entropy and the closed case

In a closed background, all potentials of an ordinary singularity type have the same mass, and integrating the equation determines the scalar explicitly; its convex dual is then the relative entropy. The variational formula for the entropy also gives estimates in nonclosed backgrounds.

For a Borel probability measure ν absolutely continuous with respect to dV , let h be its nonnegative density and define the *relative entropy*

$$\text{Ent}_{dV}(\nu) = \int_X h \log h dV, \quad 0 \log 0 = 0,$$

and set $\text{Ent}_{dV}(\nu) = +\infty$ if ν is not absolutely continuous. The integral is well defined in $(-\infty, +\infty]$, since $h \log h \geq -e^{-1}$; it may be negative when $dV(X) \neq 1$.

Lemma 14.5.1 *For every $\nu \in \mathcal{P}(X)$,*

$$\text{Ent}_{dV}(\nu) = \sup_{F \in C(X)} \left(\int_X F d\nu - \log \int_X e^F dV \right).$$

Proof If ν is not absolutely continuous, choose a compact set K with $dV(K) = 0$ and $\nu(K) > 0$. For $t > 0$, regularity gives a continuous cutoff $0 \leq \chi_t \leq 1$, equal to one on K , whose support has volume at most e^{-2t} . For $F = t\chi_t$, the expression in the supremum is at least

$$t\nu(K) - \log(dV(X) + e^{-t}),$$

which tends to infinity with t .

Suppose now that $\nu = h dV$. If its entropy is finite, Jensen's inequality for the logarithm gives

$$\int_X F d\nu - \text{Ent}_{dV}(\nu) \leq \log \int_{\{h>0\}} e^F dV \leq \log \int_X e^F dV.$$

For infinite entropy this upper bound is automatic. For the opposite inequality, set

$$F_k = \log(\max\{k^{-1}, \min\{h, k\}\}), \quad k \geq 1.$$

Then $\int_X e^{F_k} dV \rightarrow 1$ and $\int_X F_k d\nu \rightarrow \text{Ent}_{dV}(\nu)$, with the value $+\infty$ allowed: the positive parts of the integrands hF_k increase to that of $h \log h$, and their negative parts are dominated by the integrable negative part of $h \log h$. For each fixed k , approximate F_k in $L^1(dV + \nu)$ by continuous functions with the same bounds; both integrals, including the exponential one, converge to those of F_k . Hence the supremum over continuous functions is at least the value of the expression at F_k , and letting $k \rightarrow \infty$ completes the proof. $\square$

Suppose now that θ is a Kähler form. By the closed-background theory of [Xia], all potentials of the ordinary type of φ have the same non-pluripolar mass m_φ , which is positive under the standing hypotheses. For $F \in L^\infty(dV)$, integrating the equation gives

$$B_\varphi(F) = \log m_\varphi - \log \int_X e^F dV, \quad \mathcal{A}_\varphi(F) = \left\{ \frac{\int_X e^F dV}{\int_X e^F dV} \right\}. \quad (14.15)$$

For the second identity, Jensen's inequality shows, as in Proposition 14.2.3, that the normalized exponential measure is a supporting probability; differentiating in bounded directions and testing the supporting inequality with both signs of the parameter shows that it is the only one.

Proposition 14.5.1 *If θ is Kähler, then*

$$H_\varphi(\nu) = \log m_\varphi + \text{Ent}_{dV}(\nu).$$

Thus the minimum formula (14.11) becomes the usual variational formula for the logarithmic integral in (14.15).

Proof Substitute (14.15) into the defining supremum and apply Lemma 14.5.1. $\square$

The dual functional depends on the reference volume. If dV is replaced by $dV' = e^a dV$ for a continuous real a , the corresponding functionals satisfy

$$B'_\varphi(F) = B_\varphi(F + a), \quad H'_\varphi(\nu) = H_\varphi(\nu) - \int_X a \, d\nu.$$

The first identity follows from the equation, and the second, which also holds when the values are infinite, from the change of variable $G \mapsto G + a$ in the defining supremum. In a nonclosed background, H_φ is still defined by the same supremum, but the total mass need not be constant on an ordinary type, so the entropy computation no longer determines it.

14.6 Entropy bounds

For a Hermitian background and the zero reference, a lower bound for the L^q norm of the density in the equation and an upper bound coming from a Gauduchon trace place B_0 between two logarithmic integrals. Dualizing gives two-sided entropy estimates, which identify the set where H_0 is finite. Throughout this section, dV is normalized by $dV(X) = 1$.

Proposition 14.6.1 *Let $\theta = \omega$ be a Hermitian form, and let $\varphi = 0$. There are real constants A and, for every $q > 1$, a_q such that every Borel probability measure ν satisfies*

$$a_q + \frac{1}{q} \text{Ent}_{dV}(\nu) \leq H_0(\nu) \leq A + n \text{Ent}_{dV}(\nu).$$

The inequalities include the value $+\infty$. Thus $H_0(\nu) < \infty$ if and only if ν has finite entropy, and a family of probability measures has uniformly bounded values of H_0 if and only if its entropies are uniformly bounded.

Proof In dimension one, ω is a Kähler form, and [Proposition 14.5.1](#), which rests on [\(14.15\)](#), gives $H_0 = \log \int_X \omega + \text{Ent}_{dV}$, so the assertions follow. Suppose that $n \geq 2$.

For $G \in C(X)$, apply the lower bound for $\|F\|_q$ in [Theorem 10.3.1](#) to a bounded solution with density $F = e^{B_0(G)+G}$. It gives a constant $c_q > 0$, independent of G , such that

$$B_0(G) \geq \log c_q - \frac{1}{q} \log \int_X e^{qG} \, dV.$$

For the upper bound, fix a smooth Gauduchon metric γ , rescaled so that $\int_X \omega \wedge \gamma^{n-1} = 1$, and write

$$k_\gamma = \left(\frac{\gamma^n}{dV} \right)^{(n-1)/n}, \quad m = \min_X k_\gamma > 0.$$

For smooth G , the trace bound [\(4.3\)](#) gives

$$e^{B_0(G)/n} \int_X e^{G/n} k_\gamma \, dV \leq 1.$$

Uniform approximation and continuity of B_0 extend this inequality to continuous G . Consequently

$$B_0(G) \leq -n \log m - n \log \int_X e^{G/n} dV.$$

Taking the defining suprema in the two scalar bounds and applying [Lemma 14.5.1](#) with $F = qG$ and $F = G/n$, respectively, proves both inequalities for every probability measure, including infinite values, with $a_q = \log c_q$ and $A = -n \log m$. The finite-domain and bounded-family assertions follow by taking $q = 2$. $\square$

14.6.1 The mass bounds as entropy differences

In a closed background the difference between H_0 and the entropy is constant. In general it measures how much the total Monge–Ampère mass of bounded potentials varies: its infimum and supremum recover the lower and upper masses $v_-(\omega)$ and $v_+(\omega)$ of [Definition 6.5.1](#).

Let $\mathcal{P}_{\text{ent}}(X)$ denote the set of probability measures of finite entropy relative to the fixed smooth probability volume dV . By [Proposition 14.6.1](#), the difference $H_0(\nu) - \text{Ent}_{dV}(\nu)$ is a finite real number for every ν in this set.

Proposition 14.6.2 *For every Hermitian background ω ,*

$$\begin{aligned} \inf_{\nu \in \mathcal{P}_{\text{ent}}(X)} (H_0(\nu) - \text{Ent}_{dV}(\nu)) &= \log v_-(\omega), \\ \sup_{\nu \in \mathcal{P}_{\text{ent}}(X)} (H_0(\nu) - \text{Ent}_{dV}(\nu)) &= \log v_+(\omega). \end{aligned}$$

The same extrema are obtained over smooth strictly positive probability measures. Here $\log 0 = -\infty$ and $\log(+\infty) = +\infty$. Thus the difference is bounded above if and only if X has the bounded mass property, and bounded below if and only if ω has positive lower mass.

Proof Write $Z_G = \int_X e^G dV$. A bounded solution for $G \in C(X)$ has mass $e^{B_0(G)} Z_G$. If $v_-(\omega) > 0$, the lower mass bound gives

$$B_0(G) \geq \log v_-(\omega) - \log Z_G.$$

Taking the defining supremum for H_0 and using [Lemma 14.5.1](#) gives $H_0 - \text{Ent}_{dV} \geq \log v_-(\omega)$ on $\mathcal{P}_{\text{ent}}(X)$. In the same way, if $v_+(\omega) < \infty$, the upper mass bound gives $H_0 - \text{Ent}_{dV} \leq \log v_+(\omega)$. These bounds hold trivially when $v_-(\omega) = 0$ or $v_+(\omega) = +\infty$.

To prove sharpness, first take a smooth real G and its Gibbs probability $\nu_G = Z_G^{-1} e^G dV$, which has finite entropy. Testing the supremum defining H_0 with G gives

$$H_0(\nu_G) - \text{Ent}_{dV}(\nu_G) \geq B_0(G) + \log Z_G.$$

In the other direction, let σ_G be the smooth strictly positive Gauduchon adjoint probability of [Theorem 14.2.3](#). It lies in $\mathcal{A}_0(G)$, so its dual value is $B_0(G) + \int_X G d\sigma_G$, and [Lemma 14.5.1](#) yields

$$H_0(\sigma_G) - \text{Ent}_{dV}(\sigma_G) \leq B_0(G) + \log Z_G.$$

As G runs over smooth real functions, the masses $e^{B_0(G)} Z_G$ run over the masses $\int_X (\omega + \text{dd}^c u)^n$ of all smooth u with $\omega + \text{dd}^c u > 0$, since such a u solves the equation for $G = \log((\omega + \text{dd}^c u)^n / dV)$. By [Theorem 1.11.1](#), the mass of every bounded ω -plurisubharmonic function is a limit of such masses. Hence the infimum and supremum of $e^{B_0(G)} Z_G$ over smooth G are $v_-(\omega)$ and $v_+(\omega)$. Since v_G and σ_G are smooth and strictly positive, the last two inequalities prove sharpness on this smaller domain, including the cases $v_-(\omega) = 0$ and $v_+(\omega) = +\infty$. The two equivalences follow. $\square$

The difference does not depend on the smooth positive reference volume. For smooth real a , replacing dV by $dV' = e^a dV$ changes both $H_0(v)$ and $\text{Ent}(v)$ by $-\int_X a \, dv$, by the transformation formula preceding [Proposition 14.6.1](#), and finiteness of the entropy is unchanged because a is bounded. Similarly, if h is a smooth real function and $\omega + \text{dd}^c h$ is also Hermitian, transporting bounded solutions by $u \mapsto u - h$ preserves B_0 , and hence this difference. Finally, the difference is constant on $\mathcal{P}_{\text{ent}}(X)$ exactly when $v_-(\omega) = v_+(\omega)$, that is, when all bounded ω -plurisubharmonic functions have the same mass.

14.6.2 Entropy for a prescribed ordinary type

Return to the standing setting: θ is semipositive and big, and φ is a model reference, with $\varepsilon \in (0, 1)$ as in [\(12.20\)](#). The part $(1 - \varepsilon)\theta$ of the background left over by the smaller-background envelope gives a uniform lower bound for the density norm, while comparison in a larger Hermitian background gives the upper bound. Together they extend the entropy estimates to the prescribed type.

Corollary 14.6.1 *For every $q > 1$ there is a finite real a_q , and there is a finite real A , such that*

$$a_q + \frac{1}{q} \text{Ent}_{dV}(v) \leq H_\varphi(v) \leq A + n \text{Ent}_{dV}(v)$$

for every Borel probability measure v , including infinite values. Thus $H_\varphi(v)$ is finite exactly when v has finite entropy, and uniformly bounded dual values are equivalent to uniformly bounded entropies. For fixed θ and ε , the constants can be chosen independently of the model reference φ .

Proof For $G \in C(X)$, let $u \sim \varphi$ solve the equation with density ce^G , where $c = e^{B_\varphi(G)}$. The lower bound $b_q > 0$ of [Lemma 13.11.1](#) for the L^q norm of the density gives $c \|e^G\|_q \geq b_q$, hence

$$B_\varphi(G) \geq \log b_q - \frac{1}{q} \log \int_X e^{qG} \, dV.$$

For the upper bound, choose a Hermitian form $\Omega \geq \theta$, and let $B_{\Omega,0}$ and $H_{\Omega,0}$ denote its normalization scalar and dual functional for the zero reference. Let v be a bounded solution for G in this background; being bounded, it has a smaller-background envelope $P_{\delta\Omega}(v) \geq \inf_X v$ for every $0 < \delta < 1$. Moreover $u \in \text{PSH}(X, \Omega)$, $u \preceq v$, and positivity gives

$$\text{MA}_{\Omega}^{\text{ext}}(u) \geq \text{MA}_{\theta}^{\text{ext}}(u) = ce^G dV.$$

If $c > e^{B_{\Omega,0}(G)}$, the singular strict domination principle, applied in the background Ω to v and $u + t$ for every real t , would give $v \geq u + t$ for all t , which is impossible. Hence $B_{\varphi} \leq B_{\Omega,0}$, and therefore $H_{\varphi} \leq H_{\Omega,0}$; **Proposition 14.6.1** now gives the upper bound.

Taking the defining supremum in the lower scalar estimate and applying **Lemma 14.5.1** with $F = qG$ gives the lower bound for every probability measure, including infinite values, with $a_q = \log b_q$. The finite-domain and bounded-family assertions follow by taking $q = 2$. Finally, **Lemma 13.11.1** is uniform in the reference for fixed θ and ε , and the upper bound uses only Ω , which proves the last assertion. $\square$

This gives compactness when the reference varies. Let the model references φ_j satisfy the smaller-background condition with the same ε , let $G_j \in L^\infty(dV)$ satisfy $\|G_j\|_\infty \leq M$ for a fixed constant M , and choose $v_j \in \mathcal{A}_{\varphi_j}(G_j)$. With Ω as in the proof,

$$H_{\varphi_j}(v_j) = B_{\varphi_j}(G_j) + \int_X G_j d\nu_j \leq B_{\Omega,0}(0) + 2M.$$

The uniform lower estimate of **Corollary 14.6.1** bounds their entropies, and the Hermitian upper estimate then places all v_j in a single finite sublevel set of $H_{\Omega,0}$. Hence **Theorem 14.3.1**, applied in the background Ω , gives weak compactness and uniform integrability of their densities, and every weak limit has finite entropy. Identifying such a limit as a supporting probability for a limiting reference requires further information.

14.7 Changing the prescribed singularities

A more singular reference has a smaller normalization scalar. A competitor built from the smaller-background envelope also gives a quantitative comparison with the zero reference, uniform over all logarithmic densities. In this section the reference varies among the model potentials satisfying (12.20) for the fixed semipositive big background θ , and B_0, H_0 denote the functionals of the zero reference in the same background.

Proposition 14.7.1 *Let φ, ψ satisfy (12.20). If $\varphi \preceq \psi$, then $B_\varphi \leq B_\psi$ and $H_\varphi \leq H_\psi$. Moreover, if $0 < \varepsilon < 1$ and $P_{\varepsilon\theta}(\varphi) \not\equiv -\infty$, then*

$$B_0(G) + n \log(1 - \varepsilon) \leq B_\varphi(G) \leq B_0(G) \quad (G \in C(X)),$$

and

$$H_0(v) + n \log(1 - \varepsilon) \leq H_\varphi(v) \leq H_0(v) \quad (v \in \mathcal{P}(X)).$$

The dual inequalities include infinite values.

Proof Fix G , and let u_φ, u_ψ solve the equations in the ordinary types of φ and ψ , with constants c_φ, c_ψ . Then $u_\varphi \preceq u_\psi$. If $c_\varphi > c_\psi$, the singular strict domination principle applied to u_ψ and $u_\varphi + t$ would give $u_\psi \geq u_\varphi + t$ for every real t , which is impossible at a point where both are finite. This proves the monotonicity of B , and taking the defining supremum gives the monotonicity of H . Since $\varphi \preceq 0$ and the zero potential is itself a model reference, this also proves both upper bounds.

For the lower bound, let v be a bounded solution for G with the zero reference, with constant c_0 , and put

$$h = P_{\varepsilon\theta}(\varphi) + (1 - \varepsilon)v.$$

The two summands are $\varepsilon\theta$ - and $(1 - \varepsilon)\theta$ -plurisubharmonic, respectively, so positivity and homogeneity give

$$\text{MA}_\theta^{\text{ext}}(h) \geq (1 - \varepsilon)^n \text{MA}_\theta(v) = (1 - \varepsilon)^n c_0 e^G dV.$$

As in the proof of [Lemma 13.11.1](#), this inequality is justified first on finite truncation levels and then off the pole set of $P_{\varepsilon\theta}(\varphi)$, which has zero smooth volume. Also $h \preceq u_\varphi$. If $c_\varphi < (1 - \varepsilon)^n c_0$, strict domination would force $u_\varphi \geq h + t$ for every t . Thus $c_\varphi \geq (1 - \varepsilon)^n c_0$. Taking logarithms proves the scalar bound, and taking the defining suprema proves the dual bound. $\square$

14.7.1 Uniform comparison of the scalar functionals

When two scalar functionals are uniformly close, their supporting probabilities are close as well. To make this precise, define for two model references φ, ψ in the preceding setting

$$\Delta(\varphi, \psi) = \sup_{G \in C(X)} |B_\varphi(G) - B_\psi(G)|. \quad (14.16)$$

The comparison with B_0 in [Proposition 14.7.1](#) makes this number finite for every such pair. It is a pseudometric: symmetry, vanishing on the diagonal and the triangle inequality follow from the properties of the uniform norm. Distinct singularity types can have distance zero, as [Example 14.10.1](#) shows.

Proposition 14.7.2 *For these model references,*

$$\Delta(\varphi, \psi) = \sup_{\text{Ent}_{dV}(v) < \infty} |H_\varphi(v) - H_\psi(v)|,$$

where the supremum is over probability measures of finite entropy. The same value is obtained if (14.16) uses all bounded measurable G , and it does not depend on the smooth positive reference volume.

Proof By [Corollary 14.6.1](#), both duals are finite exactly on the probability measures of finite entropy; rescaling the reference volume to have mass one does not affect finiteness. A uniform bound for $|B_\varphi - B_\psi|$ passes to the defining suprema, so the supremum in the statement is at most $\Delta(\varphi, \psi)$. Conversely, denote that supremum by D . If $\nu \in \mathcal{A}_\psi(G)$, then ν has finite entropy, and the dual minimum formula gives

$$B_\varphi(G) \leq H_\varphi(\nu) - \int_X G \, d\nu \leq B_\psi(G) + D.$$

Interchanging the references gives the opposite inequality, so $\Delta(\varphi, \psi) \leq D$.

For bounded measurable G , take continuous approximations with the same uniform bound converging in $L^1(dV)$; the continuity theorem [Theorem 14.1.2](#), applied to each of the two references, extends the scalar bound to G . Finally, a change of volume $dV' = e^a dV$ replaces each $B(G)$ by $B(G + a)$, and translation by $a \in C(X)$ is a bijection of the space of tests, so the supremum is unchanged. $\square$

Proposition 14.7.3 *Let φ_j, φ be model references in the same background with $\Delta(\varphi_j, \varphi) \rightarrow 0$. Let G_j, G be uniformly bounded measurable functions with $G_j \rightarrow G$ in $L^1(dV)$, and choose $\nu_j \in \mathcal{A}_{\varphi_j}(G_j)$. Then the densities of the ν_j are uniformly integrable, every weak cluster point of (ν_j) belongs to $\mathcal{A}_\varphi(G)$, and a weakly convergent subsequence also converges weakly in L^1 . If $\mathcal{A}_\varphi(G)$ is a singleton, the whole sequence converges to it in both senses.*

Proof Write $\delta_j = \Delta(\varphi_j, \varphi)$. The bounds $|B_{\varphi_j} - B_\varphi| \leq \delta_j$ and $|H_{\varphi_j} - H_\varphi| \leq \delta_j$, together with the identity $H_{\varphi_j}(\nu_j) = B_{\varphi_j}(G_j) + \int_X G_j \, d\nu_j$, give

$$0 \leq H_\varphi(\nu_j) - \int_X G_j \, d\nu_j - B_\varphi(G_j) \leq 2\delta_j.$$

If $\|G_j\|_\infty \leq M$, then $H_\varphi(\nu_j) \leq B_\varphi(0) + 2M + 2\delta_j$, so all the measures lie in one finite sublevel set of H_φ . By [Theorem 14.3.1](#), their densities are uniformly integrable, and a weakly convergent subsequence also converges weakly in L^1 .

Let ν be the limit of such a subsequence. Uniform integrability, the common bound and convergence in measure give $\int_X |G_j - G| \, d\nu_j \rightarrow 0$; weak L^1 convergence applies to the bounded function G , and [Theorem 14.1.2](#) gives $B_\varphi(G_j) \rightarrow B_\varphi(G)$. Lower semicontinuity of H_φ in the last inequality yields

$$H_\varphi(\nu) - \int_X G \, d\nu - B_\varphi(G) \leq 0.$$

The minimum formula for bounded measurable densities in [Theorem 14.4.1](#) gives the reverse inequality, and equality means exactly that $\nu \in \mathcal{A}_\varphi(G)$. When this set is a singleton, compactness gives convergence of the whole sequence. $\square$

The smaller-background comparison gives an explicit family of references converging to the zero reference.

Corollary 14.7.1 *Let the model references φ_j satisfy $P_{\varepsilon_j \theta}(\varphi_j) \not\equiv -\infty$, where $0 < \varepsilon_j < 1$ and $\varepsilon_j \rightarrow 0$. Then $B_{\varphi_j} \rightarrow B_0$ uniformly on $C(X)$. Let $G_j, G \in C(X)$ with $G_j \rightarrow G$ uniformly, and let $\nu_j \in \mathcal{A}_{\varphi_j}(G_j)$. Then every weak cluster point of (ν_j) belongs to $\mathcal{A}_0(G)$, the densities of the ν_j are uniformly integrable, and a weakly convergent subsequence also converges weakly in $L^1(dV)$. If $\mathcal{A}_0(G)$ is a singleton, the whole sequence converges to it in both senses.*

Proof Put $\delta_j = -n \log(1 - \varepsilon_j) \rightarrow 0$. Proposition 14.7.1 gives $\Delta(\varphi_j, 0) \leq \delta_j$, which is the uniform convergence of B_{φ_j} to B_0 on $C(X)$. The assertions about supporting probabilities follow from Proposition 14.7.3 with the zero reference as limit. $\square$

For ordinary divisorial types, a comparison of positive residual forms gives a geometric criterion for this convergence of functionals, as the next two sections show. We do not know general convergence criteria for references with degenerate residuals or with arbitrary singularities.

14.8 Varying positive backgrounds

A two-sided inequality between two Hermitian forms compares their normalization scalars uniformly in the logarithmic density. This turns geometric convergence of backgrounds into the uniform comparison of functionals used above.

From this section on, each section specifies its own background and reference. Here we vary a Hermitian form β on X and use the zero reference. Write B_β, H_β and $\mathcal{A}_\beta$ for the normalization scalar, its dual functional and the supporting sets, defined as above with $\theta = \beta$ and $\varphi = 0$. For two such backgrounds, set

$$d(B_\beta, B_{\beta'}) = \sup_{F \in L^\infty(dV)} |B_\beta(F) - B_{\beta'}(F)|.$$

The supremum ranges over all bounded measurable tests, with no common bound on their norms.

Theorem 14.8.1 *Suppose $0 < \varepsilon < 1$ and $(1 - \varepsilon)\beta \leq \beta' \leq (1 + \varepsilon)\beta$. For every bounded measurable F ,*

$$n \log(1 - \varepsilon) \leq B_{\beta'}(F) - B_\beta(F) \leq n \log(1 + \varepsilon). \quad (14.17)$$

In particular, $d(B_\beta, B_{\beta'}) \leq -n \log(1 - \varepsilon)$. The same conclusion holds if the two inequalities between forms are satisfied by positive representatives $\beta + dd^c h$ and $\beta' + dd^c h'$, with h, h' smooth real functions.

Proof First let F be smooth, and let v, v' be smooth solutions in the two backgrounds. At a maximum point of $v' - (1 + \varepsilon)v$,

$$0 < \beta' + dd^c v' \leq (1 + \varepsilon)(\beta + dd^c v).$$

Taking determinants and canceling $e^F dV$ gives the upper bound. At a minimum point of $v' - (1 - \varepsilon)v$, the reverse inequality between forms gives the lower bound. For bounded measurable F , choose smooth uniformly bounded approximations converging in L^1 and apply [Theorem 14.1.2](#) in each of the two backgrounds. Finally, the correspondence $v \mapsto v - h$ preserves both boundedness and the current, so $B_{\beta+dd^c h} = B_\beta$ whenever both backgrounds are positive. This proves the assertion about representatives. $\square$

Corollary 14.8.1 *Let β_j be Hermitian forms with $(1 - \varepsilon_j)\beta \leq \beta_j \leq (1 + \varepsilon_j)\beta$, where $0 < \varepsilon_j < 1$ and $\varepsilon_j \rightarrow 0$. Suppose that $F_j \rightarrow F$ in $L^1(dV)$ with a common L^∞ bound. Then $B_{\beta_j}(F_j) \rightarrow B_\beta(F)$. For any $v_j \in \mathcal{A}_{\beta_j}(F_j)$, the densities are uniformly integrable, and every subsequence has a further subsequence converging weakly in L^1 to an element of $\mathcal{A}_\beta(F)$. If this set is a singleton, which is the case in particular when F is smooth, the whole sequence converges to it weakly in L^1 and as probability measures.*

Proof Put $\delta_j = -n \log(1 - \varepsilon_j)$. The scalar assertion follows from [\(14.17\)](#) and [Theorem 14.1.2](#) in the fixed background β . Taking suprema over tests gives the inequalities, valid also for infinite values,

$$H_{\beta_j} \leq H_\beta + \delta_j, \quad H_\beta \leq H_{\beta_j} + \delta_j.$$

In particular, the two duals are finite on the same measures, and the identity $H_{\beta_j}(v_j) = B_{\beta_j}(F_j) + \int_X F_j dv_j$ gives

$$0 \leq H_\beta(v_j) - B_\beta(F_j) - \int_X F_j dv_j \leq 2\delta_j.$$

If $\|F_j\|_\infty \leq M$, this puts the measures in the fixed sublevel set $\{H_\beta \leq B_\beta(0) + 2M + 2 \sup_j \delta_j\}$, to which [Theorem 14.3.1](#) applies. For a weak L^1 cluster point, uniform integrability gives $\int_X |F_j - F| dv_j \rightarrow 0$, and lower semicontinuity in the last inequality, together with the minimum formula of [Theorem 14.4.1](#), identifies the limit as a supporting probability at F . Compactness gives convergence of the whole sequence when that supporting probability is unique, and [Theorem 14.2.3](#) gives uniqueness for smooth F . $\square$

Smooth changes of the background also control the potentials, because the inverse of the linearized equation used in [Proposition 9.3.1](#) remains available when the form itself is included among the parameters.

Proposition 14.8.1 *Let β_j, β be Hermitian forms and F_j, F smooth real functions with $\beta_j \rightarrow \beta$ and $F_j \rightarrow F$ in C^∞ . Then the solutions v_j for (β_j, F_j) normalized by $\int_X v_j dV = 0$ converge in C^∞ to the similarly normalized solution v for (β, F) , and their scalars converge as well.*

Proof Fix $k \geq 0$ and $0 < \alpha < 1$. On the open set where $\eta + dd^c w > 0$, consider the smooth map

$$(\eta, G, w, a) \mapsto \log \frac{(\eta + \text{dd}^c w)^n}{dV} - a - G$$

defined for $C^{k,\alpha}$ forms η and functions G , mean-zero $C^{k+2,\alpha}$ potentials w and $a \in \mathbb{R}$, with values in $C^{k,\alpha}$. At the limiting solution its derivative in (w, a) is $(h, q) \mapsto \Delta_\Omega h - q$, where $\Omega = \beta + \text{dd}^c v$ and $\Delta_\Omega h = n \text{dd}^c h \wedge \Omega^{n-1} / \Omega^n$. Given a target g , choose $q = -\int_X g \, d\mu_v$, where μ_v is the adjoint probability of [Proposition 4.7.1](#). The Fredholm alternative then gives a unique mean-zero h with $\Delta_\Omega h = g + q$, and the inverse is bounded as in [Proposition 9.3.1](#). In dimension one this is the Fredholm alternative for the Poisson equation.

The implicit function theorem gives a local branch of solutions depending continuously on the parameters in these spaces. For smooth parameters, uniqueness of bounded solutions modulo constants, [Corollary 11.4.1](#), identifies this branch with the global smooth solution. Thus $v_j \rightarrow v$ in $C^{k+2,\alpha}$ for every k , which proves the assertion. $\square$

The smooth adjoint probabilities determine the functional up to its value at zero. If $\nu_{\beta,F}$ denotes the unique supporting probability at a smooth F , integrating the derivative of [Theorem 14.2.3](#) along the path $s \mapsto sF$ gives

$$B_\beta(F) = B_\beta(0) - \int_0^1 \int_X F \, d\nu_{\beta,sF} \, ds. \quad (14.18)$$

Here the derivative is continuous along the path by the implicit function theorem. Consequently, two Hermitian backgrounds on the same X , with the same dV , have the same functional on bounded measurable tests if and only if their values at zero and all their adjoint probabilities at smooth tests agree. One direction follows by differentiation; the other follows from [\(14.18\)](#) for smooth tests and from bounded L^1 approximation for the remaining tests.

14.9 Divisorial types and moving sections

For a reference given by logarithms of holomorphic sections, removing its divisorial part identifies its ordinary singularity type with the bounded potentials of the residual background. The normalization scalar therefore depends only on the residual form, whereas convergence of the full potentials also requires control of the sections defining the divisors.

In this section, θ is a smooth real $(1, 1)$ -form on X . Fix finitely many holomorphic line bundles L_r on X with smooth Hermitian metrics h_r , nonzero holomorphic sections s_r , and weights $t_r > 0$. Put

$$\varphi = \sum_r t_r \log |s_r|_{h_r}^2, \quad \Gamma = \sum_r t_r \operatorname{div}(s_r), \quad \beta = \theta - \sum_r t_r c_1(L_r, h_r),$$

where $c_1(L_r, h_r)$ is the Chern curvature form, and assume that the residual form β is positive. The empty family is allowed, with $\varphi = 0$ and $\beta = \theta$.

Theorem 14.9.1 *The ordinary singularity type of φ is described by*

$$\{u \in \operatorname{PSH}(X, \theta) : u \sim \varphi\} = \{\varphi + w : w \in \operatorname{PSH}(X, \beta) \cap L^\infty(X)\},$$

and for each such w ,

$$\operatorname{MA}_\theta^{\operatorname{ext}}(\varphi + w) = (\beta + \operatorname{dd}^c w)^n. \quad (14.19)$$

For every bounded measurable F , the equation (14.1) in this ordinary type has a unique constant and a solution unique modulo constants. Its normalization scalar $B_{\theta, [\varphi]}$ satisfies

$$B_{\theta, [\varphi]}(F) = B_\beta(F),$$

so its dual functional and supporting sets coincide with H_β and $\mathcal{A}_\beta$.

Proof The Poincaré–Lelong formula gives $\theta + \operatorname{dd}^c \varphi = [\Gamma] + \beta$, so every function on the right is θ -plurisubharmonic and has the type of φ . Conversely, let $u \in \operatorname{PSH}(X, \theta)$ with $u \sim \varphi$. Then u has the same generic Lelong numbers as φ along the components of Γ , namely the coefficients of Γ , and Lemma 1.17.1 gives

$$\theta + \operatorname{dd}^c u - [\Gamma] \geq 0.$$

The locally integrable difference $w = u - \varphi$ therefore has a β -plurisubharmonic representative. It is bounded off the divisor because $u \sim \varphi$, and the local submean property preserves both bounds across the divisor. Since u and $\varphi + w$ agree almost everywhere, they are equal as quasi-plurisubharmonic functions.

Off the divisor, the currents $\theta + \operatorname{dd}^c(\varphi + w)$ and $\beta + \operatorname{dd}^c w$ agree, and locality identifies their Monge–Ampère products there. The extended measure on the left gives the divisor zero mass, and so does the bounded product on the right, which is finite and charges no analytic set by Section 1.7. This proves (14.19). In the background β , the equation with bounded density has a continuous solution and a unique constant by Theorem 10.1.1 and Proposition 10.5.1. The density e^F is bounded above and below by positive constants, so Corollary 11.4.1 gives uniqueness modulo constants. The correspondence transfers these assertions to the whole ordinary type and identifies the functionals. $\square$

In particular, the comparison of backgrounds and the stability of supporting probabilities in Theorem 14.8.1 and Corollary 14.8.1 apply whenever the positive residual forms satisfy the two-sided inequalities there; the location of the divisors

does not enter these estimates. This statement concerns ordinary types. To interpret it in terms of model references, one also needs the envelope $P_\theta[\varphi]$ to differ from φ by a bounded function.

For a fixed positive residual β , uniformly bounded $F_j \rightarrow F$ in L^1 give uniform convergence of the residual solutions normalized by $\sup_X v_j = 0$. Indeed, continuity of the scalar gives uniformly bounded densities $e^{B_\beta(\tilde{F}_j) + F_j}$ converging in every L^p , $p < \infty$. The compactness theorem [Theorem 10.3.2](#) gives uniform convergence of subsequences, continuity of bounded products identifies the limiting equation, and [Corollary 11.4.1](#) identifies every limit. Subtracting the means gives the same conclusion for solutions normalized to have mean zero.

Theorem 14.9.2 *Keep the line bundles and metrics fixed. Let nonzero sections s_{jr} converge to $s_r \neq 0$ in the finite-dimensional spaces of global sections, and let positive weights satisfy $t_{jr} \rightarrow t_r > 0$. Given Hermitian forms β_j , define φ_j and $\theta_j = \beta_j + \sum_r t_{jr} c_1(L_r, h_r)$ by the preceding formulas. Suppose either that $\beta_j \rightarrow \beta$ in C^∞ for a Hermitian form $\beta > 0$ and $F_j \rightarrow F$ in C^∞ , or that $\beta_j = \beta$ for all j and the tests F_j converge to F in L^1 with a common L^∞ bound. Then $\varphi_j \rightarrow \varphi$ in L^1 , and the solutions $u_j \sim \varphi_j$ for (θ_j, F_j) , normalized by $\sup_X u_j = 0$, converge in L^1 to the similarly normalized solution $u \sim \varphi$. For the residual solutions v_j normalized to have mean zero, one also has*

$$\sup_X(\varphi_j + v_j) \longrightarrow \sup_X(\varphi + v).$$

The residuals converge smoothly in the first regime and uniformly in the second.

Proof The convergence of the residual solutions follows from [Proposition 14.8.1](#) in the first case and from the preceding compactness argument in the second. The fixed metrics and bounded weights give a common smooth lower bound for $\text{dd}^c \varphi_j$. The convergent sections give a common upper bound for φ_j and convergence at a point outside all limiting divisors, so the suprema of the φ_j are bounded above and below. By [Theorem 1.4.1](#), every subsequence has a further subsequence converging in L^1 . Off the limiting divisors, convergence of the sections and weights gives local uniform convergence to φ ; since those divisors have zero volume, every L^1 cluster point equals φ . Thus $\varphi_j \rightarrow \varphi$ in $L^1(X)$.

Put $C_j = \sup_X(\varphi_j + v_j)$ and $C = \sup_X(\varphi + v)$. The sums converge in L^1 and have a common smooth lower bound for their complex Hessians, since $\text{dd}^c v_j \geq -\beta_j$ and the residual forms are uniformly bounded. Applying [Lemma 1.4.1](#) at maximum points gives $\limsup_j C_j \leq C$. A maximum point of $\varphi + v$ lies off the poles of φ , and evaluation there, using local uniform convergence, gives $\liminf_j C_j \geq C$.

It follows that $u_j = \varphi_j + v_j - C_j \rightarrow \varphi + v - C = u$ in L^1 . For an empty family of divisors, the assertion reduces to the convergence of the residual solutions and of their suprema. $\square$

14.10 The mass determined by the functional

In a closed background, the information lost by the scalar functional can be described exactly: for the model references below, two functionals agree precisely when the masses agree. This also gives examples in which the supporting probabilities stay fixed while the potentials have different limits.

In this section X is a compact Kähler manifold and θ is any smooth closed big real $(1, 1)$ -form. Let $\varphi \in \text{PSH}(X, \theta)$ satisfy $P_\theta[\varphi] = \varphi$, have small unbounded locus in the sense of [Section 1.12](#), and have positive mass

$$m_\varphi = \int_X \text{MA}_\theta(\varphi) > 0.$$

Write $B_{\theta, \varphi}$ and $\mathcal{A}_{\theta, \varphi}$ for the normalization scalar and the supporting sets of the equation [\(14.1\)](#) in the ordinary type of φ , and put $Z_F = \int_X e^F dV$.

Theorem 14.10.1 *For every such pair (θ, φ) and every bounded measurable F , the equation in the ordinary type of φ has a unique constant and a solution unique modulo constants. Its normalization scalar is*

$$B_{\theta, \varphi}(F) = \log m_\varphi - \log Z_F.$$

For continuous real F , its supporting set is

$$\mathcal{A}_{\theta, \varphi}(F) = \{e^F dV / Z_F\}.$$

For two such pairs on the same X , with the same dV and possibly in different classes,

$$\sup_{F \in L^\infty} |B_{\theta, \varphi}(F) - B_{\theta', \psi}(F)| = |\log m_\varphi - \log m_\psi|. \quad (14.20)$$

Thus an invariant of these pairs is determined by the whole functional if and only if it is constant on every fiber of the map $(\theta, \varphi) \mapsto m_\varphi$.

Proof Existence follows from [Corollary 31.8.1](#). Indeed, a Kähler manifold has the bounded mass property by [Lemma 20.4.1](#), and since in a closed background all potentials of the ordinary type of φ have the same mass $m_\varphi > 0$, the reference satisfies the positive-volume model condition [\(29.5\)](#). Uniqueness modulo constants is the classical theorem on equations with prescribed singularities in closed big classes, which applies under the model and small-unbounded-locus hypotheses; see the notes in [Section 33.10](#).

Every potential of the ordinary type of φ has mass m_φ , so integrating the equation forces $cZ_F = m_\varphi$, which is the scalar formula. For continuous F , Jensen's inequality shows, as for [\(14.15\)](#), that the normalized exponential measure is a supporting probability, and differentiating at zero in both signs of every continuous direction shows that it is the only one. Subtracting the scalar formulas gives [\(14.20\)](#). Finally, $m_\varphi = dV(X) \exp B_{\theta, \varphi}(0)$, so the functional and the mass determine each other, and

an invariant factors through either one exactly when it is constant on the fibers of the mass map. $\square$

For an ordinary divisorial type whose residual form β is positive and closed, **Theorem 14.9.1** gives the same formula with mass $\int_X \beta^n$, since Stokes' theorem for bounded products in a closed background fixes the mass of every bounded β -plurisubharmonic function. This computation does not require the real weighted sum of divisors to have a model representative. If $\beta_j \rightarrow \beta$ uniformly, the masses converge by continuity of $\beta \mapsto \int_X \beta^n$; under the two-sided bounds $(1 - \varepsilon_j)\beta \leq \beta_j \leq (1 + \varepsilon_j)\beta$ one has the sharper inequalities $(1 - \varepsilon_j)^n \int \beta^n \leq \int \beta_j^n \leq (1 + \varepsilon_j)^n \int \beta^n$.

Example 14.10.1 Let $X = \mathbb{P}^n$ with $n \geq 1$, let θ be the Fubini–Study form, normalized by $\int_X \theta^n = 1$, and let D be a hyperplane. Let s_D be a section of $\mathcal{O}(1)$ defining D , measured with the Fubini–Study metric and rescaled so that $a_D = \log |s_D|^2 \leq 0$, and choose $t \in (0, 1)$. Then

$$\mathrm{dd}^c a_D = [D] - \theta, \quad \theta + \mathrm{dd}^c(ta_D) = (1 - t)\theta + t[D].$$

Put $\varphi_{t,D} = P_\theta[ta_D]$. By **Proposition 15.2.3**, this envelope fixed point has the ordinary type of ta_D . Moreover $ta_D \in \mathrm{PSH}(X, t\theta)$ and $ta_D \leq \varphi_{t,D}$, so $\varphi_{t,D}$ satisfies (12.20) with $\varepsilon = t$. Off D , the potential ta_D has Monge–Ampère measure $(1 - t)^n \theta^n$, and its non-pluripolar measure puts no mass on D .

Since mass is invariant under bounded changes of the potential in a closed background,

$$m_{\varphi_{t,D}} = (1 - t)^n, \quad B_{\varphi_{t,D}}(G) - B_0(G) = n \log(1 - t) \quad (G \in C(X, \mathbb{R})).$$

Thus the constant in **Proposition 14.7.1** is sharp.

Now let $n = 1$, and take for D two distinct points $p, q \in \mathbb{P}^1$. The corresponding references have distance zero, although $\varphi_{t,p}$ is unbounded near p and bounded near q , while $\varphi_{t,q}$ behaves in the opposite way; in particular they are not ordinarily equivalent. For every positive integer m ,

$$I(m\varphi_{t,p}) = O(-\lfloor mt \rfloor p), \quad I(m\varphi_{t,q}) = O(-\lfloor mt \rfloor q),$$

by **Lemma 1.16.1**, and for $mt \geq 1$ these ideals differ. Thus the distance Δ of (14.16) does not even separate multiplier-ideal types, and it determines neither the ordinary nor the ideal singularity type.

Fix a smooth real function F on $\mathbb{P}^1$, and let w_F be the solution of $\theta + \mathrm{dd}^c w_F = e^F dV/Z_F$ with $\int_X w_F dV = 0$. The normalized solutions for $D = p$ and $D = q$ are

$$u_{t,D} = ta_D + (1 - t)w_F - \sup_X (ta_D + (1 - t)w_F).$$

Their difference satisfies $\mathrm{dd}^c(u_{t,p} - u_{t,q}) = t([p] - [q]) \neq 0$. Hence the sequence of solutions obtained by alternating between $D = p$ and $D = q$ has two different L^1 cluster points, although the scalar functional and all its supporting sets are the same

at every step. Within this one-parameter family, the functional does recover t , since $t \mapsto (1 - t)^n$ is injective.

Example 14.10.2 On $\mathbb{P}^n$, $n \geq 2$, let ω be the Fubini–Study form, normalized as in [Example 14.10.1](#), and let f be a nonconstant smooth real function. Fix $0 < t < 1$ and put

$$\beta = e^f \omega, \quad \theta = \beta + t\omega, \quad \varphi_D = t \log |s_D|^2.$$

Here s_D defines a hyperplane D as in [Example 14.10.1](#), and $\theta + \text{dd}^c \varphi_D = \beta + t[D]$, so every hyperplane has the same positive residual form β . This form is not closed: $d\beta = e^f df \wedge \omega \neq 0$, since df is nonzero somewhere and wedging a one-form with ω^{n-1} is injective. By [Theorem 14.9.1](#), the ordinary types of all φ_D have the same functional B_β on bounded tests, hence the same supporting sets. At a smooth test, the common supporting probability is the Gauduchon adjoint probability of [Theorem 14.2.3](#).

If v_F is the common smooth residual solution, the normalized solutions are the functions $\varphi_D + v_F - \sup_X(\varphi_D + v_F)$. Two distinct hyperplanes D_1, D_2 give different poles, different divisorial coefficients and, for sufficiently large k , different multiplier ideals $\mathcal{O}(-[kt]D_i)$, by the calculation in normal coordinates of [Lemma 1.16.1](#). The potentials differ by more than a constant, since the difference of their complex Hessians is $t([D_1] - [D_2])$, and alternating between the two hyperplanes again produces two distinct L^1 limits. These conclusions come from the common residual form; for general nonclosed backgrounds we do not claim that the functional is determined by a mass.

14.11 Convex-body criteria for varying references

When the singularities of a torus-invariant reference are described by a convex body, the closed mass formula of [Theorem 14.10.1](#) turns convergence of the convex bodies into convergence of the functionals. A translated simplex contained in all the bodies keeps the limiting reference solvable, and the Hausdorff distance then controls the functionals uniformly over all continuous tests, even though the ordinary types vary.

Let $n \geq 2$, and let ω_{FS} be the Fubini–Study form on $\mathbb{P}^n$, normalized by $\int_{\mathbb{P}^n} \omega_{\text{FS}}^n = 1$. In homogeneous coordinates $[Z_0 : \cdots : Z_n]$, consider the torus $T = \{Z_0 \cdots Z_n \neq 0\}$, and put

$$x_i = \log |Z_i/Z_0|^2, \quad L(x) = \log(1 + \sum_i e^{x_i}), \quad \Sigma = \{p_i \geq 0 : \sum_i p_i \leq 1\},$$

where $1 \leq i \leq n$ and $\Sigma \subset \mathbb{R}^n$ is the standard simplex. Functions of $x = (x_1, \dots, x_n)$ are regarded as functions on T ; thus $\omega_{\text{FS}} = \text{dd}^c L$ on T . Define the continuous function ℓ on Σ by

$$\ell(p) = \sum_i p_i \log p_i + (1 - \sum_i p_i) \log(1 - \sum_i p_i), \quad 0 \log 0 = 0.$$

For a convex body $K \subset \Sigma$, that is, a compact convex set with nonempty interior, set

$$h_K(x) = \sup_{p \in K} p \cdot x, \quad g_K(x) = \sup_{p \in K} \{p \cdot x - \ell(p)\}.$$

14.11.1 Canonical models and their mass

Lemma 14.11.1 *The functions $h_K - L$ and $g_K - L$ on T extend uniquely to ω_{FS} -plurisubharmonic functions ψ_K, Φ_K on $\mathbb{P}^n$. They satisfy*

$$\begin{aligned} \psi_K &\leq \Phi_K \leq \psi_K + \log(n+1), & \sup \Phi_K &= 0, \\ P_{\omega_{\text{FS}}}[\psi_K] &= \Phi_K = P_{\omega_{\text{FS}}}[\Phi_K]. \end{aligned}$$

If $p_* + \delta\Sigma \subset K$ for some $p_* \in \mathbb{R}^n$ and $0 < \delta < 1$, then $P_{(1-\delta)\omega_{\text{FS}}}(\Phi_K) \neq -\infty$.

Proof The Legendre transform of L is $L^* = \ell$ on Σ and $+\infty$ outside it. Since $-\log(n+1) \leq \ell \leq 0$,

$$h_K \leq g_K \leq h_K + \log(n+1), \quad g_K \leq L, \quad h_K \leq h_\Sigma \leq L.$$

A finite convex function of the logarithmic moduli is plurisubharmonic: for a smooth convex function the complex Hessian is positive, and convolution gives the general case. On $T \cap \{Z_j \neq 0\}$, add the local Fubini–Study potential $\log \sum_i |Z_i/Z_j|^2$; the resulting functions are again convex functions of the logarithmic moduli of the affine coordinates, and they are bounded above by that smooth potential because $h_K, g_K \leq L$. **Lemma 1.3.7** therefore gives the extensions across the coordinate hyperplanes and the stated bounds. If $p \in \text{int } K$, then $p \in \text{int } \Sigma$, and at $x_i = \log(p_i/(1 - \sum_k p_k))$ the supremum defining $L = \ell^*$ is attained at $p \in K$, so $g_K(x) = L(x)$. This proves $\sup \Phi_K = 0$.

For $C \geq \log(n+1)$, let $v_C = P_{\omega_{\text{FS}}}(\psi_K + C, 0)$, the envelope of the obstacle $\min(\psi_K + C, 0)$. Since Φ_K is a competitor, $\Phi_K \leq v_C \leq 0$. The obstacle is upper semicontinuous, so $v_C \leq \psi_K + C$ everywhere. The compact torus acting by rotations of the coordinates preserves the obstacle, so v_C is invariant, and on T the function $f = v_C + L$ is a finite convex function of x with $f \leq L$ and $f \leq h_K + C$. The second inequality shows that the Legendre transform f^* is $+\infty$ outside K , and the first gives $f^* \geq \ell$. Thus

$$f(x) = \sup_{p \in \text{dom } f^*} \{p \cdot x - f^*(p)\} \leq g_K(x).$$

Hence $v_C \leq \Phi_K$ on T , and since both functions are quasi-plurisubharmonic and T is the complement of an analytic set, $v_C = \Phi_K$ on $\mathbb{P}^n$. Letting $C \rightarrow \infty$ gives $P_{\omega_{\text{FS}}}[\psi_K] = \Phi_K$. Since $\psi_K \leq \Phi_K \leq \psi_K + \log(n+1)$, the envelopes of $\min(\Phi_K + C, 0)$ and $\min(\psi_K + C, 0)$ interlace as $C \rightarrow \infty$, so also $P_{\omega_{\text{FS}}}[\Phi_K] = \Phi_K$.

For the final assertion put $\varepsilon = 1 - \delta$, $b = \sum_i p_{*,i}$ and $\chi = p_* \cdot x - \varepsilon L$ on T . The inclusion $p_* + \delta\Sigma \subset \Sigma$ implies $p_{*,i} \geq 0$ and $b \leq \varepsilon$, and the extension of χ to $\mathbb{P}^n$ satisfies

$$\varepsilon\omega_{\text{FS}} + \text{dd}^c\chi = \sum_i p_{*,i}[Z_i = 0] + (\varepsilon - b)[Z_0 = 0] \geq 0.$$

Since $h_K \geq p_* \cdot x + \delta h_\Sigma$ and $L - h_\Sigma \leq \log(n+1)$, one has $\chi - \delta \log(n+1) \leq \Phi_K$. Thus $\chi - \delta \log(n+1)$ is an $\varepsilon\omega_{\text{FS}}$ -plurisubharmonic competitor for $P_{\varepsilon\omega_{\text{FS}}}(\Phi_K)$, which proves the claim. $\square$

In the rest of this section, either $X = \mathbb{P}^n$ and $\pi = \text{id}$, or $\pi : X = \text{Bl}_q \mathbb{P}^n \rightarrow \mathbb{P}^n$ is the blowup at a fixed point q , with exceptional divisor E_q ; put $\Theta = \pi^*\omega_{\text{FS}}$.

Lemma 14.11.2 *The manifold X is Kähler, and Θ is smooth, closed, semipositive and big. For $r > 0$, the reference $r\pi^*\Phi_K$ satisfies $P_{r\Theta}[r\pi^*\Phi_K] = r\pi^*\Phi_K$, has small unbounded locus, and satisfies*

$$\int_X \text{MA}_{r\Theta}(r\pi^*\Phi_K) = r^n n! \text{Vol}_n(K). \quad (14.21)$$

If $p_* + \delta\Sigma \subset K$ with $0 < \delta < 1$, then $P_{(1-\delta)r\Theta}(r\pi^*\Phi_K) \neq -\infty$.

Proof On $\mathbb{P}^n$, the envelope identity is Lemma 14.11.1. In the blowup case, every $\pi^*\omega_{\text{FS}}$ -plurisubharmonic function descends to $\mathbb{P}^n$. Indeed, off E_q add a local potential of ω_{FS} ; the resulting plurisubharmonic function is bounded above near q , because the original function is bounded above near the compact fiber E_q , and therefore extends across q . The pullback of the extension agrees with the original function off E_q , hence everywhere. Pullback is therefore a bijection from $\text{PSH}(\mathbb{P}^n, \omega_{\text{FS}})$ onto $\text{PSH}(X, \Theta)$ preserving inequalities and envelopes, and positive scaling preserves them as well.

On projective space, $\Theta = \omega_{\text{FS}}$ is Kähler. For bigness in the blowup case, choose unitary homogeneous coordinates $[W_0 : \dots : W_n]$, used only in this paragraph, in which $q = [1 : 0 : \dots : 0]$, set

$$\psi_q = \log \frac{\sum_{i=1}^n |W_i|^2}{\sum_{i=0}^n |W_i|^2},$$

and let $Q : X \rightarrow \mathbb{P}^{n-1}$ be the map induced by the linear projection from q . For $0 < t < 1$,

$$\Theta + \text{dd}^c(t\pi^*\psi_q) = (1-t)\pi^*\omega_{\text{FS}} + tQ^*\omega_{\text{FS},n-1} + t[E_q].$$

The smooth part is a Kähler form, since (π, Q) embeds X as the incidence graph in $\mathbb{P}^n \times \mathbb{P}^{n-1}$ and both coefficients are positive. This proves the assertions about the manifold and the form Θ .

For a smooth convex g , the coordinates $z_i = e^{x_i/2 + i\vartheta_i}$ give

$$\text{d}^c g = \frac{1}{2\pi} \sum_i g_i \text{d}\vartheta_i, \quad \int_T (\text{dd}^c g)^n = n! \int_{\mathbb{R}^n} \det(D^2 g) \text{d}x.$$

For a finite convex g , convolution and the continuity of bounded Monge–Ampère products under local uniform convergence identify $(\text{dd}^c g)^n$ on T in the same way: its

image under $z \mapsto x$ is $n!M_g$, where M_g is the Alexandrov measure, which assigns to a Borel set of $\mathbb{R}^n$ the Euclidean volume of its subgradient image. For g_K , the bound $g_K \leq h_K + \log(n+1)$ and a separation argument put every subgradient in K . Conversely, if $p \in \text{int } K$ and $p + c\mathbb{B} \subset K$, where $\mathbb{B}$ is the closed unit ball of $\mathbb{R}^n$ and $c > 0$, then $g_K(x) - p \cdot x \geq c|x|$; this function attains a minimum, so p is a subgradient of g_K at some point. Consequently

$$\text{int } K \subset \partial g_K(\mathbb{R}^n) \subset K, \quad M_{g_K}(\mathbb{R}^n) = \text{Vol}_n(K),$$

since the boundary of a convex body has zero volume. The analytic complement of T receives no non-pluripolar mass, so this is the full mass. Locality off the exceptional divisor proves the formula after pullback, since the divisor and its image carry no non-pluripolar mass, and homogeneity gives the factor r^n . The reference is locally bounded off the coordinate hyperplanes and their inverse image, an analytic set, hence has small unbounded locus. Finally, scaling by r and pulling back the competitor found at the end of the proof of [Lemma 14.11.1](#) gives the last assertion. $\square$

14.11.2 Hausdorff control of the functional

Theorem 14.11.1 *Let convex bodies $P_j, P \subset \Sigma$ contain the same translated simplex $p_* + \delta\Sigma$, with $0 < \delta < 1$, and suppose that their Hausdorff distance $d_j = d_H(P_j, P)$ tends to zero. Let $r_j > 0$ tend to $r > 0$. On the fixed X above, set*

$$(\theta_j, \varphi_j) = (r_j\Theta, r_j\pi^*\Phi_{P_j}), \quad (\theta, \varphi) = (r\Theta, r\pi^*\Phi_P).$$

For every bounded real Borel function F , the equation (14.1) is solvable in the ordinary type of each φ_j and of φ ; these types have masses $m_j = r_j^n n! \text{Vol}_n(P_j)$ and $m = r^n n! \text{Vol}_n(P) > 0$. Fix a smooth positive volume form dV on X , put $Z_F = \int_X e^F dV$, and let B_j, B and $\mathcal{A}_j, \mathcal{A}$ be the corresponding normalization scalars and supporting sets. Then

$$B_j(F) = \log m_j - \log Z_F, \quad B(F) = \log m - \log Z_F.$$

Writing $s = \delta/(n + \sqrt{n})$, one has

$$\sup_{G \in C(X, \mathbb{R})} |B_j(G) - B(G)| \leq n |\log(r_j/r)| + n \log(1 + d_j/s). \quad (14.22)$$

Moreover, $n! \text{Vol}_n(P_j) \geq \delta^n$ and $n! \text{Vol}_n(P) \geq \delta^n$, the backgrounds converge smoothly, and the references converge in $L^1(X)$ and locally uniformly on $\pi^{-1}(T)$. For continuous real F , every supporting set at F equals $\{v_F\}$, where $v_F = e^F dV / Z_F$. If continuous F_j converge uniformly to F and $v_j \in \mathcal{A}_j(F_j)$, then

$$\int_X \left| \frac{dv_j}{dV} - \frac{dv_F}{dV} \right| dV \leq e^{2\|F_j - F\|_\infty} - 1. \quad (14.23)$$

Proof By the two preceding lemmas, each φ_j and φ is an envelope fixed point with small unbounded locus and the stated positive mass, and it satisfies the smaller-background condition. **Theorem 14.10.1** therefore gives solvability and the formulas for the scalars and supporting sets.

The common simplex contains a ball $c + s\mathbb{B}$ of radius s , the inradius of $\delta\Sigma$, where $\mathbb{B}$ is the closed unit ball. The Hausdorff distance gives $P_j \subset P + d_j\mathbb{B}$, while $s\mathbb{B} \subset P - c$ and convexity give

$$P + d_j\mathbb{B} \subset c + (1 + d_j/s)(P - c).$$

Exchanging the roles of P and P_j bounds both volume ratios by $(1 + d_j/s)^n$. Subtracting the scalar formulas and including the factor r_j^n/r^n gives (14.22). The volume bound holds because $\delta\Sigma$ has volume $\delta^n/n!$.

Let ω_ℓ be the modulus of uniform continuity of ℓ on Σ . Matching the maximizers in the definitions of g_{P_j} and g_P by points at distance at most d_j gives

$$|g_{P_j}(x) - g_P(x)| \leq d_j|x| + \omega_\ell(d_j).$$

This proves local uniform convergence on T . The common lower bound $\chi - \delta \log(n+1) \leq \Phi_{P_j}$ obtained at the end of the proof of **Lemma 14.11.1** is integrable on X , also after pullback, so boundedness of r_j and dominated convergence off the coordinate hyperplanes give L^1 convergence. Finally, the ratio of the normalized exponential densities lies in $[e^{-2\eta}, e^{2\eta}]$, where $\eta = \|F_j - F\|_\infty$. This proves (14.23) and hence convergence in total variation. $\square$

14.11.3 A family with nonanalytic isolated poles

The hypothesis of a common simplex allows ordinary singularity types that contain no potential with analytic singularities. Let $o = [1 : 0 : \cdots : 0]$ be the origin of the affine chart $Z_0 \neq 0$, with affine coordinates $z_i = Z_i/Z_0$. For $0 < a \leq 1$, define

$$P_a = \{p \in \Sigma : \sum_i \sqrt{p_i} \geq \sqrt{a}\}, \quad \kappa_n = \frac{2^n n!}{(2n)!} = \frac{1}{(2n-1)!!}.$$

Proposition 14.11.1 *The function Φ_{P_a} is locally bounded outside the single point o , where it has a pole, and it does not have the ordinary singularity type of any function with analytic singularities. Its generic Lelong number along every prime divisor of $\mathbb{P}^n$ is zero, and*

$$\int_{\mathbb{P}^n} \text{MA}_{\omega_{\text{FS}}}(\Phi_{P_a}) = 1 - \kappa_n a^n > 0. \quad (14.24)$$

The same assertions about the pole, nonanalyticity and generic Lelong numbers hold for $\pi^\Phi_{P_a}$ on the blowup $\text{Bl}_q \mathbb{P}^n$ at a fixed point $q \neq o$.*

Proof The function $p \mapsto \sum_i \sqrt{p_i}$ is concave, so P_a is convex. Set

$$b = \frac{n+1}{2n}, \quad p_{*,i} = \frac{b}{n}, \quad \delta = \frac{n-1}{4n}.$$

Then $b + \delta < 1$ and $\sum_i \sqrt{p_{*,i}} = \sqrt{(n+1)/2} > 1$. Adding a point of $\delta\Sigma$ preserves the last inequality and keeps the sum of the coordinates below one, so $p_* + \delta\Sigma$ lies in every P_a .

All the standard basis vectors e_i belong to P_a , and therefore

$$\psi_{P_a} \geq \log \frac{\max_{1 \leq i \leq n} |Z_i|^2}{\sum_{i=0}^n |Z_i|^2}.$$

Hence the reference is locally bounded away from o . The Cauchy–Schwarz inequality gives $\sum_i p_i \geq a/n$ on P_a . When all $x_i < 0$, this yields $h_{P_a}(x) \leq (a/n) \max_i x_i$, which tends to $-\infty$ as $z \rightarrow o$, and **Lemma 14.11.1** gives the pole at o . Local boundedness outside one point implies that all generic Lelong numbers along prime divisors vanish, and pulling back to the blowup at a different point introduces no pole.

To test analyticity, fix positive $\lambda_1, \dots, \lambda_n$ and approach o along $|z_i|^2 = e^{-R\lambda_i}$, $R \rightarrow \infty$. Writing $y_i = \sqrt{p_i}$, the Cauchy–Schwarz inequality gives

$$\min_{p \in P_a} \sum_i \lambda_i p_i = \frac{a}{\sum_i \lambda_i^{-1}} =: d_a(\lambda), \quad y_i = \frac{\sqrt{a}}{\lambda_i \sum_k \lambda_k^{-1}}, \quad (14.25)$$

where the minimizer satisfies $\sum_i p_i \leq a \leq 1$, so that it lies in P_a . Since $L(-R\lambda) \rightarrow 0$ and $\Phi_{P_a} - \psi_{P_a}$ is bounded, $-\Phi_{P_a}/R \rightarrow d_a(\lambda)$ along these curves.

Suppose that the type were that of $c \log \sum_k |f_k|^2$ near o , with $c > 0$ and holomorphic germs $f_k = \sum_\alpha c_{k,\alpha} z^\alpha$. Exponentiating the two inequalities expressing this equivalence and averaging over the arguments of the z_i gives the positive series

$$\sum_{k,\alpha} |c_{k,\alpha}|^2 e^{-R\alpha \cdot \lambda},$$

whose exponential decay rate in R must be $d_a(\lambda)/c$. That rate is the minimum of $\alpha \cdot \lambda$ over the monomials with nonzero coefficients: a minimizing term gives one bound, and convergence at a fixed R_0 bounds the series above by a constant times $e^{-(R-R_0) \min \alpha \cdot \lambda}$. Near any λ with positive coordinates, only finitely many monomials can attain the minimum, because these coordinates have a common positive lower bound and any one nonzero coefficient bounds the degree of the minimizing monomials. The rate is therefore locally piecewise linear in λ . But

$$d_a(s, 1, \dots, 1) = \frac{as}{1 + (n-1)s}, \quad \frac{d^2}{ds^2} d_a(s, 1, \dots, 1) = -\frac{2a(n-1)}{(1 + (n-1)s)^3} < 0.$$

This contradiction proves nonanalyticity. The assertion persists on a blowup at a point different from o , which does not change a neighborhood of the pole.

The removed corner $C_a = \{p \in \mathbb{R}^n : p_i \geq 0, \sum_i \sqrt{p_i} < \sqrt{a}\} = aC_1$ lies in Σ . The substitution $p_i = y_i^2$ gives

$$\text{Vol}_n(C_1) = 2^n \int_{y_i \geq 0, \sum y_i < 1} \prod_i y_i \, dy = \frac{2^n}{(2n)!}.$$

The last equality follows by iterated integration of monomials over a simplex. Removing the corner from Σ , whose volume is $1/n!$, and applying (14.21) gives (14.24). Since $n \geq 2$, one has $\kappa_n < 1$. $\square$

Corollary 14.11.1 *Put $a_j = 1 - 1/(j+2)$ and $r_j = 1 + 1/(j+2)$ for $j \geq 1$. On $\mathbb{P}^n$, or on its blowup at a fixed point $q \neq o$, the references $r_j \pi^* \Phi_{P_{a_j}}$ satisfy the hypotheses of Theorem 14.11.1, with limit $\pi^* \Phi_{P_1}$. Their ordinary types and masses vary with j , and*

$$\sup_G |B_j(G) - B(G)| \leq n |\log r_j| + \frac{n\kappa_n}{1 - \kappa_n} |1 - a_j| \rightarrow 0.$$

The equation is solvable in the limiting ordinary type, whose mass is $1 - \kappa_n$; for $n = 2$ this mass is $2/3$.

Proof If $p \in P_{a_j} \setminus P_1$, then $u = (\sum_i \sqrt{p_i})^2 \in [a_j, 1)$ and $p/u \in P_1$. Since $|p| \leq \sum_i p_i \leq u$, one has $|p/u - p| \leq 1 - u \leq 1 - a_j$. Thus $d_H(P_{a_j}, P_1) \leq 1 - a_j$, and the hypotheses of the theorem hold with the simplex found in the proof of Proposition 14.11.1. The mass formula (14.24) and the derivative bound $|d \log(1 - \kappa_n a^n)/da| \leq n\kappa_n/(1 - \kappa_n)$ give the estimate for the functionals. By (14.25), the directional coefficients of the j th reference are multiplied by $r_j a_j = 1 - (j+2)^{-2}$, which strictly increases with j , so the ordinary types are distinct, while the masses $r_j^n(1 - \kappa_n a_j^n)$ strictly decrease to $1 - \kappa_n > 0$. $\square$

14.11.4 Positive mass with a degenerate smooth residual

A second family has a logarithmic pole whose resolution leaves a smooth residual form degenerating along a different exceptional divisor. Let $o = [1 : 0 : \dots : 0]$ as in Section 14.11.3, and fix $q \neq o$ in $\mathbb{P}^n$. On $X = \text{Bl}_q \mathbb{P}^n$, keep $\Theta = \pi^* \omega_{\mathbb{P}^n}$. For $0 < t < 1$, put

$$\psi_t = t \log \frac{\sum_{i=1}^n |Z_i|^2}{\sum_{i=0}^n |Z_i|^2}, \quad K_t = \{p \in \Sigma : \sum_i p_i \geq t\}.$$

On T , the function $\psi_t + L$, a potential of $\omega_{\mathbb{P}^n} + \text{dd}^c \psi_t$, equals $(1-t)L + t \log \sum_i e^{x_i}$. It differs by a bounded function from

$$(1-t)h_\Sigma + t \max_i x_i = h_{K_t}, \quad K_t = (1-t)\Sigma + t \text{conv}(e_1, \dots, e_n).$$

Thus $\psi_t \sim \psi_{K_t} \sim \Phi_{K_t}$, and $n! \text{Vol}_n(K_t) = 1 - t^n$. We call ψ_t the prototype of this ordinary type.

Proposition 14.11.2 *Let $\tau : Z \rightarrow X$ be the blowup of the point of X above o , with exceptional divisor E_o , and denote the inverse image of E_q in Z again by E_q . There is a smooth semipositive closed form α_t on Z such that*

$$(\pi \circ \tau)^* \omega_{\mathbb{P}^n} + \text{dd}^c(\psi_t \circ \pi \circ \tau) = \alpha_t + t[E_o]. \quad (14.26)$$

It is positive away from E_q , has rank exactly one at every point of E_q , and satisfies $\int_Z \alpha_t^n = 1 - t^n > 0$. Moreover, for every $u \in \text{PSH}(X, \Theta)$ with the ordinary type of $\pi^* \Phi_{K_t}$, in particular for every solution of the equation in this type, the function $u \circ \tau - \psi_t \circ \pi \circ \tau$ extends from $Z \setminus E_o$ to a bounded α_t -plurisubharmonic function on Z .

Proof On $Y = \text{Bl}_o \mathbb{P}^n$, let π_o be the blowdown map and $Q_o : Y \rightarrow \mathbb{P}^{n-1}$ the map induced by the linear projection from o . As in the proof of [Lemma 14.11.2](#), the incidence graph embedding shows that

$$\beta_t = (1 - t)\pi_o^* \omega_{\text{FS}} + tQ_o^* \omega_{\text{FS}, n-1}$$

is a Kähler form, where $\omega_{\text{FS}, n-1}$ is the Fubini–Study form of $\mathbb{P}^{n-1}$. Since the two centers are distinct, Z is also the blowup $\sigma : Z \rightarrow Y$ of the point above q . Put $\alpha_t = \sigma^* \beta_t$. The Poincaré–Lelong formula gives [\(14.26\)](#); there is no term along E_q , since ψ_t is locally bounded near q .

In a blowup chart, σ is $(s, w_2, \dots, w_n) \mapsto (s, sw_2, \dots, sw_n)$. At $s = 0$ its differential has rank one and kills the $n - 1$ tangent directions of E_q . Positivity of β_t therefore gives the assertion about the rank; off E_q the map is biholomorphic.

Write $H = \pi_o^* [\omega_{\text{FS}}]$ and $E = [E_o]$ for the cohomology classes on Y . The current identity gives $[\beta_t] = H - tE$. Since $H|_{E_o} = 0$, all mixed top intersections vanish. The normal bundle of $E_o \cong \mathbb{P}^{n-1}$ is $\mathcal{O}_{\mathbb{P}^{n-1}}(-1)$, so $\int_Y E^n = (-1)^{n-1}$. Therefore

$$\int_Z \alpha_t^n = \int_Y (H - tE)^n = 1 - t^n.$$

The first equality holds because σ has degree one. Finally, if $u \sim \pi^* \Phi_{K_t} \sim \pi^* \psi_t$, then $u \circ \tau$ differs from the pulled-back prototype $\psi_t \circ \pi \circ \tau$ by a bounded function off E_o . By [\(14.26\)](#), after adding a local potential of α_t this bounded difference becomes plurisubharmonic off E_o , and it extends across E_o by [Lemma 1.3.7](#). No Monge–Ampère product of unbounded potentials is involved. $\square$

Corollary 14.11.2 *Let $t_j, t \in [t_{\min}, t_{\max}] \subset (0, 1)$ with $t_j \rightarrow t$, and let $r_j > 0$ tend to $r > 0$. The references $r_j \pi^* \Phi_{K_{t_j}}$ satisfy the hypotheses of [Theorem 14.11.1](#), so in particular the equation is solvable in the limiting ordinary type, and*

$$\sup_G |B_j(G) - B(G)| \leq n |\log(r_j/r)| + \frac{nt_{\max}^{n-1}}{1 - t_{\max}^n} |t_j - t|.$$

At continuous tests, all supporting sets consist of the normalized exponential probabilities of that theorem. At the endpoint $t = 1$, where the mass vanishes, no equation with a positive bounded density is solvable in the ordinary type of the prototype $\pi^* \psi_1$.

Proof Choose $p_{*,i} = t_{\max}/n$ and $\delta = (1 - t_{\max})/2$; then $p_* + \delta \Sigma$ lies in every K_t with $t \leq t_{\max}$. For $s \geq t$, moving a point of K_t toward a vertex e_i until its coordinate sum reaches s gives

$$d_H(K_s, K_t) \leq \frac{\sqrt{2}}{1 - t_{\max}} |s - t|.$$

Hence the stability theorem applies. Instead of its general bound, the derivative bound for $\log(1 - t^n)$ on $[t_{\min}, t_{\max}]$ and the mass formula give the sharper estimate for the functionals.

At $t = 1$, the resolved residual form α_1 is pulled back from $\mathbb{P}^{n-1}$, so $\int_Z \alpha_1^n = 0$. The argument of [Proposition 14.11.2](#) shows that every potential of the ordinary type of $\pi^*\psi_1$ has a bounded α_1 -plurisubharmonic remainder. Stokes' theorem for bounded products in a closed background gives this remainder mass zero, and positivity forces its Monge–Ampère measure to vanish. Thus no such potential can solve the equation with density $ce^F dV$ for bounded F and $c > 0$. In contrast, the endpoint $a = 1$ in [Corollary 14.11.1](#) has positive mass and remains solvable. $\square$

Scaling by $r > 0$ multiplies both the resolved residual form and the divisor coefficient by r . Solvability is obtained on X through the criterion of [Theorem 14.10.1](#), without requiring the resolved residual form to be strictly positive. These criteria use closed projective backgrounds and fixed modifications; we do not know analogous convergence criteria for general nonclosed Hermitian backgrounds, for moving modifications, or for unrestricted degenerations of the singularities. Moreover, the supporting probabilities here only identify the limiting functional: we make no claim about convergence of the solutions or of weighted adjoint products.

14.12 Selection by a vanishing exponential parameter

The equation with exponent zero can have several normalized solutions. Nevertheless, the solutions of the equations with positive exponent select one of them in the limit: the scalar functional provides a family of integral normalizations, and the selected potential is the greatest subsolution of the critical equation satisfying all of them. To prove that it is the greatest, we use supporting probabilities of a second functional, obtained by varying the forcing term in the subsolution inequality.

In this section, θ is an arbitrary smooth big real $(1, 1)$ -form on X , not necessarily semipositive. Fix a strict analytic barrier $\rho \leq 0$ as in [Section 13.12](#), and put $\Omega = X \setminus \{\rho = -\infty\}$. A potential has *minimal type* if it has the ordinary singularity type of the envelope $V_\theta = P_\theta(0)$, which has minimal singularities ([Section 1.19](#)). Fix a nonzero $0 \leq f \in L^p(dV)$, with $1 < p < \infty$. For a nonzero nonnegative density g in some L^q , $q > 1$, let $c(g) > 0$ be the unique constant of [Theorem 13.15.2](#) for which the equation $\text{MA}_\theta(v) = c(g)g dV$ has a solution v of minimal type. We call $c(g)$ the *critical scalar* of g and such solutions *critical potentials* for g ; they are continuous on Ω by [Theorem 13.16.1](#). Here MA_θ is the extended measure $\text{MA}_\theta^{\text{ext}}$. On Ω it is the locally bounded product for every potential of minimal type, and it gives zero mass to the analytic set $X \setminus \Omega$.

Put $c = c(f)$ and define

$$\begin{aligned} \kappa(r) &= \log c - \log c(e^r f), \\ \mathcal{P}_f &= \left\{ v \in \mathcal{P}(X) : \int_X r dv \leq \kappa(r) \text{ for every } r \in C(X) \right\}. \end{aligned} \quad (14.27)$$

When θ is semipositive and $f = e^F$ with $F \in C(X)$, we have $\kappa(r) = B_0(F) - B_0(F+r)$, and $\mathcal{P}_f$ is the set $\mathcal{A}_0(F)$ of supporting probabilities. The definition also applies when f vanishes on a set of positive measure and when θ is not semipositive.

Theorem 14.12.1 *For $\lambda > 0$, let u_λ be the solution of minimal type of*

$$\mathrm{MA}_\theta(u_\lambda) = e^{\lambda u_\lambda} f \, dV$$

given by Theorem 13.15.1 and unique by Corollary 13.12.1. The set $\mathcal{P}_f$ is nonempty and weakly compact, and every potential of minimal type is integrable against all its measures. As $\lambda \downarrow 0$,

$$w_\lambda = u_\lambda - \lambda^{-1} \log c$$

converges locally uniformly on Ω and in $L^1(X)$ to a potential w of minimal type, continuous on Ω . It is the greatest among the potentials s of minimal type, continuous on Ω , satisfying

$$\mathrm{MA}_\theta(s) \geq c f \, dV, \quad \int_X s \, d\nu \leq 0 \quad (\nu \in \mathcal{P}_f). \quad (14.28)$$

Moreover,

$$\mathrm{MA}_\theta(w) = c f \, dV, \quad \max_{\nu \in \mathcal{P}_f} \int_X w \, d\nu = 0.$$

Consequently, $u_\lambda - \sup_X u_\lambda$ converges to $w - \sup_X w$ in the same two topologies. For a Hermitian θ , one may take $\Omega = X$, and both convergences of potentials are uniform.

14.12.1 A norm defined by the critical scalar

Mixed products turn the comparison of critical scalars into a triangle inequality for n th roots of densities, and the subsolution estimate associated with the strict barrier gives continuity in the corresponding Lebesgue norm.

Fix $1 < q < p$ and set $\ell = nq$. On real $L^\ell(dV)$ define

$$N(a) = \begin{cases} c(|a|^n)^{-1/n}, & a \neq 0, \\ 0, & a = 0. \end{cases}$$

Proposition 14.12.1 *The function N is a lattice norm on $L^\ell(dV)$, that is, a norm satisfying $N(a) \leq N(b)$ whenever $|a| \leq |b|$. There is $C_q < \infty$, depending only on X, θ, dV and q , such that*

$$N(a) \leq C_q \|a\|_\ell, \quad |N(a) - N(b)| \leq C_q \|a - b\|_\ell. \quad (14.29)$$

Consequently, for nonzero $g, h \geq 0$ in L^q ,

$$|c(g)^{-1/n} - c(h)^{-1/n}| \leq C_q \|g - h\|_q^{1/n}.$$

Proof If a potential v of minimal type satisfies $\text{MA}_\theta(v) \geq dg \, dV$, then $d \leq c(g)$, since otherwise comparison with a critical potential for g contradicts part (1) of [Corollary 13.12.1](#). Hence $g \leq h$ implies $c(g) \geq c(h)$. Uniqueness of the critical scalar also gives $c(tg) = c(g)/t$ for $t > 0$. These facts prove that N is monotone and absolutely homogeneous, and positivity follows from $0 < c(g) < \infty$.

For the triangle inequality, let $a, b \geq 0$ be nonzero, put $A = N(a)$ and $B = N(b)$, and choose critical potentials v_a, v_b with measures $(a/A)^n dV$ and $(b/B)^n dV$. On every relatively compact subset of Ω , [\(1.12\)](#) gives

$$\text{MA}_\theta \left(\frac{Av_a + Bv_b}{A + B} \right) \geq \left(\frac{a + b}{A + B} \right)^n dV,$$

where both potentials are locally bounded. Exhausting Ω gives the inequality on X , since $X \setminus \Omega$ has zero smooth volume. The averaged potential has minimal type, so the first paragraph gives $N(a + b) \leq A + B$. The cases where a or b vanishes are trivial, and for real functions we use $|a + b| \leq |a| + |b|$ and monotonicity.

Next, apply [Lemma 13.13.1](#) with $\eta = V_\theta$ to nonnegative densities of L^q norm at most one. It gives a uniform $m > 0$ and subsolutions of minimal type, hence $c(g) \geq m$ for each such nonzero density. For $a \neq 0$, take $g = |a|^n / \|a\|_\ell^n$, which has L^q norm one. Homogeneity gives $N(a) \leq m^{-1/n} \|a\|_\ell$, which is the first bound in [\(14.29\)](#), and the reverse triangle inequality gives the second. Applying the second bound to $g^{1/n}, h^{1/n}$ and using $|g^{1/n} - h^{1/n}|^n \leq |g - h|$ proves the last assertion. $\square$

14.12.2 Norming probabilities and integral bounds

Set $a = f^{1/n} \in L^\ell(dV)$ and $A = N(a) = c^{-1/n}$. The probabilities in [\(14.27\)](#) come from positive linear functionals that norm N at a , that is, functionals dominated by N and equal to $N(a)$ at a . This representation will control integrals of unbounded potentials as well as bounded logarithmic perturbations.

With $\ell' = \ell/(\ell - 1)$, define

$$\mathcal{H}_a = \left\{ \eta \in L^{\ell'}(dV) : \eta \geq 0, \int_X a \eta \, dV = A, \int_X b \eta \, dV \leq N(b) \text{ for every } b \in L^\ell \right\}. \quad (14.30)$$

Proposition 14.12.2 *The set $\mathcal{H}_a$ is nonempty and weakly compact in $L^{\ell'}$. The function κ of (14.27) is given by*

$$\kappa(r) = n \log \frac{N(ae^{r/n})}{A},$$

and it is convex, increasing and 1-Lipschitz for the uniform norm on $C(X)$, with $\kappa(0) = 0$ and $\kappa(r + b) = \kappa(r) + b$ for constants b . Its subdifferential at zero is

$$\mathcal{P}_f = \{\nu_\eta : \eta \in \mathcal{H}_a\}, \quad d\nu_\eta = A^{-1}a\eta \, dV. \quad (14.31)$$

If z is measurable and $az \in L^\ell$, then

$$\sup_{\nu \in \mathcal{P}_f} \int_X |z| \, d\nu \leq C_q A^{-1} \|az\|_\ell. \quad (14.32)$$

If also $ae^{tz/n} \in L^\ell$ and $N(ae^{tz/n}) = A$ for some $t > 0$, then $\int_X z \, d\nu \leq 0$ for every $\nu \in \mathcal{P}_f$.

Proof The formula for κ follows from $N(ae^{r/n}) = c(e^r f)^{-1/n}$. The Hahn–Banach theorem gives a linear functional that norms N at a . By (14.29) it is continuous on L^ℓ , and hence is represented by some $\eta_0 \in L^{\ell'}$. For $b \geq 0$, testing on $\text{sgn}(\eta_0)b$ gives

$$\int_X b|\eta_0| \, dV \leq N(b).$$

Since $a \geq 0$ and $\int_X a\eta_0 \, dV = A = N(a)$, the same equality holds with $|\eta_0|$ in place of η_0 . Monotonicity of N extends the domination to real b , so $|\eta_0| \in \mathcal{H}_a$. The defining conditions of $\mathcal{H}_a$ are weakly closed and give $\|\eta\|_{\ell'} \leq C_q$, so reflexivity proves weak compactness.

For nonzero nonnegative b_0, b_1 , the weighted arithmetic–geometric mean inequality applied to $b_j/N(b_j)$, together with monotonicity and the triangle inequality, gives

$$N(b_0^{1-t}b_1^t) \leq N(b_0)^{1-t}N(b_1)^t, \quad 0 \leq t \leq 1.$$

Taking $b_j = ae^{r_j/n}$ proves convexity of κ . Monotonicity and the translation rule follow from the corresponding properties of N , and together they imply the Lipschitz bound.

Every ν_η is a probability and satisfies

$$\frac{N(ae^{r/n})}{A} \geq \int_X e^{r/n} \, d\nu_\eta.$$

Jensen’s inequality gives $\kappa(r) \geq \int_X r \, d\nu_\eta$, which proves one inclusion in (14.31). The map $\eta \mapsto \nu_\eta$ is weakly continuous, since $ar \in L^\ell$ for $r \in C(X)$.

Conversely, let $\nu \in \mathcal{P}_f$ and put $L(r) = \int_X r \, d\nu$. Differentiating the curve $t \mapsto ae^{tr/n}$ in L^ℓ at $t = 0$ gives

$$N(ae^{tr/n}) = N(a) + \frac{t}{n}N'_+(a; ar) + o(t), \quad t \downarrow 0.$$

Here the one-sided derivative $N'_+(a; \cdot)$ of the continuous convex function N exists, and the error estimate follows from its Lipschitz bound. The inequality $L \leq \kappa$, applied to tr and $-tr$, therefore gives

$$|AL(r)| \leq C_q \|ar\|_\ell, \quad AL(r) \leq N'_+(a; ar) \leq N(a + ar) - A. \quad (14.33)$$

Thus $T(ar) = AL(r)$ defines a continuous linear functional on the space of products ar , $r \in C(X)$. These products are dense in

$$S_a = \{b \in L^\ell : b = 0 \text{ almost everywhere on } \{a = 0\}\} :$$

indeed, it suffices to approximate b/a in $L^\ell(a^\ell dV)$ by continuous functions. If $ar \geq 0$, then $ar = ar_+$ almost everywhere, and the first inequality in (14.33) gives $L(r - r_+) = 0$, so $T(ar) \geq 0$. Approximating nonnegative elements of S_a by products ar with $r \geq 0$ continuous shows that the continuous extension of T to S_a is positive.

Represent this extension by some $\eta \geq 0$ in $L^{\ell'}$ vanishing on $\{a = 0\}$. Since $T(a) = A$, extending the second inequality in (14.33) to S_a and applying it to $b - a$ gives $T(b) \leq N(b)$ for $b \in S_a$. For general $b \in L^\ell$,

$$\int_X b\eta dV \leq N(b\mathbf{1}_{\{a>0\}}) \leq N(b).$$

Thus $\eta \in \mathcal{H}_a$, and ν_η agrees with ν on all continuous functions. This proves the representation (14.31), and weak compactness of $\mathcal{P}_f$ follows from that of $\mathcal{H}_a$.

The bound (14.32) follows from Hölder's inequality and $\|\eta\|_{\ell'} \leq C_q$. Under the last hypothesis, the norming inequality gives $\int_X e^{tz/n} d\nu \leq 1$. Since z is ν -integrable by (14.32), Jensen's inequality implies $\int_X z d\nu \leq 0$. $\square$

These estimates apply uniformly to all $\nu \in \text{PSH}(X, \theta)$ with $\sup_X \nu = 0$. Indeed, Lemma 1.5.1, applied in a Hermitian background larger than θ , gives uniform bounds for all finite moments of $|\nu|$, and Hölder's inequality gives

$$\int_X |\nu|^{nq} f^q dV \leq \|f\|_p^q \left(\int_X |\nu|^{nqp/(p-q)} dV \right)^{(p-q)/p}. \quad (14.34)$$

Consequently, (14.32) gives a uniform bound for $\int_X |\nu| d\nu$ over all such ν and all $\nu \in \mathcal{P}_f$; constant translates of such ν are integrable as well. The representation also shows that these probabilities charge neither $\{f = 0\}$ nor $X \setminus \Omega$.

14.12.3 Bounds for the centered potentials

We call the potentials w_λ of [Theorem 14.12.1](#) the *centered potentials*. Choose a critical potential ψ for f with $\sup_X \psi = 0$, so that $\text{MA}_\theta(\psi) = c f \, dV$. The integral normalizations prevent the centered potentials from drifting upward by constants.

Lemma 14.12.1 *There is $K < \infty$, independent of $0 < \lambda \leq 1$, such that*

$$\psi \leq w_\lambda, \quad 0 \leq k_\lambda := \sup_X w_\lambda \leq K, \quad \psi - K \leq v_\lambda := w_\lambda - k_\lambda \leq V_\theta. \quad (14.35)$$

Moreover $\int_X w_\lambda \, d\nu \leq 0$ for every $\nu \in \mathcal{P}_f$. The family w_λ is relatively compact for locally uniform convergence on Ω ; every such cluster also converges in $L^1(X)$ to a potential of minimal type.

Proof The centered potential satisfies $\text{MA}_\theta(w_\lambda) = c e^{\lambda w_\lambda} f \, dV$, while $\psi \leq 0$ gives $\text{MA}_\theta(\psi) \geq c e^{\lambda \psi} f \, dV$. Part (2) of [Corollary 13.12.1](#) therefore gives $\psi \leq w_\lambda$, hence $k_\lambda \geq 0$. For each fixed λ , the density $e^{\lambda w_\lambda} f$ lies in L^p , and its critical scalar is c . Therefore

$$N(a e^{\lambda w_\lambda / n}) = A.$$

The moment estimate above gives $a w_\lambda \in L^\ell$, so [Proposition 14.12.2](#), with $z = w_\lambda$ and $t = \lambda$, gives the asserted integral inequalities. Fix one $\nu \in \mathcal{P}_f$. Then

$$k_\lambda \leq - \int_X v_\lambda \, d\nu \leq C_q A^{-1} \|a v_\lambda\|_\ell \leq K$$

by (14.34), with K independent of λ . The normalization $\sup_X v_\lambda = 0$ gives $v_\lambda \leq V_\theta$, and subtracting k_λ from the lower bound $\psi \leq w_\lambda$ proves (14.35).

The potentials $v_\lambda = u_\lambda - \sup_X u_\lambda$ form the normalized exponential family of [Proposition 13.16.1](#), which gives subsequences converging locally uniformly on Ω and in $L^1(X)$ to potentials of minimal type. Extracting a convergent subsequence of $k_\lambda \in [0, K]$ gives the same compactness for $w_\lambda = v_\lambda + k_\lambda$. The bound $|w_\lambda| \leq |\psi| + K$ also gives L^1 convergence along every subsequence converging locally uniformly on Ω , since $X \setminus \Omega$ has zero volume. $\square$

In particular,

$$e^{\lambda \sup_X u_\lambda} = c e^{\lambda k_\lambda} \longrightarrow c.$$

Moreover, for $0 < \lambda \leq 1$ the densities of the equations satisfy $\|ce^{\lambda w_\lambda} f\|_p \leq ce^K \|f\|_p$. It matters that this bound includes the scalar factor: an L^p bound on the data alone, after an arbitrary rescaling, does not bound the normalized potentials. For example, on $\mathbb{P}^1$, with $\omega_{\text{FS}} = \text{dd}^c \log(1 + |z|^2)$ and $0 < \epsilon < 1$, the function

$$\psi_\epsilon = \log \frac{|z|^2 + \epsilon^2}{1 + |z|^2}$$

is smooth and ω_{FS} -plurisubharmonic, with supremum zero and infimum $\log \epsilon^2$. Write $\text{MA}_{\omega_{\text{FS}}}(\psi_\epsilon) = g_\epsilon \omega_{\text{FS}}$, and take L^p norms with respect to ω_{FS} in this example. The data $g_\epsilon / \|g_\epsilon\|_p$ have norm one, and ψ_ϵ solves the equation with these data and scalar $\|g_\epsilon\|_p$; but the densities g_ϵ of the equations themselves are not bounded in L^p , and the potentials are not uniformly bounded.

14.12.4 Scalar envelopes of subsolutions

To compare a cluster potential with every member of the class (14.28), fix a point $x \in \Omega$ and add a continuous forcing term r to the subsolution inequality. Let $\mathcal{S}$ be the convex set of potentials of minimal type that are continuous on Ω , and define

$$\mathcal{F}_{\lambda,x}(r) = \sup\{s(x) : s \in \mathcal{S}, \text{MA}_\theta(s) \geq ce^{\lambda s+r} f \, dV\}. \quad (14.36)$$

Lemma 14.12.2 *The functional $\mathcal{F}_{\lambda,x}$ is finite, concave, decreasing and λ^{-1} -Lipschitz for the uniform norm on $C(X)$. It satisfies*

$$\mathcal{F}_{\lambda,x}(0) = w_\lambda(x), \quad \mathcal{F}_{\lambda,x}(r+b) = \mathcal{F}_{\lambda,x}(r) - b/\lambda.$$

There is a probability measure $\nu_{\lambda,x}$ such that, for every $r \in C(X)$ and every s admissible for r in (14.36),

$$\lambda s(x) + \int_X r \, d\nu_{\lambda,x} \leq \lambda w_\lambda(x). \quad (14.37)$$

Proof By part (2) of Corollary 13.12.1, w_λ is the greatest admissible potential for $r = 0$. If $m = \min_X r$ and $M = \max_X r$, then $w_\lambda - M/\lambda$ is admissible for r , and translating any potential admissible for r by m/λ makes it admissible for $r = 0$. Hence

$$w_\lambda(x) - M/\lambda \leq \mathcal{F}_{\lambda,x}(r) \leq w_\lambda(x) - m/\lambda.$$

The mixed density inequality on Ω and the arithmetic–geometric mean inequality show that a convex combination of potentials admissible for r_0 and r_1 is admissible for the same convex combination of the forcing terms. Approximating the two suprema at x proves concavity. Inclusion of the admissible classes proves monotonicity, and translation by constants proves the translation rule and the Lipschitz bound.

Now apply the Hahn–Banach construction in the proof of [Theorem 14.2.1](#) to $-\lambda\mathcal{F}_{\lambda,x}$ at zero. This functional is finite, continuous, convex and increasing, and it satisfies $-\lambda\mathcal{F}_{\lambda,x}(r+b) = -\lambda\mathcal{F}_{\lambda,x}(r) + b$ for constants b . The same tests with nonnegative functions and constants show that its subgradient is a probability measure $\nu_{\lambda,x}$. The resulting supporting inequality, combined with $s(x) \leq \mathcal{F}_{\lambda,x}(r)$, gives [\(14.37\)](#); it is not necessary that the supremum be attained. $\square$

Proof (of [Theorem 14.12.1](#)) By [Proposition 14.12.2](#) and the moment bound following it, $\mathcal{P}_f$ has the stated properties, and [Lemma 14.12.1](#) gives precompactness of the centered potentials. It remains to identify every cluster potential.

Step 1: limits of the forcing probabilities. Fix $x \in \Omega$. For $r \in C(X)$, choose a critical potential ψ_r for $e^r f$ with supremum zero. By the definition of κ ,

$$\text{MA}_\theta(\psi_r) = ce^{-\kappa(r)+r} f \, dV.$$

Since $\psi_r \leq 0$, the potential $\psi_r - \kappa(r)/\lambda$ is admissible in [\(14.36\)](#). Thus

$$\int_X r \, d\nu_{\lambda,x} \leq \kappa(r) + \lambda(w_\lambda(x) - \psi_r(x)). \quad (14.38)$$

For fixed x and r , the values $w_\lambda(x)$ are uniformly bounded by [Lemma 14.12.1](#), and $\psi_r(x)$ is finite. Hence every weak cluster point of $\nu_{\lambda,x}$ as $\lambda \downarrow 0$ belongs to $\mathcal{P}_f$.

Step 2: a pointwise comparison. Let s satisfy [\(14.28\)](#). The function $-\lambda s$ is lower semicontinuous and bounded below on X , with the value $+\infty$ allowed, so metric inf-convolution and truncation give continuous functions $r_j \uparrow -\lambda s$. Since $r_j \leq -\lambda s$, the potential s is admissible for every r_j , and [\(14.37\)](#) bounds the integrals of the r_j from above. Monotone convergence, after subtracting a common lower bound, shows that s is integrable against $\nu_{\lambda,x}$ and gives

$$w_\lambda(x) \geq s(x) - \int_X s \, d\nu_{\lambda,x}. \quad (14.39)$$

Step 3: cluster potentials belong to the class [\(14.28\)](#). Take a sequence $\lambda_j \downarrow 0$ with $w_{\lambda_j} \rightarrow z$ locally uniformly on Ω and in $L^1(X)$. The bounds [\(14.35\)](#) show that z has minimal type, and z is continuous on Ω . Since $ce^{\lambda_j w_{\lambda_j}} f \rightarrow cf$ in L^p , by dominated convergence and the common bound $w_\lambda \leq K$, continuity of local bounded products gives $\text{MA}_\theta(z) = cf \, dV$ on Ω , and then on X because neither side charges $X \setminus \Omega$.

For each $\nu \in \mathcal{P}_f$, the bound $|w_\lambda| \leq |\psi| + K$ has a ν -integrable right-hand side, and ν charges only Ω . Dominated convergence in $\int_X w_\lambda \, d\nu \leq 0$ therefore gives $\int_X z \, d\nu \leq 0$. Hence z belongs to the class [\(14.28\)](#).

Step 4: z is the greatest element of the class. For any s in the class and fixed $x \in \Omega$, pass to a further subsequence with $\nu_{\lambda_j,x} \rightarrow \nu$, so that $\nu \in \mathcal{P}_f$ by Step 1. The potential s is upper semicontinuous and bounded above on X , so

$$\limsup_j \int_X s \, d\nu_{\lambda_j,x} \leq \int_X s \, d\nu \leq 0.$$

For an unbounded s , this follows from the portmanteau theorem applied to $\max(s, -M)$, followed by $M \rightarrow \infty$; the final integral is finite by (14.32). Passing to the limit in (14.39) gives $z(x) \geq s(x)$. This holds for every $x \in \Omega$, and hence on X by Lemma 1.3.3. Thus every cluster potential is the greatest element w of the class, and precompactness gives convergence of the whole family.

Step 5: the normalizations. The maximum of $\int_X w \, d\nu$ over $\mathcal{P}_f$ is attained, because under (14.31) it is the maximum of the weakly continuous functional $\eta \mapsto A^{-1} \int_X a w \eta \, dV$ on $\mathcal{H}_a$; note that $a w \in L^\ell$. If the maximum were negative, a small positive constant translate of w would still satisfy (14.28), contrary to greatestness. Thus it is zero.

Finally, $k_\lambda \rightarrow \sup_X w$. Indeed, from any subsequence choose a further one with $k_\lambda \rightarrow k$. Then $v_\lambda = w_\lambda - k_\lambda$ converges in L^1 to $w - k$, and Theorem 1.4.1 gives $\sup_X (w - k) = 0$. Thus $k = \sup_X w$ for every cluster point of (k_λ) . Subtracting the constants proves the convergence of $u_\lambda - \sup_X u_\lambda$. If θ is Hermitian, we may take $\rho = 0$ and $\Omega = X$, so that local uniform convergence is uniform convergence. $\square$

Together with Proposition 13.16.1, the theorem also gives convergence of the normalized potentials in the topology of uniform convergence of differences on Ω and in every local C^β topology stated there: compactness in those topologies and uniqueness of the L^1 limit force every subsequence to have the same limit. The fact that the limit is selected does not imply that the critical equation has a unique normalized solution.

14.13 Selection for logarithmic models on products

For a logarithmic reference with a positive residual background, removing the divisor turns the singular exponential equation into a bounded equation. On a product with a curve, the selected residual can then be determined by the Green operator. This also controls simultaneous changes of the reference, background and density, for which the centering constant must follow the changing data.

Let (Y, κ) be a connected compact Hermitian manifold of dimension $k \geq 1$, with $\int_Y \kappa^k = 1$, and put $X = \mathbb{P}^1 \times Y$, $N = k + 1$. Write ω_1 for the mass-one Fubini–Study form on $\mathbb{P}^1$ and $dW = \omega_1 \wedge \kappa^k$; pullbacks to X are implicit. Fix $a, d > 0$, a smooth positive nonconstant function b on $\mathbb{P}^1$, and a continuous positive function H on $\mathbb{P}^1$. Set

$$\begin{aligned} \theta &= (a + d)\omega_1 + b\kappa, & \eta &= a\omega_1 + b\kappa, \\ f &= Nb^k H, & m &= \int_{\mathbb{P}^1} H\omega_1, & c_0 &= \frac{a}{m}. \end{aligned}$$

Both forms are positive and nonclosed: the component $db \wedge \kappa$ of horizontal degree one cannot cancel the vertical component $b \, d\kappa$. For homogeneous coordinates $[Z_0 : Z_1]$, put

$$\ell = \frac{|Z_0|^2}{|Z_0|^2 + |Z_1|^2}, \quad D = \{Z_0 = 0\} \times Y, \quad \psi = d \log \ell.$$

The Poincaré–Lelong formula gives $\theta + \text{dd}^c \psi = \eta + d[D]$.

14.13.1 The ordinary model and the greatest solutions

Put $K = a + d$, $R = a/d$ and $C_* = K \log(K/d) - a \log(a/d)$. In the coordinate $z = Z_1/Z_0$ define

$$\phi_{a,d} = \begin{cases} 0, & |z|^2 \leq R, \\ a \log |z|^2 + C_* - K \log(1 + |z|^2), & |z|^2 > R, \end{cases} \quad \phi_{a,d}|_D = -\infty. \quad (14.40)$$

Proposition 14.13.1 *The function $\phi_{a,d}$ is an ordinary model reference for θ , with*

$$P_\theta[\psi] = P_\theta[\phi_{a,d}] = \phi_{a,d}, \quad \psi \leq \phi_{a,d} \leq \psi + C_*, \quad \sup_X \phi_{a,d} = 0.$$

For $d/(a+d) < \delta < 1$, the envelope $P_{\delta\theta}(\phi_{a,d})$ is not identically $-\infty$. The model has finite positive Monge–Ampère measure

$$\text{MA}_\theta(\phi_{a,d}) = Nb^k K \mathbf{1}_{\{|z|^2 < R\}} dW.$$

The difference $\phi_{a,d} - \psi$ extends continuously across D . If $(a_j, d_j) \rightarrow (a, d)$ in $(0, +\infty)^2$, these residual extensions converge uniformly.

Proof First take the ordinary envelope on the curve with background $K\omega_1$ and obstacle $\min(\psi + C, 0)$. Rotation of z preserves both the obstacle and the admissible family, so the envelope is rotation invariant. With $s = \log |z|^2$ and $F(s) = K \log(1 + e^s)$, its profile plus F is convex and lies below F . The comparison with $\psi + C$ bounds its final slope by a . At $s_* = \log R$, one has $F'(s_*) = a$. Above s_* , convexity and the final slope bound give

$$u(s) + F(s) \leq F(s_*) + a(s - s_*),$$

and below s_* the obstacle gives $u \leq 0$. The function in (14.40) attains both bounds. Its convex profile, including its logarithmic value at infinity, gives a curve potential, and direct calculation gives $\psi \leq \phi_{a,d} \leq \psi + C_*$. It is therefore a competitor for every $C \geq C_*$, so the curve envelope is exactly $\phi_{a,d}$.

A product competitor restricts to each curve $\mathbb{P}^1 \times \{y\}$ as either the constant $-\infty$ or a curve competitor. It is thus bounded above by $\phi_{a,d}$. Conversely, the curve model is a product competitor because the vertical form $b\kappa$ is positive. Hence the product envelope is the same function. Ordinary-type invariance of the singularity envelope gives its model property. Moreover,

$$\delta\theta + \text{dd}^c \psi = (\delta K - d)\omega_1 + \delta b\kappa + d[D] \geq 0,$$

which proves the smaller-background assertion.

Off D , the horizontal curvature of $\phi_{a,d}$ is $K \mathbf{1}_{\{|z|^2 < R\}} \omega_1$. The first derivatives of its convex profile agree at R , so there is no boundary-circle atom. Expanding the

product off D gives the displayed measure, and the non-pluripolar product assigns D zero mass. Finally, in terms of ℓ the residual extension is

$$\phi_{a,d} - \psi = \begin{cases} -d \log \ell, & \ell \geq d/K, \\ a \log(1 - \ell) + C_*, & \ell < d/K. \end{cases}$$

The formulas agree at the moving interface and extend to both endpoints. On compact positive parameter ranges each logarithm is used away from its singular endpoint. Joint continuity on the resulting compact set proves uniform variation. $\square$

Lemma 14.13.1 *For every $\sigma > 0$, the equation*

$$\text{MA}_\theta(s_\sigma) = e^{\sigma s_\sigma} f \, dW \quad (14.41)$$

has a solution of ordinary type $\phi_{a,d}$, unique in that type. It is the greatest exponential subsolution among all $u \in \text{PSH}(X, \theta)$ with $u \preceq \phi_{a,d}$, and its measure has finite mass.

Proof The one-sided ordinary class has the description

$$u \preceq \psi \iff u = \psi + r, \quad r \in \text{PSH}(X, \eta), \quad \text{MA}_\theta^{\text{ext}}(\psi + r) = \text{MA}_\eta^{\text{ext}}(r). \quad (14.42)$$

Indeed, $u \preceq \psi$ gives $v(u, D) \geq d$. Divisorial removal, [Lemma 1.17.1](#), shows that $\theta + \text{dd}^c u - d[D] \geq 0$. Thus the locally integrable difference $u - \psi$ has an η -plurisubharmonic representative r . The equality $u = \psi + r$ holds off D by canonical equality and on D because both sides equal $-\infty$. Conversely, adding ψ to r adds the positive current $d[D]$; since r has a finite compact upper bound, the one-sided comparison follows. Off D the currents agree, so finite-level locality identifies their extended products, including at any additional poles of r . Both measures give D zero mass, proving the global equality. The bounded ordinary type corresponds exactly to bounded r , as in [Theorem 14.9.1](#).

The function $g_\sigma = e^{\sigma \psi} f$ extends continuously by zero on D and is positive elsewhere. Since $\eta > 0$, [Theorem 10.1.2](#) gives a continuous solution R_σ of

$$\text{MA}_\eta(R_\sigma) = e^{\sigma R_\sigma} g_\sigma \, dW.$$

For this bounded density, the greatest solution of [Theorem 13.30.1](#) is bounded and coincides with R_σ by [Corollary 10.2.2](#). Thus it dominates every η -plurisubharmonic exponential subsolution. The correspondence (14.42) transfers this order to the entire one-sided ordinary class and gives $s_\sigma = \psi + R_\sigma$. Bounded residual uniqueness gives uniqueness in the ordinary type. The bounded residual equation has finite mass, so the singular equation does too. $\square$

14.13.2 The selected limit with varying data

For $x, z \in \mathbb{P}^1$, let $\text{dist}_{\text{chord}}(x, z)$ be the chordal distance and put

$$G(x, z) = \log \text{dist}_{\text{chord}}(x, z)^2 + 1.$$

This kernel satisfies $\text{dd}_x^c G = \delta_z - \omega_1$ and $\int G(x, z)\omega_1(z) = 0$. For a bounded density q , write $G * q(x) = \int G(x, z)q(z)\omega_1(z)$. Define

$$\begin{aligned} A_0 &= \frac{aH}{m}, & w_0 &= G * (A_0 - a), & S_0 &= \sup_X (\psi + w_0), \\ \text{d}v_0 &= \frac{H}{m} \text{d}W, & J &= \int_X (\psi + w_0) \text{d}v_0. \end{aligned} \quad (14.43)$$

The function w_0 is continuous, has mean zero on the curve and satisfies $\text{dd}^c w_0 = (A_0 - a)\omega_1$. We use the probability v_0 to normalize the separated potentials.

Theorem 14.13.1 *Let $a_j, d_j > 0$ converge to $a, d > 0$, let smooth positive functions b_j converge uniformly to b , and let continuous positive functions H_j converge uniformly to H . For any $\sigma_j > 0$ tending to zero, put*

$$\begin{aligned} \theta_j &= (a_j + d_j)\omega_1 + b_j\kappa, & \psi_j &= d_j \log \ell, & \phi_j &= \phi_{a_j, d_j}, \\ f_j &= Nb_j^k H_j, & m_j &= \int_{\mathbb{P}^1} H_j \omega_1, & c_{0,j} &= a_j/m_j. \end{aligned}$$

Let s_j be the greatest solution of (14.41) for these data, and set $v_j = s_j - \sup_X s_j$, $c_j = e^{\sigma_j \sup_X s_j}$. Then

$$v_j \longrightarrow v_0 = \psi + w_0 - S_0, \quad s_j - \sigma_j^{-1} \log c_{0,j} \longrightarrow s_0 = \psi + w_0 - J$$

in $L^1(X)$, in capacity, and locally uniformly on $X \setminus D$. Moreover,

$$c_j \longrightarrow c_0, \quad \sigma_j^{-1} \log(c_j/c_{0,j}) \longrightarrow S_0 - J, \quad (14.44)$$

and $\text{MA}_{\theta_j}(v_j) \rightarrow c_0 f \text{d}W$ in total variation. The limit has ordinary type $\phi_{a,d}$ and belongs to $\mathcal{E}_{\text{env}}(X, \theta, \phi_{a,d})$, with

$$\text{MA}_{\theta}(v_0) = c_0 f \text{d}W.$$

There is no restriction on the relative rates of parameter and exponent convergence.

Proof We construct uniformly bounded residuals on the curve, then use their equation to determine both the normalized limit and the scalar error.

Uniform construction. The kernel has uniformly integrable logarithmic tails and $C_G = \sup_x \int |G(x, z)|\omega_1(z) < \infty$. These facts follow by rotation invariance and the radial integral of $|\log \ell + 1|$ on $0 < \ell < 1$; the Poincaré–Lelong formula and

$\int_0^1 \log \ell \, d\ell = -1$ give its curvature and mean. Truncating the kernel shows that convolution of bounded densities is continuous.

Temporarily omit subscripts. On continuous mean-zero functions on the curve define

$$T_\sigma(w) = G^*(A(w)-a), \quad A(w) = \frac{aHe^{\sigma(\psi+w)}}{Z(w)}, \quad Z(w) = \int_{\mathbb{P}^1} He^{\sigma(\psi+w)} \omega_1.$$

For all late parameters choose fixed bounds $a \leq a_{\max}$, $d \leq d_{\max}$ and $0 < h_{\min} \leq H \leq h_{\max}$. Put $B = 4a_{\max}h_{\max}/h_{\min}$ and choose $R_0 > C_G(B + a_{\max})$. On the ball $\|w\|_\infty \leq R_0$, for sufficiently small σ ,

$$Z(w) \geq \frac{h_{\min}e^{-\sigma R_0}}{1 + \sigma d_{\max}} \geq h_{\min}/2, \quad 0 \leq A(w) \leq B.$$

Here $\int \ell^{\sigma d} \omega_1 = (1 + \sigma d)^{-1}$. Thus T_σ maps the mean-zero ball into itself. Since $\int A(w)\omega_1 = a$, its density derivative in direction h is

$$\sigma A(w) \left(h - a^{-1} \int h A(w) \omega_1 \right).$$

It follows that $\|T_\sigma(w) - T_\sigma(v)\|_\infty \leq 2\sigma BC_G \|w - v\|_\infty$. The map is a contraction for all sufficiently small exponents, uniformly over the late parameters. Its fixed point w_j has mean zero and $\|w_j\|_\infty \leq R_0$.

Write $Z_j = Z(w_j)$ and $A_j = A(w_j)$. The fixed-point equation gives $\text{dd}^c w_j = (A_j - a_j)\omega_1$, and the potential

$$\psi_j + w_j + \sigma_j^{-1} \log(a_j/Z_j) \quad (14.45)$$

has residual form $A_j\omega_1 + b_j\kappa$, continuous and semipositive. On coordinate balls, mollification of w_j converges together with its continuous complex Hessian. The local bounded product, expanded after a common strict smooth correction, therefore equals $Nb_j^k A_j \, dW$. Removing D identifies the singular product with the same measure. The identity

$$Nb_j^k A_j = e^{\sigma_j(\psi_j + w_j)} (a_j/Z_j) f_j$$

shows that (14.45) solves the exponential equation in the ordinary type. By Lemma 14.13.1, it is s_j .

Residual and normalized limits. Uniform boundedness and dominated convergence give $Z_j \rightarrow m$ and $A_j \rightarrow A_0$ in $L^1(\omega_1)$, with a common bound on A_j . For uniformly bounded densities $F_j \rightarrow 0$ in L^1 , one has

$$\|G * F_j\|_\infty \leq \|F_j\|_\infty \sup_x \int_{\{|G(x,z)| > M\}} |G(x,z)| \omega_1(z) + M \|F_j\|_1.$$

First letting $j \rightarrow \infty$ and then $M \rightarrow \infty$ proves $w_j \rightarrow w_0$ uniformly. Although $A_j = 0$ on D and $A_0 > 0$ there, the L^1 convergence suffices for this argument.

Put $S_j = \sup_X(\psi_j + w_j)$. A point with $\ell = 1$ supplies a uniformly bounded competing value. Since $d_j \geq d_{\min} > 0$, the upper bound $d_{\min} \log \ell + R_0$ tends uniformly to $-\infty$ near D , so all maximizing points stay in a fixed compact subset of $X \setminus D$. Uniform convergence there gives $S_j \rightarrow S_0$. Hence $v_j = \psi_j + w_j - S_j$ has the asserted L^1 and local uniform limits. For capacity convergence, the complements of $\{\psi < -T\}$ are compact subsets of $X \setminus D$. Choose a fixed Hermitian form for which ψ is plurisubharmonic and apply (1.15); their omitted sublevels have capacity at most C/T . Local uniform convergence, followed by $T \rightarrow \infty$, proves convergence in capacity, with the common poles omitted.

The measure formula and uniform convergence of b_j give total-variation convergence to $Nb^k A_0 dW = c_0 f dW$. The same bounded product calculation gives this equation for v_0 . The residual extensions in Proposition 14.13.1 show directly that $v_0 \sim \phi_{a,d}$. Choose C with $v_0 \geq \phi_{a,d} - C$. For every $t \geq 1$, the potential $q_t = \phi_{a,d} - tC$ satisfies

$$t^{-1}q_t + (1 - t^{-1})\phi_{a,d} \leq v_0,$$

which proves membership in the relative envelope class by Definition 12.4.1.

Scalar centering. The exact formula is $c_j = a_j e^{\sigma_j S_j} / Z_j$. In the difference quotient

$$\frac{Z_j - m_j}{\sigma_j} = \int H_j \frac{e^{\sigma_j(\psi_j + w_j)} - 1}{\sigma_j} \omega_1,$$

the negative part is bounded by $h_{\max}(d_{\max} |\log \ell| + R_0)$ and the positive part by a constant. Dominated convergence gives a limit $\int H(\psi + w_0) \omega_1 = mJ$. Since $m_j \rightarrow m > 0$,

$$\sigma_j^{-1} \log(Z_j / m_j) \longrightarrow J.$$

The identity $c_j / c_{0,j} = m_j e^{\sigma_j S_j} / Z_j$ proves (14.44). Subtracting $\sigma_j^{-1} \log c_{0,j}$ in (14.45) leaves $\psi_j + w_j - \sigma_j^{-1} \log(Z_j / m_j)$, proving the centered limit in all three topologies. $\square$

14.13.3 The critical coefficient and separated order

Corollary 14.13.1 *For the fixed data, c_0 is the largest coefficient $c > 0$ for which $u \in \text{PSH}(X, \theta)$ with $u \preceq \phi_{a,d}$ satisfies $\text{MA}_\theta^{\text{ext}}(u) \geq cf \, dW$. Among separated potentials $u = \psi + r(x) \preceq \phi_{a,d}$, the critical subsolutions are exactly the translates of $\psi + w_0$. Thus v_0 is their unique supremum-zero member, and s_0 is their greatest member with $\int_X u \, dv_0 \leq 0$.*

Proof For a separated critical subsolution, (14.42) and the product expansion give $\text{MA}_{a\omega_1}^{\text{ext}}(r) \geq A_0\omega_1$. Closed curve truncations have mass a , so the non-pluripolar measure has mass at most a . Since $\int A_0\omega_1 = a$, it must equal $A_0\omega_1$. The positive closed current $a\omega_1 + \text{dd}^c r$ also has mass a , so it has no remaining measure on the pole set. Consequently $\text{dd}^c r = (A_0 - a)\omega_1$ as distributions, and $r = w_0 + C$ because harmonic distributions on $\mathbb{P}^1$ are constant. Supremum zero gives $C = -S_0$, while the mean condition gives $C \leq -J$.

For a general $u \preceq \phi_{a,d}$ with coefficient $c > 0$, write $u = \psi + r$ by (14.42) and put $B_r = \sup_X r$. Since $\psi \leq 0$, the potential $u + \sigma^{-1} \log c - B_r$ is an exponential subsolution for every $\sigma > 0$. Greatestness gives

$$u + \sigma^{-1} \log c - B_r \leq s_\sigma.$$

At a point off D where r is finite, subtract $\sigma^{-1} \log c_0$, multiply by σ and use the fixed-data case of **Theorem 14.13.1**. This yields $\log c \leq \log c_0$. The potential v_0 attains c_0 . $\square$

The scalar in the centering follows the varying data. Replacing $c_{0,j}$ by c_0 adds $\sigma_j^{-1} \log(c_{0,j}/c_0)$ to the centered potential, and this term need not vanish. For example, take $a = 1$, $d = 1/4$, $H = 1$ and $b = 2 + t$, where t is the sphere height. Then $w_0 = 0$, $S_0 = 0$, $J = -1/4$ and $c_0 = 1$, so $s_0 = \psi + 1/4$ and the scalar-error limit is $1/4$. If $a_j = 1 + \sqrt{\sigma_j}$ and the other data are fixed, the appropriate centering uses $c_{0,j} = a_j$. Centering by 1 instead adds

$$\frac{\log(1 + \sqrt{\sigma_j})}{\sigma_j} \longrightarrow +\infty.$$

These examples can be taken on a non-Kähler manifold by choosing Y to be the scalar Hopf surface with its Hermitian form rescaled to unit volume. The product cannot be Kähler, since a Kähler form would restrict to one on the Hopf fiber. The pole divisor remains present in the selected ordinary type.

14.13.4 Weak adjoints on a product surface

When the Hermitian factor is also a projective line, the averaging probability of (14.43) is the full supporting probability of the singular equation. The residual form is positive with continuous coefficients, so its weak linearization is defined directly. A separation into spherical harmonics proves uniqueness without imposing regularity on an invariant measure.

In this subsection take $Y = \mathbb{P}_y^1$, $\kappa = \omega_2$ and $k = 1$. Keep $a, d, b, H, \theta, \eta, \psi$ and $dW = \omega_1 \wedge \omega_2$ as above, and write $\phi = \phi_{a,d}$, $A = A_0 = c_0 H$ and $u = \psi + w_0$. Choose a smooth positive probability volume form $dV = q dW$ and put $F = \log(2bH/q)$. Then

$$\Omega = A\omega_1 + b\omega_2, \quad \theta + dd^c u = \Omega + d[D], \quad \text{MA}_\theta(u) = \Omega^2 = c_0 e^F dV.$$

The model has the admissibility properties of Proposition 14.13.1, and $u \sim \phi$, so $B_\phi(F) = \log c_0$. Since $dd^c \theta = (dd^c b) \wedge \omega_2 \neq 0$, none of its smooth positive potential perturbations is Gauduchon. Indeed, $dd^c b = 0$ would make b harmonic and therefore constant on the compact curve, and $dd^c(\theta + dd^c v) = dd^c \theta$ for every smooth v .

For a smooth function h on the product, define its partial Laplacians by $dd_i^c h = (\Delta_i h)\omega_i$. With the mass-one Fubini–Study normalization, Δ_i is the Laplacian of the unit round sphere.

Lemma 14.13.2 *Let $V > 0$ be continuous on $\mathbb{P}^1$, and let T be a finite signed measure such that*

$$\int_{\mathbb{P}^1} (\Delta f - V f) dT = 0 \quad (f \in C^\infty(\mathbb{P}^1)).$$

Then $T = 0$.

Proof Let H_t be the sphere heat operator. On spherical harmonics of degree ℓ , it acts by $e^{-t\ell(\ell+1)}$. The harmonic series defines a smooth heat solution for $t > 0$; for smooth initial functions, the maximum principle gives positivity and contraction in the uniform norm. Density of smooth functions extends H_t to a positive, strongly continuous contraction on $C(\mathbb{P}^1)$. Choose $M \geq \max V$ and define

$$R_M g = \int_0^\infty e^{-Mt} H_t g dt.$$

Then $\|R_M\| \leq M^{-1}$ and $(M - \Delta)R_M g = g$ in distributions. For any $g \in C(\mathbb{P}^1)$, the map

$$f \mapsto R_M((M - V)f - g)$$

contracts by at most $1 - \min V/M < 1$. Its continuous fixed point satisfies $\Delta f = Vf + g$ in distributions, with a continuous right-hand side. The functions $f_\varepsilon = H_\varepsilon f$ are smooth and satisfy

$$f_\varepsilon \longrightarrow f, \quad \Delta f_\varepsilon = H_\varepsilon(Vf + g) \longrightarrow Vf + g$$

uniformly. Thus $(\Delta - V)f_\varepsilon \rightarrow g$ uniformly. Testing against the finite measure T gives $\int g \, dT = 0$ for every continuous g , hence $T = 0$. $\square$

Theorem 14.13.2 *The weight and current*

$$\rho = \frac{1}{2ab}, \quad Q = \rho\Omega = \frac{A}{2ab}\omega_1 + \frac{1}{2a}\omega_2$$

satisfy $dQ = 0$ and $\int_X \rho\Omega^2 = 1$. For smooth real h , the measure-valued and logarithmic linearizations at u are

$$D_u \text{MA}_\theta(h) = 2\Omega \wedge dd^c h, \quad L_u h = \frac{2\Omega \wedge dd^c h}{\Omega^2} = \frac{\Delta_1 h}{A} + \frac{\Delta_2 h}{b}.$$

The only Borel probability satisfying $\int_X L_u h \, d\mu = 0$ for every smooth real h is

$$\nu = \rho\Omega^2 = \frac{A}{a} dW, \quad \mathcal{A}_\phi(F) = \{\nu\}. \quad (14.46)$$

If $r \geq 0$ is measurable, $\int_X r\Omega^2 = 1$ and $dd^c(r\Omega) = 0$, then $r = \rho$ almost everywhere.

Proof We first define the weighted current and variation, then prove invariant-measure uniqueness and apply the supporting inequality on the full space $C(X)$.

The current and operator. Since A/b depends only on the first curve, $d((A/b)\omega_1) = 0$ distributionally; this follows also by uniform smooth approximation of its coefficient. Thus Q is closed, and $\int \rho\Omega^2 = \int A\omega_1/a = 1$. The coefficient ρ is smooth and Ω is continuous, so the product defining Q is well defined. Uniform positivity of Ω gives $\Omega + tdd^c h > 0$ for sufficiently small signed t . The bounded-product calculation used in [Theorem 14.13.1](#), now with the smooth perturbation th , gives

$$\text{MA}_\theta(u + th) = \Omega^2 + 2t\Omega \wedge dd^c h + t^2(dd^c h)^2.$$

This proves the two linearizations; mixed components of $dd^c h$ have zero wedge with the diagonal Ω . Distributional Stokes gives $\int L_u h \, d\nu = 2 \int dd^c h \wedge Q = 0$.

Invariant probabilities. Choose real spherical harmonics e_j on the second sphere, with $e_0 = 1$ and $\Delta_2 e_j = -\lambda_j e_j$. Only the constant mode has eigenvalue zero. For an invariant probability μ , define finite signed measures T_j on the first sphere by

$$\int f \, dT_j = \int_X \frac{f(x)e_j(y)}{A(x)} \, d\mu.$$

Testing L_u on $f(x)e_j(y)$ gives

$$\int \left(\Delta_1 f - \lambda_j \frac{A}{b} f \right) dT_j = 0.$$

For $j = 0$, testing on spherical harmonics of the first sphere shows that $T_0 = C\omega_1$. Their finite span is uniformly dense, because restrictions of polynomials decompose

into harmonics and polynomials are dense on the sphere. The first marginal of μ is therefore $CA\omega_1$, and probability normalization gives $C = 1/a$. For every nonconstant mode, [Lemma 14.13.2](#) with $V = \lambda_j A/b > 0$ gives $T_j = 0$. As these are identities of measures, their test functions may then be multiplied by the continuous function A . They determine all spherical harmonic moments of μ . Uniform density of harmonics and of finite product tests gives $\mu = (A/a)\omega_1 \wedge \omega_2$.

Supporting probabilities and weights. Let $\mu \in \mathcal{A}_\phi(F)$ and, for smooth real h , set

$$F_t = F + \log \frac{(\Omega + t \operatorname{dd}^c h)^2}{\Omega^2}.$$

This is continuous, and $u + th$ solves the ordinary-type equation with density e^{F_t} and scalar c_0 . Thus $B_\phi(F_t) = B_\phi(F)$, by uniqueness of the scalar. Uniform positivity gives $F_t - F = tL_u h + O(t^2)$ in the uniform norm. Apply [\(14.3\)](#) for both signs of t to obtain $\int L_u h d\mu = 0$. The perturbed density need not depend on the first curve alone: the inequality is the one on all of $C(X)$. Invariant uniqueness and nonemptiness of $\mathcal{A}_\phi(F)$ from [Theorem 14.2.1](#) now prove [\(14.46\)](#).

Finally, Ω^2/dW is bounded above and below by positive constants, so a normalized r as in the statement belongs to $L^1(dW)$ and $r\Omega$ is an order-zero current. Distributional Stokes makes $r\Omega^2$ invariant. The probability uniqueness just proved gives $r\Omega^2 = \rho\Omega^2$, hence $r = \rho$ almost everywhere. $\square$

Proposition 14.13.2 *Let $w_j \in C^\infty(X)$ be real and suppose*

$$\Omega_j = \eta + \operatorname{dd}^c w_j > 0, \quad \Omega_j \longrightarrow \Omega \quad \text{uniformly as } (1, 1)\text{-forms}.$$

Put $u_j = \psi + w_j$ and $F_j = \log(\Omega_j^2/(c_0 dV))$. Let $\rho_j > 0$ be the smooth residual adjoint weight, normalized by

$$\operatorname{dd}^c(\rho_j \Omega_j) = 0, \quad \int_X \rho_j \Omega_j^2 = 1.$$

Then $F_j \rightarrow F$ uniformly, and the entire sequence satisfies

$$\rho_j \Omega_j^2 \rightarrow \nu, \quad \rho_j \Omega_j \rightarrow Q, \quad \rho_j dW \rightarrow \rho dW.$$

Such approximations exist with $w_j \rightarrow w_0$ uniformly and can depend on both curve variables.

Proof Existence of the smooth positive weights is [Theorem 4.1.1](#), applied to the residual metrics Ω_j on the surface. Put $\nu_j = \rho_j \Omega_j^2$ and $L_j h = 2\Omega_j \wedge \operatorname{dd}^c h / \Omega_j^2$. Distributional Stokes gives $\int L_j h d\nu_j = 0$. Uniform convergence to the positive form Ω supplies a common determinant lower bound and gives $L_j h \rightarrow L_u h$ uniformly for every fixed smooth h . Every weak cluster point of the probabilities ν_j is therefore invariant for L_u . By [Theorem 14.13.2](#), it equals ν , proving convergence of the whole sequence. The same determinant convergence gives $F_j \rightarrow F$ uniformly.

For a smooth real $(1, 1)$ test form ξ , the ratios $\Omega_j \wedge \xi / \Omega_j^2$ converge uniformly to $\Omega \wedge \xi / \Omega^2$. Consequently,

$$\int_X \rho_j \Omega_j \wedge \xi = \int_X \frac{\Omega_j \wedge \xi}{\Omega_j^2} dv_j \longrightarrow \int_X \rho \Omega \wedge \xi.$$

Similarly, the positive densities $p_j = \Omega_j^2 / dW$ converge uniformly to $p = \Omega^2 / dW$. For every $g \in C(X)$,

$$\int_X g \rho_j dW = \int_X (g / p_j) dv_j \longrightarrow \int_X (g / p) dv = \int_X g \rho dW.$$

These arguments require no pointwise control of the weights.

For existence, heat-smooth A on the first sphere to positive smooth functions A_j of the same mean a , converging uniformly to A . Green inversion gives smooth mean-zero $w_j(x)$ with $dd^c w_j = (A_j - a)\omega_1$ and $w_j \rightarrow w_0$ uniformly. Their residuals converge uniformly to Ω . Adding $\varepsilon_j h(x, y)$ for a fixed smooth function depending on both variables and $\varepsilon_j \rightarrow 0$ preserves positivity for all sufficiently small coefficients and supplies nonsymmetric examples. Each u_j retains the fixed logarithmic divisor, and its non-pluripolar equation has scalar c_0 and logarithmic density F_j . $\square$

Example 14.13.1 Take $a = 1$, $d = 1/4$, $q = 1$, and let t be the sphere height

$$t = \frac{|Z_0|^2 - |Z_1|^2}{|Z_0|^2 + |Z_1|^2}, \quad b = 2 + t, \quad H = A = \frac{1}{2} + |t|.$$

Here $c_0 = 1$ and $F = \log(2bA)$ is Lipschitz but not C^1 . The residual has continuous positive coefficients with the same loss of differentiability. Its supporting probability differs from normalized Monge–Ampère volume:

$$\int_X \Omega^2 = 4, \quad \int_X t dv = 0, \quad \int_X t \frac{\Omega^2}{4} = \frac{5}{24}.$$

Even for smooth constant H , approximation of the pole by globally smooth potentials need not recover the weak adjoint. For $H = a$, so that $w_0 = 0$ and $v = dW$, put

$$\psi_\delta = d \log(\ell + \delta(1 - \ell)), \quad P_\delta = \omega_1 + dd^c(\psi_\delta / d), \quad 0 < \delta \leq 1.$$

The smooth potentials ψ_δ decrease pointwise to ψ , converge in L^1 and smoothly off D , but the classical adjoint probabilities of $\theta + dd^c \psi_\delta$ converge to

$$\frac{a\omega_1 + d\delta_p}{a + d} \wedge \omega_2, \quad p = \{Z_0 = 0\}.$$

This limit assigns mass $d/(a + d) > 0$ to D , and the weighted currents also retain a nonzero divisor component.

Proof The height t is uniform on $[-1, 1]$, so $\int A\omega_1 = 1$ and $\int tA\omega_1 = 0$. Since $\Omega^2 = 2bA\,dW$, its mass is four and its normalized height moment is

$$\frac{1}{2} \int_{-1}^1 t^2 \left(\frac{1}{2} + |t|\right) \frac{dt}{2} = \frac{5}{24}.$$

The weight is $1/(2b)$ and $\nu = A\,dW$. Moreover, $dd^c\theta = -2t\,dW$, so the background has no smooth positive Gauduchon potential perturbation.

For the smoothing family, direct differentiation gives

$$\frac{P_\delta}{\omega_1} = \frac{4\delta}{((1+\delta) + (1-\delta)t)^2}.$$

It is positive of mass one and converges weakly to δ_p . Thus the positive smooth forms are $\widehat{\Omega}_\delta = a\omega_1 + dP_\delta + b\omega_2$. Their classical weights and probabilities are

$$\widehat{\rho}_\delta = \frac{1}{2(a+d)b}, \quad \widehat{\nu}_\delta = \frac{a\omega_1 + dP_\delta}{a+d} \wedge \omega_2.$$

The weighted forms are closed, so these are the normalized classical adjoints. Their limits follow from the curve measure convergence. In particular, the weighted-current limit contains $d[D]/(2(a+d)b(p))$. These smoothings fill the pole and do not satisfy the fixed-divisor and uniform-residual hypotheses of [Proposition 14.13.2](#). $\square$

Chapter 15

Multiplier-ideal envelopes and $\mathcal{I}$ -goodness

Throughout this chapter, X is a connected compact complex manifold of dimension n and θ is a smooth real $(1, 1)$ -form, which need not be closed. We fix a smooth positive probability volume form dV on X and take L^1 norms with respect to it. For $u \in \text{PSH}(X, \theta)$, $\text{MA}_\theta(u)$ denotes the extended non-pluripolar Monge–Ampère measure $\text{MA}_\theta^{\text{ext}}(u)$ of [Theorem 6.1.1](#); its total mass may be infinite. We write $u \preceq v$ and $u \sim v$ for the ordinary singularity order and equivalence of [Definition 1.12.1](#), and $u \preceq_{\mathcal{I}} v$ and $u \sim_{\mathcal{I}} v$ for inclusion and equality of the multiplier ideals $\mathcal{I}(ku)$ and $\mathcal{I}(kv)$ at every weight $k > 0$, as in [Section 1.12](#). Finally, $P_\theta[u]$ and $P_{\theta,F}[u]$ denote the ordinary singularity envelopes of [Definition 1.19.1](#), below zero and below a smooth obstacle F , and $V_\theta = P_\theta(0)$ is the potential with minimal singularities of [Section 1.19](#).

Multiplier ideals record weighted holomorphic integrability. Two potentials can have the same multiplier ideals at every weight although their ordinary envelopes differ, so passing from the ordinary singularity type of a potential to its multiplier-ideal class loses information. Analytic approximation makes this loss visible: along dyadic Demailly approximations, the envelopes converge to the greatest nonpositive representative of the multiplier-ideal class, which may exceed the ordinary envelope of the original potential.

In the Kähler theory, equality of these two envelopes is also characterized by a mass condition. In a nonclosed background the equality remains meaningful even when the potential has infinite mass, and we therefore study both envelopes along analytic approximations. Examples on curves show that this still does not give continuity of mass or completeness, because diffuse polar curvature can disappear in the limit. The same examples explain why the obstacle has to be taken into account when the background changes.

15.1 The Kähler characterization

First suppose that X is Kähler, that θ is a smooth closed big real $(1, 1)$ -form, and that $u \in \text{PSH}(X, \theta)$ has positive non-pluripolar mass. Let $P_\theta[u]_{\mathcal{I}}$ be the multiplier-ideal envelope of **Definition 15.2.1** below, and let d_S be the singularity pseudometric of [Xia, Section 6.2]. The characterization of $\mathcal{I}$ -good singularities in [Xia, Theorem 7.1.1] states that the following three conditions are equivalent:

u lies in the d_S -closure of analytic singularities,

$$\int_X \text{MA}_\theta(u) = \int_X \text{MA}_\theta(P_\theta[u]_{\mathcal{I}}),$$

$$P_\theta[u] = P_\theta[u]_{\mathcal{I}}.$$

The last condition involves only envelopes. It therefore offers a starting point for the Hermitian problem even where the metric and the mass characterizations are unavailable.

The integral on the right of the middle condition is the *multiplier-ideal volume* of [Xia]. The upper and lower volumes of **Definition 12.3.1**, by contrast, vary the potential within its ordinary singularity type. The distinction matters in a nonclosed background, where even a bounded change of the potential can alter its total mass.

15.2 Ideal projection

We return to the general setting fixed at the beginning of the chapter. The multiplier-ideal envelope is the greatest nonpositive potential in a multiplier-ideal class. Taking a supremum over the class could a priori enlarge the multiplier ideals; the increasing-limit form of strong openness rules this out, and the envelope is then a projection onto the class.

Definition 15.2.1 For $u \in \text{PSH}(X, \theta)$ define

$$P_\theta[u]_{\mathcal{I}} := (\sup\{v \in \text{PSH}(X, \theta) : v \leq 0, v \sim_{\mathcal{I}} u\})^*.$$

As for ordinary envelopes, the members of the defining family are called *competitors*. The family is nonempty because it contains $u - \sup_X u$; bounded perturbations do not change multiplier ideals. Since it is bounded above by zero, its regularized supremum is a θ -plurisubharmonic function. The envelope depends only on the multiplier-ideal class of u .

Theorem 15.2.1 For every $u \in \text{PSH}(X, \theta)$,

$$P_\theta[u]_{\mathcal{I}} \sim_{\mathcal{I}} u, \quad P_\theta[P_\theta[u]_{\mathcal{I}}]_{\mathcal{I}} = P_\theta[u]_{\mathcal{I}}.$$

The regularization in **Definition 15.2.1** does not change the pointwise supremum. Moreover,

$$\sup_X P_\theta[u]_I = 0.$$

Proof Write $q = P_\theta[u]_I$. By Choquet's lemma, some sequence from the defining family has regularized supremum q . Replacing its terms by successive finite maxima, we obtain by [Lemma 1.16.3](#) an increasing sequence v_j that remains in the family and converges to q almost everywhere.

Fix $x \in X$ and $\lambda > 0$. On a coordinate ball about x , choose one smooth function r such that every $v_j + r$ and $q + r$ is plurisubharmonic; this is possible because all these functions have complex Hessian bounded below by the same smooth form $-\theta$. The increasing-limit assertion of [Theorem 1.16.1](#) gives

$$I(\lambda(q + r))_x = I(\lambda(v_j + r))_x = I(\lambda u)_x$$

for all large j ; the second equality holds because smooth additions do not change multiplier ideals. Hence $q \sim_I u$.

Since $q \leq 0$, it belongs to its own defining family. The pointwise supremum is therefore at least q , and it is at most its regularization q ; this proves the assertion about regularization. The defining families for $P_\theta[q]_I$ and $P_\theta[u]_I$ coincide, which proves idempotence. Finally, if $\sup_X q < 0$, then $q - \sup_X q$ would be a larger competitor, which is impossible. $\square$

Proposition 15.2.1 *For every $u \in \text{PSH}(X, \theta)$,*

$$u - \sup_X u \leq P_\theta[u] \leq P_\theta[u]_I \leq V_\theta.$$

Moreover,

$$\begin{aligned} P_\theta[u] &\sim_I u, & P_\theta[P_\theta[u]]_I &= P_\theta[u]_I, \\ P_\theta[P_\theta[u]_I] &= P_\theta[u]_I. \end{aligned}$$

Proof Let $h \leq 0$ be a competitor for the ordinary envelope, so that $h \preceq u$. The function $\max(h, u - \sup_X u)$ is nonpositive, ordinarily equivalent to u , and dominates h . Since ordinarily equivalent potentials have the same multiplier ideals, it is a competitor for the ideal envelope. Taking regularized suprema gives $P_\theta[u] \leq P_\theta[u]_I$; the two outer inequalities follow directly from the defining families.

Projection and monotonicity of local integrability now give, for every $\lambda > 0$,

$$I(\lambda u) \subseteq I(\lambda P_\theta[u]) \subseteq I(\lambda P_\theta[u]_I) = I(\lambda u).$$

Thus the ordinary envelope preserves all multiplier ideals, and it has the same ideal envelope as u . For $q = P_\theta[u]_I$, the inequalities already proved and idempotence give $q \leq P_\theta[q] \leq P_\theta[q]_I = q$. $\square$

We call $u \in \text{PSH}(X, \theta)$ *normalized* if $\sup_X u = 0$. Recall from [Definition 1.19.1](#) that u is an ordinary model, or envelope fixed point, if $P_\theta[u] = u$; we call u an *ideal model* if $P_\theta[u]_I = u$. Models of either kind are normalized, and by the last identity in [Proposition 15.2.1](#) every ideal model is an ordinary model. The map $u \mapsto P_\theta[u]_I$ is called *ideal projection*.

Corollary 15.2.1 *If θ is semipositive and big, then $P_\theta[u]_{\mathcal{I}}$ has finite extended Monge–Ampère mass for every $u \in \text{PSH}(X, \theta)$.*

Proof By the last identity in [Proposition 15.2.1](#), $P_\theta[u]_{\mathcal{I}}$ is an ordinary model, that is, an envelope fixed point. The mass estimate for envelope fixed points in [Proposition 12.1.4](#) applies. $\square$

Proposition 15.2.2 *For $u, v \in \text{PSH}(X, \theta)$,*

$$u \preceq_{\mathcal{I}} v \implies P_\theta[u]_{\mathcal{I}} \leq P_\theta[v]_{\mathcal{I}}.$$

For $a > 0$ one has $P_{a\theta}[au]_{\mathcal{I}} = aP_\theta[u]_{\mathcal{I}}$. For smooth real $(1, 1)$ -forms θ_i and potentials $u_i \in \text{PSH}(X, \theta_i)$, $i = 1, 2$,

$$P_{\theta_1}[u_1]_{\mathcal{I}} + P_{\theta_2}[u_2]_{\mathcal{I}} \leq P_{\theta_1 + \theta_2}[u_1 + u_2]_{\mathcal{I}}.$$

Proof Let h be a competitor for $P_\theta[u]_{\mathcal{I}}$. Since $h \sim_{\mathcal{I}} u \preceq_{\mathcal{I}} v$, the Lelong-number criterion in [Theorem 1.16.1](#) shows that $\max(h, v - \sup_X v)$ is multiplier-ideal equivalent to v . This function is nonpositive and dominates h , so it is a competitor for $P_\theta[v]_{\mathcal{I}}$; taking the supremum over h proves that the envelope preserves the order. Multiplication by a is a bijection between the defining families in the scaling identity. For the sum, $P_{\theta_1}[u_1]_{\mathcal{I}} + P_{\theta_2}[u_2]_{\mathcal{I}}$ is nonpositive and $(\theta_1 + \theta_2)$ -plurisubharmonic, and it is multiplier-ideal equivalent to $u_1 + u_2$ by projection and [Lemma 1.16.3](#). It is therefore a competitor for the envelope on the right. $\square$

15.2.1 Analytic and divisorial singularities

For a potential a with analytic singularities, the multiplier-ideal order controls the ordinary order: by [Lemma 1.17.9](#), every quasi-plurisubharmonic v with $v \preceq_{\mathcal{I}} a$ satisfies $v \preceq a$. The ideal envelope of a is then a competitor for its ordinary envelope, and the two envelopes coincide. This extends [[Xia](#), Proposition 3.2.10] to smooth backgrounds.

Proposition 15.2.3 *Let $a \in \text{PSH}(X, \theta)$ have analytic singularities. Then*

$$a \sim P_\theta[a] = P_\theta[a]_{\mathcal{I}}.$$

In particular the common envelope has analytic singularities with the same coefficient and ideal as a , up to a bounded remainder.

Proof Set $q = P_\theta[a]_{\mathcal{I}}$. Projection gives $q \sim_{\mathcal{I}} a$, so [Lemma 1.17.9](#) gives $q \preceq a$. Since $q \leq 0$, it is a competitor for $P_\theta[a]$. Together with [Proposition 15.2.1](#), this yields

$$a - \sup_X a \leq P_\theta[a] \leq q \leq P_\theta[a].$$

Hence the two envelopes are equal and ordinarily equivalent to a . Since they differ from a by a bounded function, they inherit its analytic presentation. $\square$

The same argument applies to the potential of a countable divisorial current of finite mass, with [Lemma 1.17.4](#) in place of [Lemma 1.17.9](#).

Corollary 15.2.2 *Let S be a closed positive divisorial current of finite mass on a connected compact complex manifold Z , and choose a smooth residual decomposition $S = \beta + dd^c v$ as in [Corollary 1.17.1](#). For every Hermitian form Ω with $v \in \text{PSH}(Z, \Omega)$,*

$$P_\Omega[v] = P_\Omega[v]_I \sim v.$$

Proof Set $q = P_\Omega[v]_I$. Projection gives $q \sim_I v$, and [Lemma 1.17.4](#) gives $q \preceq v$. Thus q is a competitor for $P_\Omega[v]$. Together with [Proposition 15.2.1](#), this yields $v - \sup_Z v \leq P_\Omega[v] = q \preceq v$. $\square$

15.3 Changes of background and envelope mass

A smooth change of representative $(\theta, u) \mapsto (\theta + dd^c f, u - f)$ preserves the current $\theta + dd^c u$ but moves the zero obstacle. The resulting envelopes remain ordinarily equivalent after transport. In a nonclosed background, however, their masses can differ.

Proposition 15.3.1 *Let $u \in \text{PSH}(X, \theta)$ and $f \in C^\infty(X, \mathbb{R})$. Set $\theta' = \theta + dd^c f$, $u' = u - f$, $m = \min_X f$ and $M = \max_X f$. Then*

$$P_\theta[u]_I + m \leq P_{\theta'}[u']_I + f \leq P_\theta[u]_I + M.$$

The same inequalities hold for the ordinary envelopes.

Proof If v is a competitor for $P_\theta[u]_I$, then $v - f + m$ is θ' -plurisubharmonic, nonpositive and multiplier-ideal equivalent to u' . Therefore $v \leq P_{\theta'}[u']_I + f - m$, and taking the envelope gives the first inequality. Conversely, a competitor v' in the new background gives the competitor $v' + f - M$ in the old one, which proves the second inequality. For the ordinary envelopes, the same calculation applies with the ordinary singularity order in place of multiplier-ideal equivalence. $\square$

For $u \in \text{PSH}(X, \theta)$, put

$$W_\theta(u) = \int_X \text{MA}_\theta(P_\theta[u]_I) \in [0, +\infty].$$

This quantity depends on the decomposition of the current, even for smooth potentials.

Proposition 15.3.2 *There are two smooth decompositions of the same positive current for which the corresponding values of W are different.*

Proof Use the Hermitian form ω and the smooth function $g = u_t$ of [Example 2.3.1](#), with $t \neq 0$ sufficiently small. Both ω and $\omega' = \omega + \text{dd}^c g$ are Hermitian, and

$$\omega + \text{dd}^c 0 = \omega' + \text{dd}^c (-g).$$

For a smooth potential in a Hermitian background, all multiplier ideals are trivial and zero is a competitor for its multiplier-ideal envelope, so that envelope is zero. Consequently

$$W_\omega(0) = \int_X \omega^2, \quad W_{\omega'}(-g) = \int_X (\omega + \text{dd}^c g)^2.$$

By the explicit formula [\(2.3\)](#), the two integrals differ. $\square$

The underlying torus is Kähler; the dependence comes from the chosen nonclosed background. In the closed theory, the invariance of mass under bounded changes of the potential gives the missing step after [Proposition 15.3.1](#).

Singularity volumes, on the other hand, range over the entire ordinary type, so the bijection of competitors in the gauge change preserves them. Under bounded mass, [Proposition 29.9.1](#) accordingly transports ordinary models of positive volume and preserves their upper-volume comparison.

15.3.1 Envelope equality and infinite mass

For each $u \in \text{PSH}(X, \theta)$, the equality

$$P_\theta[u] = P_\theta[u]_{\mathcal{I}} \tag{15.1}$$

is meaningful. We call it *envelope goodness in the fixed background*. Its relation to mass differs from the Kähler characterization: it can hold when the potential has infinite mass while its envelope has finite mass.

Proposition 15.3.3 *If a Hermitian metric ω fails the bounded mass property of [Definition 6.5.1](#), there exists $U \in \text{PSH}(X, \omega)$ such that*

$$P_\omega[U] = P_\omega[U]_{\mathcal{I}} = 0, \quad U \in \mathcal{E}_{\text{env}}(X, \omega, 0), \quad \text{MA}_\omega^{\text{ext}}(U)(X) = +\infty,$$

where $\mathcal{E}_{\text{env}}(X, \omega, 0)$ is the relative envelope class of [Definition 12.4.1](#).

Proof Take the potential U of [Proposition 12.6.1](#), which has the stated ordinary envelope, class membership and infinite mass. Since $P_\omega[U] = V_\omega = 0$, [Proposition 15.2.1](#) gives $P_\omega[U]_{\mathcal{I}} = 0$. $\square$

15.4 L^1 geometry of ideal classes

Ideal projection selects a canonical representative of each multiplier-ideal class, so the L^1 distance between these representatives defines a metric on the classes. Since the representatives have supremum zero, normalized compactness makes this metric totally bounded and its completion compact. The points added in the completion, however, need not be ideal models. On a curve this happens as badly as possible: approximating curvature measures by finite atomic measures shows that the completion contains every normalized potential.

Let

$$\mathfrak{S}_I(X, \theta) = \text{PSH}(X, \theta) / \sim_I, \quad \mathfrak{M}_I(X, \theta) = \{q \in \text{PSH}(X, \theta) : P_\theta[q]_I = q\}$$

be the set of multiplier-ideal classes and the set of ideal models, and write $[u]_I$ for the multiplier-ideal class of u . By [Theorem 15.2.1](#), the map $[u]_I \mapsto P_\theta[u]_I$ identifies these two sets, and every ideal envelope has supremum zero.

Proposition 15.4.1 *The formula*

$$d_{I, \theta, dV}([u]_I, [v]_I) = \int_X |P_\theta[u]_I - P_\theta[v]_I| dV \quad (15.2)$$

defines a finite metric on $\mathfrak{S}_I(X, \theta)$. This metric space is totally bounded. Its metric completion is canonically the L^1 closure of $\mathfrak{M}_I(X, \theta)$ inside the compact space $\mathcal{K}_\theta$ of normalized θ -plurisubharmonic functions in [Theorem 1.4.1](#). Changing dV to another smooth positive probability volume form gives a bi-Lipschitz equivalent metric.

Proof The ideal envelopes are integrable and depend only on the ideal classes, so the formula is well defined and finite; symmetry and the triangle inequality are those of the L^1 norm. If the distance is zero, the two envelopes agree almost everywhere, hence everywhere by [Lemma 1.3.3](#), and projection shows that the two ideal classes coincide. Conversely, equal ideal classes have the same envelope.

By the normalized compactness theorem, $\mathfrak{M}_I$ lies in the compact space $\mathcal{K}_\theta$. Every subset of a compact metric space is totally bounded, and its completion is its closure in that space. Finally, the ratio of two smooth positive volume forms on the compact manifold X is bounded above and below by positive constants, and multiplying the integral by these bounds proves the last assertion. $\square$

15.4.1 Completion on a curve

On a curve, a normalized potential is determined by its curvature measure. Replacing that measure by finite atomic approximations produces ideal models converging to the potential, even when the potential itself is not an ideal model.

Theorem 15.4.1 *Let Y be a compact connected Riemann surface and θ a smooth positive form of total mass one. Fix a smooth positive probability volume form on Y , again denoted by dV , and use $\mathcal{K}_\theta$, the envelopes and the ideal metric on Y in place of X . Then the ideal models with finitely many logarithmic poles and zero non-pluripolar mass are dense in $\mathcal{K}_\theta$ for the L^1 topology. The logarithmic coefficients can be chosen rational, so these approximants have analytic singularities in the convention of [Xia]. Consequently the completion in Proposition 15.4.1 is all of $\mathcal{K}_\theta$, and the metric on ideal classes is not complete.*

Proof We first show that the normalized Green potentials of finite atomic probability measures are ideal models, and then approximate the curvature measure of an arbitrary $u \in \mathcal{K}_\theta$ by such measures.

Let δ_p denote the Dirac mass at p . For distinct points $p_1, \dots, p_N \in Y$, consider a finitely supported probability measure

$$\nu = \sum_{j=1}^N a_j \delta_{p_j}, \quad a_j > 0, \quad \sum_j a_j = 1.$$

The Green-kernel construction gives a potential q_ν with

$$\theta + dd^c q_\nu = \nu, \quad \sup_Y q_\nu = 0.$$

Indeed, choose a kernel with $dd_x^c G(x, p) = \delta_p - \theta$. The sum $\sum_j a_j G(x, p_j)$ has curvature ν , and subtracting its finite supremum gives q_ν . In a coordinate z centered at p_j , the function q_ν is $a_j \log |z|^2$ plus a smooth function, and it is smooth away from the finite support of ν . Since all of its curvature lies on its pole set, its non-pluripolar measure is zero.

We claim that $P_\theta[q_\nu]_{\mathcal{I}} = q_\nu$. Let $w \in \text{PSH}(Y, \theta)$ satisfy $w \sim_{\mathcal{I}} q_\nu$. The Lelong-number criterion of Theorem 1.16.1 gives $\nu(w, p_j) = a_j$, where $\nu(w, p_j)$ is the Lelong number of w at p_j . On a curve, this Lelong number is exactly the mass of the atom at p_j of the positive measure $\theta + dd^c w$. By distributional Stokes, that measure has total mass one, so the prescribed atoms already exhaust its mass and $\theta + dd^c w = \nu$. Thus $dd^c(w - q_\nu) = 0$, and the difference is a harmonic distribution, hence a smooth function that is constant on the compact connected curve. Among these translates, the greatest nonpositive one is q_ν , which proves the claim. By Proposition 15.2.1, every such q_ν is also an ordinary model.

Now let $u \in \mathcal{K}_\theta$. Its curvature $\nu = \theta + dd^c u$ is a positive probability measure. Choose finitely supported probability measures ν_j converging weakly to ν . For instance, partition the compact metric space Y into finitely many Borel sets of diameter tending to zero, place the mass of each set at a chosen point of it, and omit the sets of mass zero; uniform continuity of each continuous test function gives weak convergence.

The weights can be made rational. For a partition with weights $a_1, \dots, a_N$, choose a large integer M , replace a_i by $b_i = \lfloor Ma_i \rfloor / M$ for $i < N$, put $b_N = 1 - \sum_{i < N} b_i$, and discard zero weights. The total absolute change is at most $2(N-1)/M$, which

can be made to tend to zero along the partitions, so weak convergence is preserved. Writing $b_i = m_i/M$, the corresponding Green potential has the analytic type

$$\left(\frac{1}{M}, O_Y \left(- \sum_i m_i p_i \right) \right)$$

with smooth local remainders.

Let $q_j = q_{\nu_j}$. By normalized compactness, every subsequence has a further subsequence converging in L^1 to some $q \in \mathcal{K}_\theta$. Passing to the limit in the curvature identity in the sense of distributions gives

$$\theta + \text{dd}^c q = \nu = \theta + \text{dd}^c u.$$

By the same harmonic argument, $q - u$ is constant, and the constant is zero because both suprema vanish. Every cluster value is therefore u , so the whole sequence converges to u in L^1 . This proves the density assertion and identifies the completion.

To see incompleteness concretely, choose a nonconstant smooth real function f . For sufficiently small $\varepsilon > 0$, one has $\theta + \varepsilon \text{dd}^c f > 0$, so $u = \varepsilon f - \sup_Y(\varepsilon f)$ is a smooth, normalized and nonconstant element of $\mathcal{K}_\theta$. Its multiplier ideals are all trivial, so zero is a competitor and $P_\theta[u]_I = 0$. Thus $u \notin \mathfrak{M}_I(Y, \theta)$, although u lies in the completion. The set of ideal models is therefore not closed in its completion, and the metric is not complete. $\square$

15.4.2 Mass and capacity convergence

The approximation in [Theorem 15.4.1](#) loses all non-pluripolar mass. For the nonconstant smooth u at the end of its proof, the approximants q_j have zero non-pluripolar measure, whereas $\text{MA}_\theta(u) = \theta + \text{dd}^c u > 0$.

After normalization to mean zero, the same sequence converges in the Gauduchon trace metric of [Corollary 5.2.1](#). Nevertheless, the sequence q_j does not converge to u in capacity. Otherwise, since $q_j, u \leq 0$, [Theorem 7.3.1](#) would give

$$0 = e^{q_j} \text{MA}_\theta(q_j) \rightarrow e^u (\theta + \text{dd}^c u),$$

contradicting the strict positivity of the limiting measure. Thus weak convergence of traces and L^1 convergence do not imply convergence in capacity, even on a curve.

The same sequence shows that ideal projection is not continuous for the L^1 topology: $P_\theta[q_j]_I = q_j \rightarrow u$, whereas $P_\theta[u]_I = 0$. The completion therefore distinguishes smooth normalized potentials that the quotient by multiplier-ideal equivalence identifies.

The loss of mass also occurs along sequences of fixed positive mass.

Proposition 15.4.2 *In the curve setting above, for every rational $0 < \tau < 1$ there are ideal models r_j with analytic singularities such that*

$$\begin{aligned} d_{\mathcal{I}, \theta, \text{dV}}([r_j]_{\mathcal{I}}, [0]_{\mathcal{I}}) &\longrightarrow 0, \\ \text{MA}_{\theta}(r_j)(Y) &= \tau, \quad \text{MA}_{\theta}(r_j) \rightharpoonup \tau\theta. \end{aligned}$$

In particular, non-pluripolar mass is not continuous for this metric, even on a family whose masses have a fixed positive lower bound.

Proof Choose finitely supported probability measures ν_j with rational weights converging weakly to θ , and let q_j be their normalized Green potentials; the preceding proof gives $q_j \rightarrow 0$ in L^1 . Put $a = 1 - \tau$ and $r_j = P_{\theta}[aq_j]_{\mathcal{I}}$. The scaled potential lies in the same background, since

$$\theta + \text{dd}^c(aq_j) = (1 - a)\theta + a\nu_j \geq 0.$$

Since aq_j is a competitor, $aq_j \leq r_j \leq 0$, and hence $r_j \rightarrow 0$ in L^1 . By projection, r_j is an ideal model. By [Proposition 15.2.3](#), it has exactly the logarithmic coefficients of aq_j , which are rational, with bounded local remainders, and it is locally bounded away from the finite pole set. On the curve, removing the polar part of the curvature therefore gives

$$\text{MA}_{\theta}(r_j) = \theta + \text{dd}^c r_j - a\nu_j.$$

By distributional Stokes, this measure has total mass $1 - a = \tau$. The positive curvature measures $\theta + \text{dd}^c r_j$ have mass one and converge as distributions, hence weakly, to θ . Since $\nu_j \rightharpoonup \theta$, the last identity gives $\text{MA}_{\theta}(r_j) \rightharpoonup \tau\theta$. Finally, $P_{\theta}[0]_{\mathcal{I}} = 0$, so the distance in the statement is $\int_Y |r_j| \text{dV}$, which tends to zero. The limiting potential 0 has non-pluripolar measure θ , of mass one. $\square$

For comparison, let $d_{S, \theta}$ denote the singularity pseudometric d_S recalled at the beginning of the chapter, computed in the background θ . Since $r_j \leq 0$, the ordered-distance formula of [\[Xia, Lemma 6.2.2\]](#) applies and gives

$$d_{S, \theta}(r_j, 0) = \frac{1}{2} \left(\int_Y \theta - \int_Y \text{MA}_{\theta}(r_j) \right) = \frac{1 - \tau}{2} > 0.$$

Thus $d_{S, \theta}$ keeps the fixed mass gap that disappears in the elementary ideal metric.

15.4.3 Comparison with scalar normalization

We return to X of arbitrary dimension, with the fixed volume form dV . The scalar pseudometric Δ of (14.16) compares the normalization scalars B_φ of Section 14.1 uniformly over all continuous logarithmic densities. When an analytic singularity is shrunk to zero, the estimate in a smaller background makes this scalar distance tend to zero. At a fixed mass, however, the normalization scalar in a closed background does not see the location of the poles.

Example 15.4.1 Let θ be semipositive and big, and let $a \in \text{PSH}(X, \theta)$ have analytic singularities with $a \leq 0$. Use the normalization scalars B_φ and the sets $\mathcal{A}_\varphi(G)$ of supporting probabilities from Sections 14.1 and 14.2, defined with the fixed volume form dV . Set

$$\varphi_t = P_\theta[ta], \quad t \in \mathbb{Q} \cap (0, 1).$$

By Proposition 15.2.3, $\varphi_t \sim ta$; since the ordinary envelope depends only on the ordinary type, $P_\theta[\varphi_t] = \varphi_t$. Moreover $ta \in \text{PSH}(X, t\theta)$ and $ta \leq \varphi_t$, so the envelope $P_{t\theta}(\varphi_t)$ in the smaller background is not identically $-\infty$. By Proposition 14.7.1,

$$\sup_{G \in C(X)} |B_{\varphi_t}(G) - B_0(G)| \leq -n \log(1 - t) \longrightarrow 0 \quad (t \downarrow 0).$$

When θ is Hermitian and G is fixed and smooth, every choice in $\mathcal{A}_{\varphi_t}(G)$ converges weakly in L^1 to the smooth Gauduchon adjoint probability, by Corollary 14.7.1 and Theorem 14.2.3.

By contrast, the projective references in Example 14.10.1 have equal mass and identical normalization functionals, although their poles and multiplier ideals differ.

15.5 Limits of analytic envelopes

By the curve construction of Theorem 15.4.1, convergence of potentials alone does not determine the limit of their ideal envelopes. Two further conditions do: a common lower bound in the multiplier-ideal order, and convergence of all divisorial Lelong numbers. Together they force every cluster value of the envelopes to have the multiplier ideals of the limiting potential, and maximality of the envelope then identifies the cluster value. The dyadic analytic approximants satisfy both conditions.

In this section, θ is again an arbitrary smooth real $(1, 1)$ -form. We fix $u \in \text{PSH}(X, \theta)$ and a Hermitian form h on X , which will absorb the curvature errors of the approximants. Recall from Section 1.17 that a local divisor E over X is a prime divisor on a smooth modification π of a coordinate neighborhood in X , and that $\nu_E(u) = \nu(u \circ \pi, E)$ is the generic Lelong number of the pullback of u along E .

Proposition 15.5.1 *Let $\epsilon_j \geq 0$ tend to zero, and let $a_j \in \text{PSH}(X, \theta + \epsilon_j h)$ satisfy*

$$u \preceq_{\mathcal{I}} a_j, \quad v_E(a_j) \longrightarrow v_E(u) \quad \text{for every local divisor } E \text{ over } X.$$

Then

$$P_{\theta + \epsilon_j h}[a_j]_{\mathcal{I}} \longrightarrow P_{\theta}[u]_{\mathcal{I}} \quad \text{in } L^1.$$

If the a_j have analytic singularities, their ordinary envelopes converge to $P_{\theta}[u]$ in L^1 if and only if $P_{\theta}[u] = P_{\theta}[u]_{\mathcal{I}}$.

Proof Set $p = P_{\theta}[u]_{\mathcal{I}}$ and $q_j = P_{\theta + \epsilon_j h}[a_j]_{\mathcal{I}}$. Projection and the ideal order give

$$p \leq P_{\theta + \epsilon_j h}[p]_{\mathcal{I}} \leq q_j \leq 0.$$

The first inequality holds because p is a competitor in the larger background, and the second follows from **Proposition 15.2.2**, since $p \sim_{\mathcal{I}} u \preceq_{\mathcal{I}} a_j$. All q_j have supremum zero and belong to $\text{PSH}(X, \theta + Ch)$ for a fixed $C \geq \sup_j \epsilon_j$. By normalized compactness, every subsequence therefore has a further subsequence converging in L^1 . Let q be such a limit. Passing to the limit in the current inequalities gives $q \in \text{PSH}(X, \theta)$, and **Lemma 1.3.3** gives $p \leq q \leq 0$.

Fix a local modification $\pi : Z \rightarrow U$ and a prime divisor $E \subset Z$. By **Lemma 1.22.3**, the chosen subsequence still converges in L^1_{loc} after pullback. Since $q_j \sim_{\mathcal{I}} a_j$, the two functions have the same divisorial Lelong numbers, and the pointwise semicontinuity in **Lemma 1.17.5** yields

$$v_E(q) \geq \limsup_j v_E(q_j) = \lim_j v_E(a_j) = v_E(u).$$

Indeed, at every point of E the pullback of each q_j has Lelong number at least $v_E(q_j)$; it remains to apply the pointwise inequality at a point of E where the pullback of q has Lelong number $v_E(q)$. On the other hand, $p \leq q$ gives $v_E(q) \leq v_E(p) = v_E(u)$. Thus q and u have the same Lelong numbers along all local divisors. Blowing up a point of any local modification recovers the pointwise Lelong number there as a generic divisorial number; on a curve the point is already a divisor. By **Theorem 1.16.1**, $q \sim_{\mathcal{I}} u$.

Consequently q is a competitor for p , so $q \leq p$. Every cluster value is therefore p , which proves convergence of the whole sequence. For analytic a_j , **Proposition 15.2.3** identifies the ordinary and ideal envelopes, and the last assertion follows from uniqueness of L^1 limits and **Lemma 1.3.3**. $\square$

The divisorial convergence follows from inclusions of multiplier ideals at fixed weights. The local Bergman estimate bounds the error in terms of the log discrepancy, and this error tends to zero after division by the weight.

Corollary 15.5.1 *Let $\epsilon_j \geq 0$ tend to zero, and let $a_j \in \text{PSH}(X, \theta + \epsilon_j h)$ satisfy $u \preceq_I a_j$. Suppose that, for every integer $m \geq 1$ and every $\delta > 0$,*

$$I((1 + \delta)ma_j) \subseteq I(mu) \quad \text{for all sufficiently large } j.$$

Then the conclusions of Proposition 15.5.1 hold.

Proof Fix a local divisor E over a coordinate neighborhood U , and write $A = A_U(E)$ for its log discrepancy. By Lemma 1.17.7, the assumed inclusion implies

$$(1 + \delta)m\nu_E(a_j) \geq \text{ord}_E I((1 + \delta)ma_j) \geq \text{ord}_E I(mu) \geq m\nu_E(u) - A$$

for all large j . Taking the lower limit in j first, and then letting $m \rightarrow \infty$ and $\delta \downarrow 0$, we obtain $\liminf_j \nu_E(a_j) \geq \nu_E(u)$. The opposite inequality $\nu_E(a_j) \leq \nu_E(u)$ holds for every j because $u \preceq_I a_j$. Hence Proposition 15.5.1 applies. $\square$

The common ideal bound cannot be omitted, even when all divisorial Lelong numbers converge. In the atomic approximation of Theorem 15.4.1, every individual atom can tend to zero while the limiting potential is not an ideal model.

Example 15.5.1 On a compact connected curve Y with a positive form θ of total mass one, there are normalized $a_j \in \text{PSH}(Y, \theta)$ with analytic singularities and a smooth $u \in \text{PSH}(Y, \theta)$ such that

$$a_j \rightarrow u \text{ in } L^1, \quad \nu_E(a_j) \rightarrow \nu_E(u) \text{ for every local divisor } E,$$

but $P_\theta[a_j] = P_\theta[a_j]_I \rightarrow u \neq P_\theta[u] = P_\theta[u]_I$ in L^1 .

Proof Choose u smooth, nonconstant and normalized, with $\theta + \text{dd}^c u > 0$, and apply the construction in Theorem 15.4.1 to the smooth probability measure $\nu = \theta + \text{dd}^c u$. Since ν has no atoms, the largest mass of a cell tends to zero along partitions of vanishing diameter. Choose the rational approximations of the weights so that their total absolute error tends to zero. The resulting atomic probability measures ν_j converge weakly to ν , and their largest atoms tend to zero.

By the same theorem, their normalized Green potentials a_j have analytic singularities, satisfy $P_\theta[a_j] = P_\theta[a_j]_I = a_j$, and converge to u in L^1 . At every point $y \in Y$,

$$0 \leq \nu(a_j, y) = \nu_j(\{y\}) \leq \max_{z \in Y} \nu_j(\{z\}) \rightarrow 0 = \nu(u, y).$$

Since local modifications of a smooth curve are isomorphisms, this gives all the required divisorial limits. As u is bounded and $\theta > 0$, both of its envelopes are zero, and since u is not constant, the envelopes do not converge to them. Each a_j has a logarithmic pole, so $u \preceq_I a_j$ fails. $\square$

15.5.1 Dyadic regularization

Demailly regularization provides the common ideal bound, since its approximants lie above u , and the Bergman estimate gives convergence of each divisorial Lelong number. Along dyadic indices, subadditivity of multiplier ideals also orders the ordinary singularity types of the approximants, which makes their envelopes decrease pointwise. This is the mechanism used in [Xia, Theorem 7.1.1, proof of (3) $\Rightarrow$ (1), Step 1].

Apply **Theorem 1.15.1** to u , with $\gamma = -\theta$, along the indices $m_j = 2^j$, starting at a sufficiently large index. Denote the resulting potentials by a_j , and choose numbers $\epsilon_j > 0$ decreasing to zero such that

$$a_j \in \text{PSH}(X, \theta + \epsilon_j h), \quad a_j \geq u, \quad a_j \text{ has type } (1/m_j, \mathcal{I}(m_j u)). \quad (15.3)$$

These approximants satisfy $a_j \rightarrow u$ in L^1 . Their values need not decrease, but their ordinary singularity types do: the subadditivity property in (1.21) gives

$$\mathcal{I}(2m_j u) \subseteq \mathcal{I}(m_j u)^2, \quad a_{j+1} \preceq a_j,$$

where the ordinary comparison follows by taking logarithms of local generators, with a constant that may depend on j .

Theorem 15.5.1 *For every $u \in \text{PSH}(X, \theta)$ and every choice in (15.3), put*

$$q_j = P_{\theta + \epsilon_j h}[a_j].$$

Then q_j has analytic singularities, and

$$q_j = P_{\theta + \epsilon_j h}[a_j]_{\mathcal{I}} \searrow P_{\theta}[u]_{\mathcal{I}}$$

pointwise and in L^1 . The limit is independent of the choice of the approximants a_j , of the error bounds ϵ_j and of the metric h .

Proof By **Proposition 15.2.3**, $q_j = P_{\theta + \epsilon_j h}[a_j]_{\mathcal{I}} \sim a_j$. Since the backgrounds decrease and $a_{j+1} \preceq a_j$, the function q_{j+1} is a competitor for $P_{\theta + \epsilon_j h}[a_j]$. Hence $q_{j+1} \leq q_j$.

The inequality $a_j \geq u$ gives $u \preceq_{\mathcal{I}} a_j$. For every local divisor E , **Lemma 1.17.7** gives

$$v_E(a_j) = \frac{1}{m_j} \text{ord}_E \mathcal{I}(m_j u) \longrightarrow v_E(u).$$

By **Proposition 15.5.1**, $q_j \rightarrow p := P_{\theta}[u]_{\mathcal{I}}$ in L^1 , and $p \leq q_j \leq 0$. The decreasing limit of the q_j is therefore bounded below by p ; it is a θ -plurisubharmonic function that agrees with p almost everywhere, hence everywhere. This identifies the limit in terms of θ and the multiplier-ideal class of u alone, which proves the asserted independence. $\square$

Corollary 15.5.2 *For the sequence above, the following are equivalent:*

$$P_\theta[u] = P_\theta[u]_I, \quad q_j \longrightarrow P_\theta[u] \text{ in } L^1, \quad q_j \searrow P_\theta[u] \text{ pointwise.}$$

They hold for one choice in (15.3) if and only if they hold for every such choice. For the fixed volume form dV ,

$$\lim_j \int_X (q_j - P_\theta[u]) dV = \int_X (P_\theta[u]_I - P_\theta[u]) dV \geq 0,$$

and the vanishing of this limit is a further equivalent condition.

Proof The theorem identifies both limits of the q_j as $P_\theta[u]_I$ for every such choice, and its L^1 convergence gives the integral formula. By Proposition 15.2.1, the limiting difference is nonnegative. Its integral therefore vanishes exactly when the two envelopes agree almost everywhere, hence everywhere by Lemma 1.3.3. This proves all the equivalences. $\square$

15.5.2 Absorbing the curvature error

When $\theta = \omega$ is Hermitian, we can take $h = \omega$, and dividing the approximants by $1 + \epsilon_j$ absorbs the curvature error. If the error bounds are rational, the analytic coefficients remain rational, so the whole approximation takes place in the fixed class $\text{PSH}(X, \omega)$.

Corollary 15.5.3 *Let ω be Hermitian and let $u \in \text{PSH}(X, \omega)$. There are $b_j \in \text{PSH}(X, \omega)$ with analytic singularities and decreasing ordinary singularity types, such that $b_j \rightarrow u$ in L^1 and*

$$P_\omega[b_j] = P_\omega[b_j]_I \searrow P_\omega[u]_I.$$

Consequently the classes of potentials with analytic singularities are dense in the whole metric space of ideal classes of Proposition 15.4.1. The equality $P_\omega[u] = P_\omega[u]_I$ is equivalent to convergence of these ordinary envelopes to $P_\omega[u]$ in L^1 .

Proof Use $h = \omega$ in (15.3). Enlarge the error bounds to positive rational numbers $\epsilon_j \downarrow 0$, and set

$$c_j = \frac{1}{1 + \epsilon_j}, \quad b_j = c_j a_j.$$

Then $c_j \uparrow 1$ is rational and

$$\omega + \text{dd}^c b_j = c_j((1 + \epsilon_j)\omega + \text{dd}^c a_j) \geq 0.$$

The analytic coefficient of b_j is c_j/m_j . Moreover $b_j \rightarrow u$ in L^1 , since $a_j \rightarrow u$ there and the sequence has bounded L^1 norm. Because $a_{j+1} \preceq a_j$, $c_{j+1} \geq c_j$, and each a_j is bounded above, one has $b_{j+1} \preceq b_j$.

Put $q_j = P_{(1+\epsilon_j)\omega}[a_j] = P_{(1+\epsilon_j)\omega}[a_j]_I$. The preceding theorem gives $q_j \searrow P_\omega[u]_I$ pointwise and in L^1 . Since b_j has analytic singularities, [Proposition 15.2.3](#) and the homogeneity in [Proposition 15.2.2](#) give

$$r_j := P_\omega[b_j] = P_\omega[b_j]_I = c_j q_j.$$

Here $q_j \leq 0$ decreases and $c_j \uparrow 1$, so r_j also decreases, with pointwise limit $P_\omega[u]_I$. Moreover

$$P_\omega[u]_I \leq q_j \leq r_j \leq 0.$$

Since the lower bound is integrable, dominated convergence gives convergence in L^1 .

The distance in [Proposition 15.4.1](#) from $[b_j]_I$ to $[u]_I$ is exactly the L^1 distance from r_j to $P_\omega[u]_I$, so it tends to zero. The last assertion follows because the limit of the r_j has been identified. $\square$

15.6 A topology on ordinary singularity types

The ordinary and the ideal envelope of a potential record different parts of its singularity. If a topology on ordinary singularity types requires both envelopes to converge, their equality becomes a closed condition, which every limit of analytic singularity types satisfies. For the converse, the dyadic approximants of a potential with equal envelopes must converge to it. We therefore add coordinates that these approximants control in a fixed Hermitian background: controlled inclusions of multiplier ideals, and the weighted total variation of divisorial Lelong numbers on each fixed modification. The closure of the analytic types is then exactly the set of types with equal envelopes, on the whole space of ordinary types.

This topology depends on the zero obstacle hidden in the envelopes, and a smooth change of background moves that obstacle. Testing all smooth obstacles removes this dependence, and raises the question whether equality of the envelopes below zero implies equality below every obstacle. Examples of zero volume built from divisors in fibrations and products over curves answer this question on explicit classes of potentials. On these classes, polar curvature on the curve factors also gives complete metrics, which we compare with the complete topologies known in positive volume at the end of the section. From [Section 15.6.3](#) on, several constructions use the volume comparison of ordinary models and the curve models of [Chapter 29](#); those results do not depend on the present section, and the reader may consult them as they are cited.

Fix a Hermitian form ω on X and write

$$\mathfrak{S}(X, \omega) = \text{PSH}(X, \omega) / \sim.$$

In this section $[u]$ denotes the ordinary class of u , that is, its class modulo bounded differences. For each smooth compact modification $\pi : Y \rightarrow X$, fix a Hermitian form γ_π on Y . For a prime divisor $E \subset Y$, set $w_E = \int_E \gamma_\pi^{n-1}$, and let $v_E(u) = v(u \circ \pi, E)$ be the generic Lelong number of [Section 1.17](#).

Lemma 15.6.1 *For $u, v \in \text{PSH}(X, \omega)$, the sum*

$$d_\pi([u], [v]) = \sum_{E \in Y \text{ prime}} w_E |v_E(u) - v_E(v)| \quad (15.4)$$

is finite and defines a pseudometric on $\mathfrak{S}(X, \omega)$. Changing γ_π gives an equivalent pseudometric for the fixed modification π .

Proof The current $T = \pi^*\omega + \text{dd}^c(u \circ \pi)$ is positive. Divisorial removal in [Lemma 1.17.1](#) gives, for every finite family of prime divisors,

$$\sum_E w_E v_E(u) \leq \int_Y T \wedge \gamma_\pi^{n-1} < \infty.$$

Taking the supremum over finite families shows that the sum converges and that only countably many coefficients are positive. The same bound holds for v . Bounded changes of u or v do not affect the coefficients, and the triangle inequality holds term by term. Finally, two Hermitian forms on the compact manifold Y bound one another by fixed positive multiples, and so do the corresponding divisor weights. $\square$

For $t > 0$ and $a > 1$, let

$$\mathcal{U}(t, a) = \{([u], [v]) : I(atu) \subseteq I(tv), \quad I(atv) \subseteq I(tu)\}. \quad (15.5)$$

These are relations between ordinary classes, since a bounded change leaves every multiplier ideal unchanged. Let d_I be the pullback of the metric (15.2), in background ω , under $[u] \mapsto [u]_I$, and put

$$d_O([u], [v]) = \|P_\omega[u] - P_\omega[v]\|_{L^1(dV)}.$$

Both are pseudometrics on ordinary classes: d_I compares the ideal envelopes, whereas d_O also detects differences of ordinary envelopes within a single multiplier-ideal class.

Proposition 15.6.1 *Finite intersections of the relations $d_O < r$, $d_I < r$, $d_\pi < r$ and $\mathcal{U}(t, a)$, with $r, t > 0$ and $a > 1$, form a base of entourages for a uniformity on $\mathfrak{S}(X, \omega)$. Denote its topology by $\tau_{\omega, 0}$, where the subscript 0 records the zero obstacle in the envelopes. A net $[u_j]$ converges to $[u]$ if and only if both envelopes converge in L^1 , $d_\pi([u_j], [u]) \rightarrow 0$ for every fixed π , and $([u_j], [u]) \in \mathcal{U}(t, a)$ eventually for every fixed t, a . Smooth positive choices of dV and of the γ_π do not change the uniformity.*

Proof All generators are symmetric and contain the diagonal. Multiplier ideals decrease as the weight increases, as one sees from local integrability after subtracting a local upper bound from the potential. For $b = \sqrt{a}$, put $\mathcal{V} = \mathcal{U}(t, b) \cap \mathcal{U}(bt, b)$. If $([x], [y]), ([y], [z]) \in \mathcal{V}$, then

$$I(atx) \subseteq I(bty) \subseteq I(tz),$$

and the same argument with x and z exchanged shows that $\mathcal{V} \circ \mathcal{V} \subseteq \mathcal{U}(t, a)$. For the pseudometric relations, halving the radius gives the corresponding refinement under composition. Taking finite intersections of these refinements proves the axioms of a uniformity, and convergence in it means eventual membership in each generating entourage. Bounded ratios of smooth positive volume forms and [Lemma 15.6.1](#) show that the auxiliary choices do not matter. $\square$

Each entourage involves only finitely many fixed modifications. The definition therefore requires neither a countable cofinal family of modifications nor convergence that is uniform over all modifications.

15.6.1 Analytic closure

We now show that the dyadic approximants of [Corollary 15.5.3](#) converge in $\tau_{\omega,0}$ exactly when the two envelopes agree. Let $\mathcal{A}_\omega$ be the set of ordinary classes with analytic singularities, with rational coefficients as in [Section 1.13](#); the rational curvature correction in [Corollary 15.5.3](#) keeps the approximants in this set. In the controlled ideal relations, the scale factor of that correction has to be taken into account.

Theorem 15.6.1 *The closure and the sequential closure of $\mathcal{A}_\omega$ in $\tau_{\omega,0}$ are both equal to*

$$\mathcal{G}_\omega = \{[u] : P_\omega[u] = P_\omega[u]_{\mathcal{I}}\}. \quad (15.6)$$

For every $u \in \text{PSH}(X, \omega)$, the dyadic sequence b_j of [Corollary 15.5.3](#) satisfies

$$[b_j] \longrightarrow [u] \text{ in } \tau_{\omega,0} \iff [u] \in \mathcal{G}_\omega.$$

The approximants may be chosen with one positive rational analytic coefficient on all charts.

Proof We use the notation of [Corollary 15.5.3](#): $m_j = 2^j$, a_j has type $(1/m_j, \mathcal{I}(m_j u))$, $c_j = (1 + \epsilon_j)^{-1} \uparrow 1$ is rational, and $b_j = c_j a_j$. The ordinary and ideal envelopes of b_j agree and decrease to $P_\omega[u]_{\mathcal{I}}$. Thus the two envelope coordinates of $[b_j]$ converge to those of $[u]$ exactly when $[u] \in \mathcal{G}_\omega$. It remains to show that the other coordinates always converge.

Fix $t > 0$ and $a > 1$, and choose $1 < s < a$. For large j , one has $ac_j > s$ and $m_j \geq st/(s-1)$, so [Lemma 1.14.1](#) gives

$$\mathcal{I}(atb_j) = \mathcal{I}(atc_j a_j) \subseteq \mathcal{I}(sta_j) \subseteq \mathcal{I}(tu).$$

Since $u \preceq a_j \preceq b_j$, the reverse relation $\mathcal{I}(atu) \subseteq \mathcal{I}(tb_j)$ holds for every j . The factor c_j enters the weight in the first inclusion, which is why we chose $s < a$.

For a divisor E on a fixed modification π , the Bergman divisorial estimate gives

$$c_j \max \left\{ v_E(u) - \frac{A(E)}{m_j}, 0 \right\} \leq v_E(b_j) \leq c_j v_E(u) \leq v_E(u),$$

where $A(E)$ is the log discrepancy, computed over a coordinate neighborhood of the center of E . Each coefficient therefore converges to $v_E(u)$, and the summability in [Lemma 15.6.1](#) gives $d_\pi([b_j], [u]) \rightarrow 0$ by dominated convergence. This proves convergence of all the remaining coordinates.

Finally, analytic classes have equal envelopes by [Proposition 15.2.3](#). The map $[u] \mapsto (P_\omega[u], P_\omega[u]_I)$ is continuous into $L^1 \times L^1$, whose diagonal is closed. Thus every limit of a net of analytic classes lies in $\mathcal{G}_\omega$. The sequence b_j gives the converse and the sequential assertion. $\square$

15.6.2 Separation and mass

The topology $\tau_{\omega,0}$ sees an ordinary class only through its envelopes, its multiplier ideals and its divisorial Lelong numbers. Distinct ordinary types can have the same ordinary envelope, and such types cannot be separated.

Proposition 15.6.2 *Two classes have the same $\tau_{\omega,0}$ neighborhoods if and only if their ordinary envelopes coincide. This topology is not T_0 and cannot be induced by a metric on $\mathfrak{S}(X, \omega)$.*

Proof The coordinate d_O distinguishes different ordinary envelopes. Conversely, potentials with equal ordinary envelopes have equal multiplier ideals at every weight $w \in \text{PSH}(X, \omega)$. Put $\chi(s) = 1 - \sqrt{1-s}$ for $s \leq 0$ and $u = \chi(w)$. The inequalities $0 < \chi' \leq 1/2$ and $\chi'' \geq 0$, applied first to bounded truncations, give $u \in \text{PSH}(X, \omega)$. In local coordinates z centered at the pole, u has size comparable to $\sqrt{-\log |z|^2}$, so it is unbounded and e^{-tu} is integrable for every $t > 0$. Hence all its multiplier ideals are trivial and $P_\omega[u]_I = 0$.

To produce distinct classes of this kind, choose a cutoff logarithmic pole $w \leq 0$ supported in a coordinate ball, plurisubharmonic near its pole and smooth on the annulus where the cutoff varies. After multiplication by a small positive constant, $w \in \text{PSH}(X, \omega)$. Put $\chi(s) = 1 - \sqrt{1-s}$ for $s \leq 0$ and $u = \chi(w)$. The inequalities $0 < \chi' \leq 1/2$ and $\chi'' \geq 0$, applied first to bounded truncations, give $u \in \text{PSH}(X, \omega)$. In local coordinates z centered at the pole, u has size comparable to $\sqrt{-\log |z|^2}$, so it is unbounded and e^{-tu} is integrable for every $t > 0$. Hence all its multiplier ideals are trivial and $P_\omega[u]_I = 0$.

For every $0 < \delta \leq 1$, the function $\delta s - \chi(s)$ is bounded above on $(-\infty, 0]$. Hence $\delta w \preceq u$, and δw is a competitor for the ordinary envelope of u . Letting $\delta \downarrow 0$ off the pole gives $P_\omega[u] = 0$. Thus $[u]$ and $[0]$ are distinct classes with the same neighborhoods. $\square$

By [Theorem 6.1.1](#), the two envelopes have the extended masses

$$\int_X \text{MA}_\omega(P_\omega[u]), \quad \int_X \text{MA}_\omega(P_\omega[u]_I).$$

In the present positive background, both are at most $\int_X \omega^n$. For the ideal envelope this follows from [Propositions 12.1.4](#) and [15.2.1](#). For the ordinary envelope, normalize $u \leq 0$ and put $p_j = P_\omega(u + j, 0)$ and $p = P_\omega[u]$, with the obstacle envelopes of [Section 1.19](#). Then $p_j \rightarrow p$ in capacity by [Lemma 1.8.6](#). For $k > 0$, set $\eta_k = \min\{1, (u + k)_+\}$. If $j > k$, the contact set of p_j with $u + j$ lies outside $\{\eta_k > 0\}$, so [Proposition 12.1.3](#) gives $\eta_k \text{MA}_\omega(p_j) \leq \eta_k \omega^n$. Testing against a nonnegative continuous function and applying [Lemma 6.3.1](#), we obtain the same inequality for p . Letting $k \rightarrow \infty$ proves $\text{MA}_\omega(p) \leq \omega^n$, since the remaining set $\{u = -\infty\}$ is pluripolar.

The potential itself can nevertheless have infinite mass: [Proposition 15.3.3](#) gives such a u whose two envelopes are both zero. Its ordinary class belongs to $\mathcal{G}_\omega$. Thus the topology and its analytic-closure criterion need no mass condition on the representative, whereas the two canonical envelopes never have infinite mass in a Hermitian background.

15.6.3 Transport with an obstacle

A smooth change of background $\omega' = \omega + \text{dd}^c \chi$ identifies $\text{PSH}(X, \omega)$ with $\text{PSH}(X, \omega')$ by $u \mapsto u - \chi$, but it moves the zero obstacle to $-\chi$. To compare the topologies in different backgrounds, we therefore need envelopes below an arbitrary smooth obstacle.

For a smooth real obstacle F , we use the ordinary envelope $P_{\omega, F}[u]$ of [Definition 1.19.1](#), and we write $P_{\omega, F}[u]_{\mathcal{I}}$ for the ideal envelope defined with $v \leq F$ in place of $v \leq 0$. The competitor family of the latter contains a translate of u . Replacing a competitor by its maximum with this translate shows that the ideal envelope may equivalently be defined with the condition $v \preceq_{\mathcal{I}} u$. The same notation applies to any smooth real background that admits u . Define $\tau_{\omega, F}$ by replacing the two envelope coordinates in [Proposition 15.6.1](#) by these obstacle envelopes.

Proposition 15.6.3 *Let $\chi \in C^\infty(X, \mathbb{R})$ and $\omega' = \omega + \text{dd}^c \chi > 0$. The map $[u] \mapsto [u - \chi]$ is a uniform isomorphism*

$$(\mathfrak{S}(X, \omega), \tau_{\omega, F}) \longrightarrow (\mathfrak{S}(X, \omega'), \tau_{\omega', F - \chi}).$$

For $s > 0$, $[u] \mapsto [su]$ is a uniform isomorphism from $\tau_{\omega, F}$ to $\tau_{s\omega, sF}$. Both maps transport the ordinary and the ideal envelopes exactly.

Proof For either envelope operator P , the correspondence of competitors gives

$$P_{\omega', F - \chi}[u - \chi] = P_{\omega, F}[u] - \chi, \quad P_{s\omega, sF}[su] = sP_{\omega, F}[u].$$

Smooth additions leave all multiplier ideals and divisorial Lelong numbers unchanged. Scaling multiplies the divisorial and envelope distances by s and changes the ideal weights by $t \mapsto st$. Each map and its inverse therefore transport the generating entourages to generating entourages. $\square$

For two smooth obstacles, translation of competitors gives

$$P_{\omega,F}[u] + \min_{\chi}(G - F) \leq P_{\omega,G}[u] \leq P_{\omega,F}[u] + \max_{\chi}(G - F),$$

and the same inequalities hold for the ideal envelopes. By the local construction in [Theorem 6.1.1](#), the extended measures satisfy $\text{MA}_{\omega'}(u - \chi) = \text{MA}_{\omega}(u)$ and $\text{MA}_{s\omega}(su) = s^n \text{MA}_{\omega}(u)$, also when the total mass is infinite. If instead the zero obstacle is kept in both backgrounds, the transport gives $P_{\omega',0}[u - \chi] = P_{\omega,\chi}[u] - \chi$, so the change of background compares the obstacles 0 and χ . The bounded comparison of obstacles does not make this change continuous, even on a curve.

Proposition 15.6.4 *Let Y be a compact connected Riemann surface and $\theta > 0$ a smooth form of mass one. If F is a nonconstant smooth function with $\theta' = \theta + \text{dd}^c F > 0$, then the bijection*

$$\Gamma_F : (\mathfrak{S}(Y, \theta), \tau_{\theta,0}) \longrightarrow (\mathfrak{S}(Y, \theta'), \tau_{\theta',0}), \quad [u] \longmapsto [u - F],$$

and its inverse are both discontinuous. Equivalently, $\tau_{\theta,0}$ and $\tau_{\theta,F}$ are incomparable topologies on the same space of ordinary types.

Proof The smooth function θ'/θ has integral one against the probability measure θ , and it is not constant: otherwise $\text{dd}^c F = 0$, and the harmonic function F would be constant on Y . Choose c with $\min_Y(\theta'/\theta) < c < 1$, so that $\theta' \not\leq c\theta$.

Next choose probability measures μ_j without atoms, each carried by a polar set, that converge weakly to θ . To construct them, start with finite atomic probability measures converging weakly to θ , as in [Theorem 15.4.1](#), and replace each atom by a nonatomic probability measure carried by a polar Cantor set in a small coordinate disk about that atom, keeping its weight; the construction in [Example 29.12.2](#) provides such measures in every disk. If the diameters of the disks tend to zero uniformly, uniform continuity of continuous test functions preserves weak convergence, and the finite union of the polar carriers is polar.

Let q_j be the normalized Green potentials with $\theta + \text{dd}^c q_j = \mu_j$ and $\sup_Y q_j = 0$. By normalized compactness, the sequence has L^1 cluster values, and each of them has curvature θ and supremum zero, hence vanishes. Thus $q_j \rightarrow 0$ in L^1 . Put $u_j = cq_j$. Then

$$\theta + \text{dd}^c u_j = (1 - c)\theta + c\mu_j, \quad u_j \leq P_{\theta}[u_j] \leq 0.$$

Since μ_j has no atoms, all point Lelong numbers of u_j vanish. Because modifications of a smooth curve are isomorphisms, [Theorem 1.16.1](#) gives trivial multiplier ideals at every weight. Thus $P_{\theta}[u_j]_{\mathcal{I}} = 0$, all controlled ideal relations with $[0]$ hold, and every divisorial distance to $[0]$ vanishes. The bounds above give convergence of the ordinary envelopes to zero in L^1 . Consequently $[u_j] \rightarrow [0]$ in $\tau_{\theta,0}$.

Set $v_j = P_{\theta,F}[u_j]$. Every competitor $h \preceq u_j$ satisfies $\theta + \text{dd}^c h \geq c\mu_j$, by [Corollary 1.6.1](#). The family of competitors below F contains a translate of u_j and is stable under finite maxima, so Choquet selection and distributional convergence of increasing maxima show that v_j satisfies the same inequality. If $[u_j] \rightarrow [0]$ in $\tau_{\theta,F}$, the ordinary-envelope coordinate would give $v_j \rightarrow P_{\theta,F}[0] = F$ in L^1 , because

F is a bounded θ -plurisubharmonic competitor. Passing to the limit in the current inequality would then give $\theta' \geq c\theta$, a contradiction.

By [Proposition 15.6.3](#), $[u] \mapsto [u - F]$ is a uniform isomorphism from $\tau_{\theta, F}$ onto $\tau_{\theta', 0}$, so the sequence above shows that Γ_F is discontinuous. The same argument applied to θ' and $-F$ shows that the inverse is discontinuous. Under this transport, continuity of Γ_F and of its inverse are precisely the two comparisons between $\tau_{\theta, 0}$ and $\tau_{\theta, F}$, which proves incomparability. $\square$

The sequence u_j has trivial multiplier ideals, and its polar curvature in the sense of [Section 1.6.1](#), that is, the restriction $\mathbf{1}_{\{u_j = -\infty\}}(\theta + \text{dd}^c u_j)$ of its curvature to its pole set, is $c\mu_j$. By the classification of curve models through their polar curvature in [Lemma 29.12.1](#) and the bounded obstacle comparison, its ordinary envelopes in both backgrounds have non-pluripolar mass $1 - c$. The discontinuity therefore persists among models whose masses are bounded below by a fixed positive constant. On the same curve, the total variation of polar curvature is a complete metric on ordinary models, by [Theorem 29.12.1](#), and after ordinary projection it is invariant under smooth changes of background; it keeps the diffuse curvature that the sequence above loses.

15.6.4 All smooth obstacles

We return to the Hermitian background ω on X . By [Proposition 15.6.4](#), a smooth change of background need not preserve convergence when the obstacle is kept at zero. Requiring convergence below every smooth obstacle gives a topology that is stable under such changes. The dyadic approximation still determines its analytic closure, which is now described by equality of the two envelopes below every obstacle.

Let τ_ω^{all} be the topology of the uniformity generated by all the uniformities $\tau_{\omega, F}$ with $F \in C^\infty(X, \mathbb{R})$. Thus an entourage involves finitely many distances between obstacle envelopes, together with finitely many of the controlled ideal relations and divisorial distances defined above.

Proposition 15.6.5 *A countable family $\{F_k\}_{k \geq 1} \subset C^\infty(X, \mathbb{R})$ that is dense for the uniform norm suffices for the obstacle coordinates of τ_ω^{all} . For smooth χ with $\omega' = \omega + \text{dd}^c \chi > 0$, the map $[u] \mapsto [u - \chi]$ is a uniform isomorphism between τ_ω^{all} and $\tau_{\omega'}^{\text{all}}$. For $s > 0$, positive scaling gives the corresponding uniform isomorphism onto $\tau_{s\omega}^{\text{all}}$. This topology is not T_0 on ordinary classes.*

Proof For either envelope operator, the obstacle comparison gives

$$\|P_{\omega, F}[u] - P_{\omega, G}[u]\|_{L^1(\text{dV})} \leq \|F - G\|_\infty.$$

Hence the two envelope distances for a pair $[u], [v]$ differ by at most $2\|F - G\|_\infty$, uniformly in the pair. The space $C^\infty(X, \mathbb{R})$ contains a countable subset that is dense for the uniform norm: approximate each member of a countable dense subset of $C(X)$ by smooth functions with errors $1/m$, $m \geq 1$. Given an entourage, we approximate each of its finitely many obstacles by a member of the family and shrink the radii accordingly; this proves that the family generates the same uniformity. The divisorial coordinates still range over all fixed compact modifications.

The transport in [Proposition 15.6.3](#) relabels the entire family of smooth obstacles by $F \mapsto F - \chi$, or by $F \mapsto sF$. These are bijections of the family, which proves both isomorphisms.

For nonseparation, use the unbounded function $u = 1 - \sqrt{1 - w}$ of [Proposition 15.6.2](#). It has trivial multiplier ideals and zero divisorial Lelong numbers, and $\delta w \preceq u$ for $0 < \delta \leq 1$. Fix F and put $q = P_\omega(F)$, the envelope of the obstacle F in the sense of [Section 1.19](#). Since $\omega > 0$, the constant $\min_X F$ is a competitor, so q is bounded and $q \leq F$. The function

$$h_\delta = (1 - \delta)q + \delta w - \delta\|F\|_\infty$$

is ω -plurisubharmonic, lies below F , and satisfies $h_\delta \preceq u$. Letting $\delta \downarrow 0$ off the pole of w gives $P_{\omega, F}[u] = q = P_{\omega, F}[0]$. Since u and 0 have the same multiplier ideals, their ideal envelopes below F also agree. Every generating entourage therefore has identical sections at $[u]$ and $[0]$, although these ordinary classes differ. $\square$

Below a smooth obstacle, the ideal envelope is the ordinary envelope of the ideal model obtained with the zero obstacle. Equality of the two envelopes below every obstacle therefore reduces to a question about ordinary envelopes alone.

Proposition 15.6.6 *Let θ be a smooth real $(1, 1)$ -form, let $u \in \text{PSH}(X, \theta)$ and put $q = P_\theta[u]_I$. For every smooth real F ,*

$$P_{\theta, F}[q] = P_{\theta, F}[u]_I \sim q.$$

If $u \in \mathcal{E}_{\text{env}}(X, \theta, q)$, then also

$$P_{\theta, F}[u] = P_{\theta, F}[u]_I \quad \text{for every smooth real } F.$$

Proof Set $q_F = P_{\theta,F}[u]_I$. Translation of competitors gives

$$q + \min_X F \leq q_F \leq q + \max_X F,$$

so $q_F \sim q$. The identity $q_F - F = P_{\theta+\text{dd}^c F}[u - F]_I$ and **Theorem 15.2.1** give $q_F \sim_I u$. Since $q_F \leq F$ and $q_F \sim q$, it is a competitor for $P_{\theta,F}[q]$. Conversely, the maximum of a competitor for $P_{\theta,F}[q]$ with a sufficiently low translate of q is a competitor for $P_{\theta,F}[q]_I$, and this ideal envelope equals q_F because $q \sim_I u$. These bounds give

$$q_F \leq P_{\theta,F}[q] \leq P_{\theta,F}[q]_I = q_F.$$

The last assertion follows from **Proposition 12.4.3**, which gives $P_{\theta,F}[u] = P_{\theta,F}[q]$. $\square$

Theorem 15.6.2 *The closure and the sequential closure of $\mathcal{A}_\omega$ in τ_ω^{all} are both equal to*

$$\mathcal{G}_\omega^{\text{all}} = \{[u] : P_{\omega,F}[u] = P_{\omega,F}[u]_I \text{ for every smooth } F\}.$$

*It suffices to test equality on the countable dense family above. The dyadic sequence b_j of **Corollary 15.5.3** converges to $[u]$ in this topology if and only if $[u] \in \mathcal{G}_\omega^{\text{all}}$.*

Proof Fix a smooth obstacle F . As in the preceding proof, transport of the obstacle and **Theorem 15.2.1** give $P_{\omega,F}[u]_I \sim_I u$. For a with analytic singularities, **Lemma 1.17.9** therefore makes this ideal envelope a competitor for the ordinary envelope, so $P_{\omega,F}[a] = P_{\omega,F}[a]_I$.

Write $p = P_{\omega,F}[u]_I$ and $q_j = P_{\omega,F}[b_j]_I$. The dyadic construction gives $u \preceq_I b_j$, decreasing ordinary types, and convergence of every local divisorial Lelong number of b_j to that of u . The ideal envelope preserves the ideal order, as one sees by taking maxima with a translate of b_j below F , so $p \leq q_j \leq F$. Since $q_j = P_{\omega,F}[b_j]$ and the ordinary types decrease, the sequence q_j decreases. Its limit q is bounded below by p , so it is ω -plurisubharmonic, and $p \leq q \leq F$; the same bounds give convergence in L^1 .

Convergence after pullback and semicontinuity of Lelong numbers, as in **Proposition 15.5.1**, give $\nu_E(q) \geq \nu_E(u)$ for every local divisor E , and $p \leq q$ gives the reverse inequality. The Lelong-number criterion of **Theorem 1.16.1** yields $q \sim_I u$. Since $q \leq F$, it is a competitor for p , which proves

$$P_{\omega,F}[b_j] = P_{\omega,F}[b_j]_I \searrow P_{\omega,F}[u]_I.$$

The controlled ideal relations and all divisorial distances on fixed modifications converge by the proof of **Theorem 15.6.1**; they do not depend on F . Consequently this one dyadic sequence converges in τ_ω^{all} exactly when the stated envelope equalities hold.

For each F , equality of the two L^1 envelope coordinates is a closed condition. Analytic classes satisfy all these equalities, so the closure of the analytic classes under nets lies in $\mathcal{G}_\omega^{\text{all}}$, and the dyadic sequence proves the converse. Finally, the uniform obstacle bound in the proof of **Proposition 15.6.5** extends equality from a dense family to every smooth obstacle. $\square$

Before turning to examples, we record how the envelopes and the relative envelope classes behave under finite unramified coverings; this will be used for fibrations with disconnected fibers. Recall from [Definition 12.4.1](#) that $u \in \mathcal{E}_{\text{env}}(X, \theta, \varphi)$ means that $u \preceq \varphi$ and that, for every $a \in (0, 1)$, there is a *stretching competitor* $h \in \text{PSH}(X, \theta)$ with $a\varphi + (1-a)h \leq u$; here $a = 1 - b^{-1}$ in the notation of that definition. Pullback of competitors and the maximum over the fibers of the covering identify the envelopes upstairs and downstairs, and the same fiber maximum transfers stretching competitors from the covering space to the base.

Proposition 15.6.7 *Let $r : Y \rightarrow X$ be a finite unramified holomorphic covering between connected compact complex manifolds. Let θ be a smooth real $(1, 1)$ -form on X , let $u, \varphi \in \text{PSH}(X, \theta)$, and put $\theta' = r^*\theta$ and $u' = u \circ r$. For every $F \in C(X, \mathbb{R})$,*

$$\begin{aligned} P_{\theta', F \circ r}[u'] &= P_{\theta, F}[u] \circ r, \\ P_{\theta', F \circ r}[u']_I &= P_{\theta, F}[u]_I \circ r. \end{aligned}$$

Moreover,

$$u' \in \mathcal{E}_{\text{env}}(Y, \theta', \varphi \circ r) \iff u \in \mathcal{E}_{\text{env}}(X, \theta, \varphi).$$

Proof For $v \in \text{PSH}(Y, \theta')$, define

$$v_{\max}(x) = \max_{y \in r^{-1}(x)} v(y).$$

Over a sufficiently small ball in X , this is the finite maximum of the functions obtained by composing v with the local inverse branches of r . Each of them is θ -plurisubharmonic, so $v_{\max} \in \text{PSH}(X, \theta)$ by [Lemma 1.3.1](#). If $v \preceq u'$, then $v_{\max} \preceq u$. If $v \sim_I u'$, a local biholomorphic change of variables makes each branch multiplier-ideal equivalent to u , and the maximum rule in [Lemma 1.16.3](#) gives $v_{\max} \sim_I u$. The obstacle bound $v \leq F \circ r$ gives $v_{\max} \leq F$.

Thus every competitor upstairs is dominated by the pullback of a corresponding competitor downstairs. Conversely, pullback of a competitor downstairs preserves the background inequality, the ordinary order or multiplier-ideal equivalence, and the obstacle bound. These two correspondences between the competitor families give the envelope identities; upper regularization commutes with r , since r is locally biholomorphic.

Since r is surjective, it reflects the ordinary order: $u' \preceq \varphi \circ r$ if and only if $u \preceq \varphi$. Fix $a \in (0, 1)$. Pullback takes any stretching competitor h with $a\varphi + (1-a)h \leq u$ to a stretching competitor upstairs. Conversely, if $v \in \text{PSH}(Y, \theta')$ satisfies

$$a\varphi \circ r + (1-a)v \leq u',$$

then taking the maximum over the fibers gives $a\varphi + (1-a)v_{\max} \leq u$; this also holds at poles, because the convex sums are defined there. Applying the definition of the relative class for every a proves the last assertion. $\square$

Taking $F = 0$ gives $\mathcal{G}_{\omega}^{\text{all}} \subseteq \mathcal{G}_{\omega}$. For the reverse inclusion, let $q = P_{\omega}[u]_I$. By [Proposition 15.6.6](#), it suffices to show that $P_{\omega, F}[u] = P_{\omega, F}[q]$ for every F , and

membership $u \in \mathcal{E}_{\text{env}}(X, \omega, q)$ is sufficient for this. Under bounded mass and positive lower volume of q , this membership is equivalent to equality of the envelopes below zero, by [Proposition 29.8.1](#). On curves the two closures coincide even at zero mass, by [Proposition 29.12.3](#). We do not know whether the reverse inclusion holds in general. The following subsections prove it for explicit classes of potentials of zero volume in higher dimension. The reduction along a divisor in a fibration gives such classes over curves, and one example of this kind has a base potential in the required relative envelope class and an ambient background with unbounded mass ([Example 15.6.3](#)). Although $\tau_{\omega}^{\text{all}}$ removes the dependence on a fixed obstacle, it still has incomplete curve families and is strictly weaker than polar total variation on ordinary curve models, by [Proposition 29.12.4](#). On the classes of models constructed below, complete metrics come instead from polar curvature.

15.6.5 Relative divisors and fiber obstacles

To test equality of the envelopes below all obstacles beyond curves, we need potentials whose envelopes can be computed. Consider a holomorphic submersion with compact connected fibers, and a potential that is the sum of a logarithmic potential Ψ with fixed weights along some divisors and the pullback of a potential w on the base. Every competitor has at least the poles of Ψ , and removing them leaves a current pulled back from the base. Since the fibers are compact and connected, the remaining potential descends to the base, and minimizing the obstacle over the fibers reduces both envelopes to envelopes on the base. Over a fiber contained in the divisor the induced obstacle is infinite, but normalized compactness still bounds the competitors. Because the remaining current comes from a base of smaller dimension, all these potentials have zero top-degree mass. The reduction gives criteria on the base for membership in relative envelope classes and for equality of the envelopes below all obstacles. The divisors may be singular or ramified over the base; only the explicit product formula for the multiplier ideals requires relative normal crossings.

Let $p : M \rightarrow Y$ be a surjective holomorphic submersion between connected compact complex manifolds, with connected fibers, and put $d = \dim Y$ and $n = \dim M$, where $1 \leq d < n$. Let $H_1, \dots, H_s$ be a nonempty finite family of distinct prime divisors on M and put $H = \bigcup_j H_j$. For positive real weights λ_j , choose smooth Hermitian metrics h_j on $\mathcal{O}_M(H_j)$, with canonical sections s_j and Chern curvatures κ_j . Set

$$A = \sum_{j=1}^s \lambda_j H_j, \quad \Psi = \sum_{j=1}^s \lambda_j \log |s_j|_{h_j}^2, \quad \kappa_A = \sum_{j=1}^s \lambda_j \kappa_j.$$

Thus $\kappa_A + \text{dd}^c \Psi = [A] = \sum_j \lambda_j [H_j]$. For a smooth real $(1, 1)$ -form β on Y and $w \in \text{PSH}(Y, \beta)$, put

$$\Theta = p^* \beta + \kappa_A, \quad u = \Psi + w \circ p.$$

The form β need not be closed or positive. Envelopes below continuous real obstacles are defined by the same competitor families as for smooth obstacles. Let

$$Z = \{y \in Y : p^{-1}(y) \subset H\}$$

be the set of points over which the whole fiber lies in H .

Proposition 15.6.8 *For every $F \in C(M, \mathbb{R})$, the function*

$$\widehat{F}(y) = \inf_{x \in p^{-1}(y) \setminus H} \{F(x) - \Psi(x)\}, \quad \inf \emptyset = +\infty,$$

is continuous in the extended real sense, finite on $Y \setminus Z$ and equal to $+\infty$ on Z . Defining the base envelopes below this extended-real obstacle by the usual competitor families, one has

$$\begin{aligned} P_{\Theta, F}[u] &= \Psi + P_{\beta, \widehat{F}}[w] \circ p, \\ P_{\Theta, F}[u]_I &= \Psi + P_{\beta, \widehat{F}}[w]_I \circ p. \end{aligned} \tag{15.7}$$

Every representative of the ordinary type of u or of $P_{\Theta}[u]_I$ has zero extended mass. Consequently both singularity volumes of these types are zero.

If the ordinary and ideal envelopes of w agree below every smooth obstacle on Y , then those of u agree below every smooth obstacle on M .

Proof We first study the induced obstacle and bound the base competitors, then describe all competitors upstairs by divisorial removal and descent, and finally prove the mass assertion.

Step 1: the induced obstacle. Since p is open, $Y \setminus Z = p(M \setminus H)$ is open and nonempty. The function $F - \Psi$ is bounded below by $\min_M F - \sup_M \Psi$ and tends to $+\infty$ near H , because $\Psi \rightarrow -\infty$ there. On every fiber that meets $M \setminus H$, its infimum is therefore attained outside H . A local holomorphic section through a minimizer gives upper semicontinuity of $\widehat{F}$. Conversely, let $y_j \rightarrow y$ with bounded fiber minima. By compactness, a subsequence of the minimizers converges, and its limit lies outside H because $F - \Psi$ remains bounded along it; this gives lower semicontinuity. If $y \in Z$, the same limit would lie in H , a contradiction. Thus $\widehat{F} \rightarrow +\infty$ at Z , and $\widehat{F}$ is continuous in the extended sense.

Step 2: a uniform bound for the base competitors. Choose a relatively compact nonempty ball U in the base and a holomorphic section s of p on a neighborhood of $\overline{U}$ with image outside H . There is a finite C_U with $\widehat{F} \leq F \circ s - \Psi \circ s \leq C_U$ on U . Fix a smooth probability volume form dV on Y . For every $b \in \text{PSH}(Y, \beta)$ below $\widehat{F}$, normalized compactness in [Theorem 1.4.1](#) gives

$$-C_\beta \leq \int_U (b - \sup_Y b) dV \leq (C_U - \sup_Y b) \int_U dV.$$

Hence every such b satisfies $\sup_Y b \leq K_F = C_U + C_\beta / \int_U dV$. A sufficiently low translate of w belongs to both base competitor families. Their regularized suprema

are therefore β -plurisubharmonic functions, not identically $-\infty$, and by the extended continuity of $\widehat{F}$ they still lie below $\widehat{F}$.

Step 3: the competitors upstairs. The pullback of w is quasi-plurisubharmonic, so its generic Lelong numbers are nonnegative, and $v(u, H_j) = \lambda_j + v(w \circ p, H_j) \geq \lambda_j$. Let v be an ordinary competitor for u , or an ideal competitor with $v \sim_{\mathcal{I}} u$. By the ordinary order or by [Theorem 1.16.1](#), its generic Lelong number along H_j is at least λ_j . Divisorial removal in [Lemma 1.17.1](#) gives

$$\Theta + \text{dd}^c v - [A] \geq 0.$$

Hence $v - \Psi$ has a quasi-plurisubharmonic representative a satisfying $p^* \beta + \text{dd}^c a \geq 0$. Descent along the compact connected fibers, [Proposition 1.22.1](#), gives $a = b \circ p$ for a unique $b \in \text{PSH}(Y, \beta)$, and $v = \Psi + b \circ p$ for the canonical representatives. Conversely, every potential of this form is Θ -plurisubharmonic.

For such v , one has $v \preceq u$ if and only if $b \preceq w$. Indeed, canceling Ψ outside H gives the base inequality almost everywhere, by Fubini's theorem in product charts, hence everywhere by [Lemma 1.3.3](#); the reverse implication follows by pullback and addition. Similarly, $v \sim_{\mathcal{I}} u$ if and only if $b \sim_{\mathcal{I}} w$: [Lemma 1.16.3](#) permits both addition and cancellation of Ψ , the pullback formula in [Lemma 1.16.4](#) then gives one direction, and restriction of the extended ideals along any local section gives the other. This comparison of ideals does not need a section outside H .

If the divisors have relative simple normal crossings, the ideals have an explicit form. Here this means that near every point there are product coordinates (y, z) with $p(y, z) = y$ in which the components through the point are distinct coordinate hyperplanes in the fiber variables. Then

$$\mathcal{I}(t(\Psi + b \circ p)) = \mathcal{O}_M \left(- \sum_j \lfloor t\lambda_j \rfloor H_j \right) (\mathcal{I}(tb)\mathcal{O}_M) \quad (t > 0). \quad (15.8)$$

To see this, work in such coordinates. Up to a smooth correction, Ψ is the sum of the weights $\lambda_j \log |z_j|^2$ over the components through the point. Since b is locally bounded above, integrability forces vanishing to order at least $\lfloor t\lambda_j \rfloor$ along each hyperplane. After this product of coordinate powers is factored out, the remaining fiber weight is

$$\prod_j |z_j|^{-2(t\lambda_j - \lfloor t\lambda_j \rfloor)}.$$

It is integrable and bounded below by a positive constant on a small polydisk. Integrability of the quotient against this weight therefore implies integrability against the pullback of e^{-tb} alone, and [Lemma 1.16.4](#) puts the quotient in the extension of $\mathcal{I}(tb)$. Conversely, local generators of that ideal are weighted-integrable against the integrable product weight, by Fubini's theorem. Outside H the formula is the same pullback lemma. For one smooth divisor of weight one transverse to the fibers, the first factor is the ideal sheaf of the divisor raised to the power $\lfloor t \rfloor$.

Step 4: the envelope identities. The bound $v \leq F$ is equivalent to $b \leq \widehat{F}$, with no constraint over Z . The competitor families upstairs and on the base therefore

correspond to each other, which gives (15.7) outside H , since regularization commutes with pullback in product coordinates there. On H both sides equal $-\infty$: every competitor is at most $\Psi + K_F$, by the bound $b \leq K_F$, and this upper semicontinuous function equals $-\infty$ on H , so regularization does not change the values there.

Step 5: equality below all obstacles. Suppose that the two base envelopes agree below every smooth obstacle. Uniform obstacle comparison extends this equality to continuous real obstacles. The functions $G_j = \min(\widehat{F}, j)$ are continuous and real-valued. Every base competitor below $\widehat{F}$ has finite supremum and hence lies below G_j for every sufficiently large integer j . Each full competitor family is thus the union of its subfamilies below the G_j , and equality for all G_j gives equality below $\widehat{F}$ after taking regularized suprema. By the reduction, the envelopes upstairs agree below every smooth obstacle.

Step 6: zero mass. Take any $b \in \text{PSH}(Y, \beta)$ and write $a = \Psi + b \circ p$. On a relatively compact chart outside H , the functions $b_j = \max(b, -j)$ are locally bounded and quasi-plurisubharmonic, and there

$$\Theta + \text{dd}^c(\Psi + b_j \circ p) = p^*(\beta + \text{dd}^c b_j).$$

Since $n > d$, the n th bounded product of this current is zero by Lemma 1.7.2. This identity does not require b_j to be β -plurisubharmonic: Proposition 1.7.1 defines the products for locally bounded quasi-plurisubharmonic potentials. By plurifine locality, this zero product agrees with $\text{MA}_{\Theta}^{\text{ext}}(a)$ on $\{b \circ p > -j\}$ in the chart. These sets cover the locus where $b \circ p$ is finite, while the remaining pole set and H receive no extended mass. Thus $\text{MA}_{\Theta}^{\text{ext}}(a) = 0$.

By divisorial removal and descent, every representative ordinarily equivalent to u has this form. By the identity already proved, the ideal model is also of this form, with base potential $P_{\beta, \widehat{0}}[w]_I$, where $\widehat{0}$ is the induced obstacle for $F = 0$. The same removal and descent apply to every representative of its ordinary type. All these masses are zero, which proves both volume assertions. $\square$

Proposition 15.6.9 For $\varphi \in \text{PSH}(Y, \beta)$ put $v = \Psi + \varphi \circ p$. Then

$$u \in \mathcal{E}_{\text{env}}(M, \Theta, v) \iff w \in \mathcal{E}_{\text{env}}(Y, \beta, \varphi).$$

In particular, for $q_M = P_\Theta[u]_I$ and $q_Y = P_\beta[w]_I$,

$$u \in \mathcal{E}_{\text{env}}(M, \Theta, q_M) \iff w \in \mathcal{E}_{\text{env}}(Y, \beta, q_Y).$$

Every ordinary representative of u or q_M has zero extended mass, so both singularity volumes of these types vanish.

Proof The ordinary order $u \preceq v$ is equivalent to $w \preceq \varphi$. One implication follows by addition and pullback. Conversely, cancel Ψ outside H , which has smooth volume zero; Fubini's theorem in product charts gives the base inequality almost everywhere, and [Lemma 1.3.3](#) makes it hold everywhere. Membership in the relative envelope class requires, for every $a \in (0, 1)$, a stretching competitor $h \in \text{PSH}(M, \Theta)$ with

$$av + (1 - a)h \leq u.$$

A base competitor $c \in \text{PSH}(Y, \beta)$ with $a\varphi + (1 - a)c \leq w$ gives such an h , namely $h = \Psi + c \circ p$.

Conversely, put $\rho_j = v(w \circ p, H_j)$ and $\sigma_j = v(\varphi \circ p, H_j)$. The ordinary order $w \preceq \varphi$ gives $\rho_j \geq \sigma_j \geq 0$. Comparing generic Lelong numbers along H_j in the inequality above gives

$$a(\lambda_j + \sigma_j) + (1 - a)v(h, H_j) \geq \lambda_j + \rho_j.$$

Consequently $v(h, H_j) \geq \lambda_j + (\rho_j - a\sigma_j)/(1 - a) \geq \lambda_j$. Divisorial removal and descent along the fibers give $h = \Psi + c \circ p$ with $c \in \text{PSH}(Y, \beta)$. Canceling Ψ outside H and the pole sets, and applying Fubini's theorem, we obtain $a\varphi + (1 - a)c \leq w$ almost everywhere on the base, and hence on all of Y by [Lemma 1.3.3](#). This proves the first equivalence.

For the ideal reference, [Theorem 15.2.1](#) gives $q_M \sim_I u$. The generic divisorial coefficients of q_M are therefore at least λ_j , and removal and descent give

$$q_M = \Psi + b \circ p, \quad b \in \text{PSH}(Y, \beta).$$

Cancellation in [Lemma 1.16.3](#) gives $b \circ p \sim_I w \circ p$. By [Lemma 1.16.4](#), these ideals are extensions of the base ideals, so restriction along any local section gives $b \sim_I w$, even over a fiber contained in H .

Put $C = \max\{0, \sup_M \Psi\}$ and $K = \max\{0, \sup_Y b\}$. The potential $\Psi + q_Y \circ p - C$ is nonpositive and multiplier-ideal equivalent to u , so it is a competitor for q_M . Likewise, $b - K$ is a competitor for q_Y . Canceling Ψ in the first inequality almost everywhere and extending as above gives

$$q_Y - C \leq b \leq q_Y + K.$$

Thus $b \sim q_Y$. The first equivalence with reference b , together with the invariance of the class under ordinarily equivalent references in [Proposition 12.4.1](#), proves the second equivalence. This argument works with the ideal model itself and does not require the induced fiber obstacle to be finite. If w belongs to the base relative class, [Proposition 15.6.6](#) gives equality of the two envelopes upstairs below every smooth obstacle.

For any ordinary representative of u or q_M , removal and descent give the form $\Psi + c \circ p$ with $c \in \text{PSH}(Y, \beta)$. Outside H , replace c locally by $\max(c, -k)$ and keep Ψ . The resulting bounded quasi-plurisubharmonic potentials have currents pulled back from the d -dimensional base, so their n th products vanish by [Lemma 1.7.2](#), since $n > d$. By plurifine locality, this product agrees with the original extended measure on $\{c \circ p > -k\}$. These sets cover the locus where $c \circ p$ is finite, and the pole sets and H receive no mass. This proves the mass and volume assertions. $\square$

Corollary 15.6.1 *The ordinary and ideal envelopes of u agree below every smooth obstacle on M if and only if those of w agree below every smooth obstacle on Y .*

Put $q = P_\beta[w]_I$. If $w \in \mathcal{E}_{\text{env}}(Y, \beta, q)$, then

$$P_{\Theta, F}[u] = P_{\Theta, F}[u]_I \quad \text{for every smooth real } F.$$

If Y is a curve, write

$$T_w = \beta + \text{dd}^c w, \quad \mu_w = \mathbf{1}_{\{w=-\infty\}} T_w, \quad D_w = \sum_{y \in Y} v(w, y) \delta_y$$

for the curvature measure of w , its polar part and its atomic part. Then equality of the two envelopes of u below zero, the equality $\mu_w = D_w$, and equality of the two envelopes of u below every smooth obstacle are equivalent. They are also equivalent to

$$u \in \mathcal{E}_{\text{env}}(M, \Theta, P_\Theta[u]_I).$$

These equivalences also hold when $\int_Y \beta = 0$.

Proof The forward implication is part of [Proposition 15.6.8](#). For the converse, we approximate a smooth obstacle on the base by the induced obstacles of continuous obstacles upstairs. Suppose that the envelopes upstairs agree below every smooth obstacle. Uniform obstacle comparison extends this equality to continuous real obstacles. Fix a smooth real function B on Y and put $G = \bar{0}$. The continuous obstacles

$$F_j = B \circ p + \max(\Psi, -j) \quad (j \geq 1)$$

have induced base obstacles

$$G_j = B + \max(G - j, 0),$$

with value $+\infty$ on Z . By the reduction and the assumed equality,

$$q_j = P_{\beta, G_j}[w]_I = P_{\beta, G_j}[w].$$

Write $q_B = P_{\beta,B}[w]_{\mathcal{I}}$. Then $q_B \leq q_j \leq q_1$, and the q_j decrease to a β -plurisubharmonic potential r , not identically $-\infty$, with convergence in L^1 ; indeed, their negative parts are bounded by that of q_B , and [Corollary 1.4.1](#) applies. The set Z has smooth volume zero: in each product chart of the submersion, the preimage of Z lies in H , which has smooth volume zero, and Fubini's theorem gives the assertion on the base. Off Z , the bounds $q_j \leq G_j \downarrow B$ give $r \leq B$, and almost-everywhere order in [Lemma 1.3.3](#) extends the inequality to all of Y .

Each q_j is multiplier-ideal equivalent to w . To see this without assuming G_j finite, put $Q_0 = P_{\Theta}[u]_{\mathcal{I}}$ and $Q_j = P_{\Theta,F_j}[u]_{\mathcal{I}}$. Translation of the competitor families gives

$$Q_0 + \min_M F_j \leq Q_j \leq Q_0 + \max_M F_j.$$

Thus $Q_j \sim Q_0 \sim_{\mathcal{I}} u$ by [Theorem 15.2.1](#). Since $Q_j = \Psi + q_j \circ p$, cancellation and reflection of multiplier ideals under submersions, [Lemmas 1.16.3](#) and [1.16.4](#), give $q_j \sim_{\mathcal{I}} w$. The same bounded comparison with $P_{\beta}[w]_{\mathcal{I}}$ gives $q_B \sim_{\mathcal{I}} w$.

Let π be any smooth local modification of a coordinate neighborhood in the base. The bounds $q_B \circ \pi \leq q_j \circ \pi \leq q_1 \circ \pi$ give decreasing local L^1 convergence to $r \circ \pi$. At every point x of this modification, [Lemma 1.17.5](#) and the ordinary order give

$$v(w \circ \pi, x) \leq v(r \circ \pi, x) \leq v(q_B \circ \pi, x) = v(w \circ \pi, x).$$

All these Lelong numbers are therefore equal, and [Theorem 1.16.1](#) gives $r \sim_{\mathcal{I}} w$. Together with $r \leq B$, this makes r a competitor for q_B . Hence $r = q_B$.

Put $\epsilon_j = \max\{0, \sup_Y(q_j - B)\}$. The moving-point estimate in [Lemma 1.4.1](#) gives $\epsilon_j \rightarrow 0$: otherwise a subsequence of maximizers of $q_j - B$ converges to some y , where that estimate contradicts $q_B(y) \leq B(y)$. Every ordinary competitor b below G_j satisfies $b \leq q_j$, so $b - \epsilon_j \leq B$ and $b - \epsilon_j \preceq w$. Taking regularized suprema yields

$$q_j - \epsilon_j \leq P_{\beta,B}[w].$$

Since $q_B \leq q_j$, letting $j \rightarrow \infty$ proves $q_B \leq P_{\beta,B}[w]$. The reverse inequality always holds, so the two envelopes agree below B . Since B was arbitrary, this proves the converse.

Under the relative-class hypothesis, [Proposition 15.6.6](#) gives equality of the two base envelopes below every smooth obstacle, and the equivalence just proved gives the stated equality upstairs.

In the curve case, put $G = \widehat{0}$ and $L = -\sup_M \Psi$. The uniform bound in Step 2 of the proof of [Proposition 15.6.8](#) gives a finite K with $\sup_Y b \leq K$ for every $b \in \text{PSH}(Y, \beta)$ below G . Since $G \geq L$, translation of the two competitor families gives

$$\begin{aligned} P_\beta[w] + L &\leq P_{\beta,G}[w] \leq P_\beta[w] + K, \\ q + L &\leq P_{\beta,G}[w]_I \leq q + K. \end{aligned}$$

By [Proposition 29.13.1](#) and [Corollary 1.6.1](#), the polar curvatures of these two base envelopes are μ_w and D_w , respectively. Thus equality of the envelopes upstairs below zero forces $\mu_w = D_w$. Conversely, under this equality of measures, [Corollary 29.13.1](#) gives equality below every smooth obstacle on the base. As in Step 5 of the proof of [Proposition 15.6.8](#), this extends to every induced obstacle $\widehat{F}$, and the reduction gives equality upstairs below every smooth obstacle. Taking $F = 0$ proves the remaining implication. The same curve criterion identifies the equality of measures with membership of w in the base relative envelope class of q , and the equivalence for ideal references in [Proposition 15.6.9](#) gives the last assertion upstairs. $\square$

The normal-crossing hypothesis is needed only for the explicit formula (15.8). The reduction of the envelopes holds without it.

Example 15.6.1 On $M = \mathbb{P}^1 \times \mathbb{P}^1$, let p, r be the projections and let σ be the probability Fubini–Study form. With homogeneous coordinates $[y_0 : y_1]$ and $[z_0 : z_1]$, the divisor

$$H = \{y_0 z_0^2 + y_1 z_1^2 = 0\}$$

is smooth, meets every fiber properly and ramifies over the first factor. Give $\mathcal{O}_M(H) = \mathcal{O}_M(1, 2)$ its product metric, with logarithmic divisor potential Ψ and curvature $\kappa_H = p^* \sigma + 2r^* \sigma$. Put $\Theta = 2p^* \sigma + 2r^* \sigma$ and choose $w \in \text{PSH}(\mathbb{P}^1, \sigma)$ with $\sigma + \text{dd}^c w = \delta_{[0:1]}$. Both obstacle envelopes of $u = \Psi + w \circ p$ reduce to the base, but the product formula for its multiplier ideals fails at a ramification point.

Proof For each $[z_0 : z_1]$ there is a unique point $[y_0 : y_1] = [-z_1^2 : z_0^2]$ on H , so H is a smooth graph over the second factor, and its projection to the base has degree two. In particular no fiber of p lies in H . Since $\Theta = p^* \sigma + \kappa_H$, [Proposition 15.6.8](#) gives both envelope identities.

Near $([0 : 1], [1 : 0])$, use $y = y_0/y_1$ and $z = z_1/z_0$. Up to smooth additions,

$$\Psi = \log |y + z^2|^2, \quad w = \log |y|^2, \quad u = \log |y(y + z^2)|^2.$$

At $t = 3/4$, each of the two weights separately has trivial multiplier ideal, so the right side of (15.8) would be $\mathcal{O}_M$. However, $1 \notin I(3u/4)$ at this point. Indeed, consider the region where $y = cz^2$ with $|c - 1| < 1/4$ and $0 < |z| < \epsilon$; for fixed z , it has area comparable to $|z|^4$ in the y variable. The weighted integral of 1 is therefore bounded below by a positive constant times

$$\int_{0 < |z| < \epsilon} |z|^{-6} |z|^4 d\lambda_z = 2\pi \int_0^\epsilon \frac{dr}{r} = +\infty,$$

where $d\lambda_z$ is planar area. Thus the multiplier ideal is proper. The envelope identities follow instead from the behavior of multiplier-ideal equivalence under addition, and do not require the product formula. $\square$

If the divisor contains an entire fiber, the induced obstacle is infinite over that fiber. The next example still admits an explicit model for the zero obstacle.

Example 15.6.2 Let $M = \mathbb{P}^2 \times \mathbb{P}^1$, with projections p, r , and let σ_j be the standard Fubini–Study form on $\mathbb{P}^j$. In the positive closed background

$$\Theta = 2p^*\sigma_2 + r^*\sigma_1,$$

there is a logarithmic potential Ψ of a smooth prime divisor containing the fiber over $E = [0 : 0 : 1]$. Its fiber infimum for the zero obstacle is finite and continuous off E and tends to $+\infty$ at E . Nevertheless,

$$P_\Theta[\Psi] = P_\Theta[\Psi]_I = \Psi + q \circ p,$$

where $q \in \text{PSH}(\mathbb{P}^2, \sigma_2)$ is bounded, $0 \leq q \leq \log 4$ and $q(E) = \log 4$. Every ordinary representative of this model has zero extended mass, so both singularity volumes vanish. The two envelopes also agree below every smooth obstacle.

Proof Use homogeneous coordinates $[y_0 : y_1 : y_2]$ and $[z_0 : z_1]$, and take

$$H = \{y_0 z_0 + y_1 z_1 = 0\}, \quad \Psi = \log \frac{|y_0 z_0 + y_1 z_1|^2}{(|y_0|^2 + |y_1|^2 + |y_2|^2)(|z_0|^2 + |z_1|^2)}.$$

Outside E , the divisor is the graph $[z_0 : z_1] = [-y_1 : y_0]$. Its closure contains the whole fiber over E , so H is prime. It is smooth outside that fiber by the graph description, and smooth along it because the derivatives in the y_0 and y_1 directions are z_0 and z_1 , which cannot both vanish. Its product metric has curvature $p^*\sigma_2 + r^*\sigma_1$, hence

$$\Theta + \text{dd}^c \Psi = p^*\sigma_2 + [H].$$

Writing $S = |y_0|^2 + |y_1|^2$, the Cauchy–Schwarz inequality gives the fiber obstacle

$$G(y) = -\max_{z \in \mathbb{P}^1} \Psi(y, z) = \log \frac{S + |y_2|^2}{S}, \quad G(E) = +\infty.$$

It has no finite continuous extension at E .

We claim that the largest σ_2 -plurisubharmonic potential below G is

$$q(y) = \begin{cases} \log \frac{4|y_2|^2}{S + |y_2|^2}, & S \leq |y_2|^2, \\ \log \frac{S + |y_2|^2}{S}, & S \geq |y_2|^2. \end{cases}$$

To see that q is σ_2 -plurisubharmonic, work on $y_2 \neq 0$ with $x = (y_0/y_2, y_1/y_2)$ and $t = \log |x|^2$. Adding the Fubini–Study potential $L(x) = \log(1 + |x|^2)$ gives

$$q + L = \begin{cases} \log 4, & t \leq 0, \\ 2 \log(1 + e^t) - t, & t \geq 0. \end{cases}$$

This function and its first derivative are continuous at $t = 0$. For $t > 0$, its first two derivatives are $(e^t - 1)/(e^t + 1) \geq 0$ and $2e^t/(1 + e^t)^2 > 0$. It is therefore a convex nondecreasing function of t , hence plurisubharmonic in x , across the unit sphere as well. The expression is constant near $x = 0$, and $q = G$ is smooth near $y_2 = 0$, so q is globally σ_2 -plurisubharmonic and bounded.

If $b \in \text{PSH}(\mathbb{P}^2, \sigma_2)$ lies below G , then $b + L \leq \log 4$ on $|x| = 1$, and the maximum principle on the unit ball gives $b \leq q$ inside it. Outside the ball, the obstacle already gives $b \leq G = q$. For $0 < R = |x|^2 \leq 1$, the inequality $q \leq G$ reads $4R \leq (1 + R)^2$, and at E it is automatic. The formula for q also gives the asserted bounds, which proves the claim.

For every ordinary or ideal competitor v for Ψ , the ordinary order or [Theorem 1.16.1](#) gives $v(v, H) \geq 1$. Divisorial removal and descent along the fibers, [Lemma 1.17.1](#) and [Proposition 1.22.1](#), give $v = \Psi + b \circ p$ with $b \in \text{PSH}(\mathbb{P}^2, \sigma_2)$. The bound $v \leq 0$ gives $b \leq G$ off E , hence everywhere with the extended value at E . Thus $v \leq \Psi + q \circ p$. Conversely, this upper bound is a competitor for both envelopes, since it is nonpositive and differs boundedly from Ψ . This proves the envelope identities directly.

On $M \setminus H$, bounded local truncations of b have products pulled back from a two-dimensional base, so their third products vanish by [Lemma 1.7.2](#), and plurifine locality gives zero extended mass. Divisorial removal puts every ordinary representative of the model in this form, which proves both volume assertions. Finally, since the model is ordinarily equivalent to Ψ , [Proposition 12.4.1](#) gives $\Psi \in \mathcal{E}_{\text{env}}(M, \Theta, P_{\Theta}[\Psi]_I)$, and [Proposition 15.6.6](#) gives equality below every smooth obstacle. $\square$

Example 15.6.3 There is a Hermitian background Θ on a compact fourfold that fails the bounded mass property and admits a potential u without an analytic ordinary type such that

$$P_{\Theta}[u] = P_{\Theta}[u]_I = \Psi, \quad u \not\sim \Psi.$$

Both envelopes agree below every smooth obstacle, and their common model for the zero obstacle has both singularity volumes zero.

Proof Let (Y, ω) be the Hopf threefold of [Theorem 8.0.1](#). On $\mathbb{P}^1$, let σ be the probability Fubini–Study form, choose a point D and a logarithmic potential ψ with $\sigma + \text{dd}^c \psi = [D]$ and $\sup \psi = 0$. On $M = Y \times \mathbb{P}^1$, with projections p, r , put

$$\Theta = p^* \omega + r^* \sigma, \quad H = Y \times D, \quad \Psi = \psi \circ r.$$

Take the potential $U \in \mathcal{E}_{\text{env}}(Y, \omega, 0)$ of infinite mass from [Proposition 12.6.1](#), which satisfies $P_\omega[U] = 0$. Its multiplier ideals are trivial, so also $P_\omega[U]_I = 0$. Set $u = \Psi + U \circ p$. Here $\widehat{0} = 0$, so [Proposition 15.6.8](#) and [Corollary 15.6.1](#) give the envelope identities, the equality below all obstacles and the vanishing of the singularity volumes. Moreover $u \in \mathcal{E}_{\text{env}}(M, \Theta, \Psi)$ by [Proposition 15.6.9](#). Since U has infinite extended mass, it is unbounded; restriction to a section outside H therefore proves $u \not\sim \Psi$. If a potential a with analytic singularities were ordinarily equivalent to u , [Proposition 15.2.3](#) would give $u \sim a \sim P_\Theta[a] = P_\Theta[u] = \Psi$, a contradiction.

Finally, let V_j be the smooth potentials of [Theorem 8.0.1](#). Their pullbacks are bounded and Θ -plurisubharmonic, and [Proposition 18.8.1](#) gives

$$\int_M \text{MA}_\Theta(V_j \circ p) = 4 \int_Y \text{MA}_\omega(V_j) \longrightarrow +\infty.$$

Thus Θ itself fails the bounded mass property. $\square$

The descent of potentials uses that the fibers are connected. Otherwise the residual potential can take independent values on different components of a fiber, as a finite isogeny shows.

Example 15.6.4 There is a surjective holomorphic submersion $p : M \rightarrow Y$ from a connected compact Kähler surface to an elliptic curve, with four components in every fiber, for which both identities in (15.7) fail. The pole divisor is smooth and maps onto Y , and the obstacle upstairs is smooth.

Proof Let $E = \mathbb{C}/(\mathbb{Z} + i\mathbb{Z})$, let β be its flat probability form, and let $q : E \rightarrow E$ be multiplication by two. On $M = E \times \mathbb{P}^1$, denote the projections by a, r and put $p = q \circ a$. Then q is an unramified covering of degree four and $q^* \beta = 4\beta$. The manifold M is connected, whereas every fiber of p is the disjoint union of four projective lines.

On $\mathbb{P}^1$ take the probability Fubini–Study form σ , a point D and a logarithmic potential ψ with $\sigma + \text{dd}^c \psi = [D]$ and $\sup \psi = 0$. Put

$$H = E \times D, \quad \Psi = \psi \circ r, \quad \Theta = p^* \beta + r^* \sigma = 4a^* \beta + r^* \sigma.$$

Thus $\Theta + \text{dd}^c \Psi = p^* \beta + [H]$, which corresponds to the base potential $w = 0$. Choose $\epsilon > 0$ so small that

$$f(\zeta) = \epsilon \cos(2\pi \text{Re } \zeta) \in \text{PSH}(E, 4\beta),$$

and set $F = f \circ a$. The function f is well defined and smooth on E . Since it changes sign under translation by $1/2$, it is not constant on the fibers of q .

Apply **Proposition 15.6.8** to the projection a , which has connected fibers, with base background 4β and base potential zero. Its induced obstacle is f , since $\sup \psi = 0$. The bounded potential f is a competitor for both base envelopes and equals their obstacle, so

$$P_{\Theta, F}[\Psi] = P_{\Theta, F}[\Psi]_I = \Psi + f \circ a.$$

For the map p , the fiber obstacle of **Proposition 15.6.8** would instead be

$$\widehat{F}(y) = \min_{q(\zeta)=y} f(\zeta).$$

Every expression $\Psi + b \circ p$ is invariant under translation of the first factor by points of the kernel of q . The computed envelope is not invariant under translation by $1/2$, because Ψ is unchanged and f changes sign. It therefore cannot equal either right side of (15.7) for p . $\square$

The correct formula takes the fiber minimum over each connected component of a fiber separately. These components are the points of the finite covering of the base in **Lemma 1.22.2**.

Corollary 15.6.2 *Let $p : M \rightarrow Y$ be a surjective holomorphic submersion between connected compact complex manifolds, with $1 \leq \dim Y < \dim M$; its fibers may be disconnected. Use the weighted divisor data A, H, Ψ, κ_A above, let β be a smooth real $(1, 1)$ -form on Y , and let $w \in \text{PSH}(Y, \beta)$. Put*

$$\Theta = p^* \beta + \kappa_A, \quad u = \Psi + w \circ p.$$

*For the factorization $p = r \circ \pi$ of **Lemma 1.22.2**, set $\beta' = r^* \beta$ and $w' = w \circ r$. For $F \in C(M, \mathbb{R})$ define*

$$\widehat{F}_{\text{comp}}(y') = \inf_{x \in \pi^{-1}(y') \setminus H} \{F(x) - \Psi(x)\}, \quad \inf \emptyset = +\infty.$$

This obstacle is continuous in the extended real sense on Y' , and

$$\begin{aligned} P_{\Theta, F}[u] &= \Psi + P_{\beta', \widehat{F}_{\text{comp}}}[w'] \circ \pi, \\ P_{\Theta, F}[u]_I &= \Psi + P_{\beta', \widehat{F}_{\text{comp}}}[w']_I \circ \pi. \end{aligned}$$

Every representative of the ordinary type of u or of $P_{\Theta}[u]_I$ has zero extended mass, and both singularity volumes of these types are zero. The ordinary and ideal envelopes of u agree below every smooth obstacle on M if and only if those of w' agree below every smooth obstacle on Y' .

For $\varphi \in \text{PSH}(Y, \beta)$, put $v = \Psi + \varphi \circ p$. Then

$$u \in \mathcal{E}_{\text{env}}(M, \Theta, v) \iff w \in \mathcal{E}_{\text{env}}(Y, \beta, \varphi).$$

For $q_M = P_{\Theta}[u]_I$ and $q_Y = P_{\beta}[w]_I$, one also has

$$u \in \mathcal{E}_{\text{env}}(M, \Theta, q_M) \iff w \in \mathcal{E}_{\text{env}}(Y, \beta, q_Y).$$

If Y is a curve, let μ_w, D_w be the polar and atomic measures of [Corollary 15.6.1](#). Then equality of the envelopes of u below zero, the equality $\mu_w = D_w$, and equality of the envelopes of u below every smooth obstacle are equivalent. They are also equivalent to $u \in \mathcal{E}_{\text{env}}(M, \Theta, q_M)$.

Proof The covering map r preserves the curvature inequality, so $w' \in \text{PSH}(Y', \beta')$. Moreover $\dim Y' = \dim Y < \dim M$, and

$$\Theta = \pi^* \beta' + \kappa_A, \quad u = \Psi + w' \circ \pi.$$

Applying [Proposition 15.6.8](#) to the submersion π , which has connected fibers, gives the obstacle identities and the mass assertions, and [Corollary 15.6.1](#) for the same submersion gives the equivalence for all obstacles. In [Example 15.6.4](#), this factorization has $Y' = E$, $r = q$ and $\pi = a$, so it recovers the computed envelope.

For the assertions on relative classes, apply [Proposition 15.6.9](#) to π , with reference $\varphi \circ r$ on Y' , and then transfer membership through r by [Proposition 15.6.7](#). That proposition, applied with the zero obstacle, also gives

$$P_{\beta'}[w']_I = q_Y \circ r.$$

Applying the same two equivalences with these ideal references proves the assertion for q_M and q_Y .

In the curve case, Y' is a curve. The covering is locally biholomorphic, so curvature measures and point Lelong numbers pull back without multiplicities. The pole set of w' is $r^{-1}\{w = -\infty\}$, and therefore

$$\mu_{w'} = r^* \mu_w, \quad D_{w'} = r^* D_w,$$

where the pullback of a measure is defined on each sheet through the local inverse of r . Such pullbacks reflect equality: over every sufficiently small ball in Y , the restriction of a measure is recovered from any sheet over that ball. Hence $\mu_{w'} = D_{w'}$ if and only if $\mu_w = D_w$. The curve case of [Corollary 15.6.1](#), applied to π , identifies the former equality with the equality of the envelopes upstairs below zero, with their equality below every smooth obstacle and with membership in the relative envelope class upstairs. This proves the last assertion. $\square$

15.6.6 Divisorial products and zero volume

The simplest case of the fibration reduction is a product of a curve C with a compact Kähler manifold Z , with the poles of Ψ along $C \times D$ for a smooth divisor $D \subset Z$. If the divisor potential on Z has supremum zero, the induced zero obstacle on C is zero, so the envelopes of $\Psi + w \circ p$ are determined by those of w on the curve. Projective products then give potentials without analytic ordinary type whose two envelopes agree, as well as distinct models with the same zero volumes. Since top-degree mass vanishes on all these models, volumes cannot distinguish them. Polar curvature on the curve can, and it gives a complete metric on the resulting class of product models.

Let C be a compact connected curve with a smooth positive form η , and let Z be a connected compact Kähler manifold of dimension $k \geq 1$. Suppose that $D \subset Z$ is a nonempty smooth reduced divisor, κ is a Kähler form on Z , and $\psi \in \text{PSH}(Z, \kappa)$ is smooth off D and satisfies

$$\kappa + \text{dd}^c \psi = [D], \quad \sup_Z \psi = 0.$$

Thus, near D , ψ is $\log |z_1|^2$ plus a smooth function, where z_1 is a local equation of D . On $M = C \times Z$, write $p : M \rightarrow C$ and $r : M \rightarrow Z$ for the projections, and put

$$\Theta = p^* \eta + r^* \kappa, \quad \Psi = \psi \circ r, \quad H = C \times D.$$

For $w \in \text{PSH}(C, \eta)$ set $u = \Psi + w \circ p$.

On the curve (C, η) , we use the description of models given in [Section 29.12](#). Recall from [Section 1.6.1](#) that the polar curvature of $q \in \text{PSH}(C, \eta)$ is the restriction of the curvature measure $\eta + \text{dd}^c q$ to the pole set $\{q = -\infty\}$; it is a positive measure carried by a polar set, of mass at most $\int_C \eta$. By [Lemma 29.12.1](#), every such measure is the polar curvature of exactly one ordinary model, and the ordinary envelope of any potential is the model with the same polar curvature. Ideal projection replaces the polar curvature by its atomic part, by [Lemma 18.5.1](#) and [Proposition 29.12.1](#). Finally, the total variation of the difference of polar curvatures is a complete geodesic metric on ordinary models, which coincides with the upper-volume comparison d_η of [Definition 29.6.1](#), by [Theorem 29.12.1](#) and [Corollary 29.12.1](#).

Proposition 15.6.10 For $F \in C^\infty(M, \mathbb{R})$, the function

$$\widehat{F}(y) = \min_{z \in Z \setminus D} \{F(y, z) - \psi(z)\} \quad (y \in C)$$

is finite and continuous. The two envelopes satisfy

$$\begin{aligned} P_{\Theta, F}[u] &= \Psi + P_{\eta, \widehat{F}}[w] \circ p, \\ P_{\Theta, F}[u]_I &= \Psi + P_{\eta, \widehat{F}}[w]_I \circ p. \end{aligned} \quad (15.9)$$

Proof Apply **Proposition 15.6.8** to $p : M \rightarrow C$, with $H = C \times D$, $\beta = \eta$ and $\Psi = \psi \circ r$. The local logarithmic form of ψ defines a smooth metric on $\mathcal{O}_M(H)$ with curvature $r^*\kappa$. Thus $\Theta + \text{dd}^c \Psi = p^*\eta + [H]$, and H is smooth and transverse to the fibers. The induced fiber minimum is the function $\widehat{F}$ above. For $F = 0$, the normalization $\sup_Z \psi = 0$ gives $\widehat{0} = 0$. $\square$

Example 15.6.5 Take $C = \mathbb{P}^1$ and $Z = \mathbb{P}^k$, $k \geq 1$, with their standard Fubini–Study forms, and let D be a hyperplane. In this product setting there is a potential u without an analytic ordinary type such that

$$P_\Theta[u] = P_\Theta[u]_I = \Psi, \quad u \not\sim \Psi,$$

and the two envelopes of u agree below every smooth obstacle. Their common model for the zero obstacle has zero singularity volume.

Proof Use the unbounded curve potential w constructed in the proof of **Proposition 15.6.2**, whose two envelopes are zero. A logarithmic potential of a hyperplane on Z gives ψ with $\kappa + \text{dd}^c \psi = [D]$ and supremum zero. Set $u = \Psi + w \circ p$ and apply **Proposition 15.6.10** and **Corollary 15.6.1**. Fixing $z \notin D$ shows that $u - \Psi = w \circ p$ is unbounded, so $u \not\sim \Psi$. If a potential a with analytic singularities were ordinarily equivalent to u , **Proposition 15.2.3** would give $u \sim a \sim P_\Theta[a] = P_\Theta[u] = \Psi$, a contradiction. $\square$

Vanishing of the volumes does not force the two envelopes to agree.

Example 15.6.6 In the product setting, take $C = \mathbb{P}^1$ and $Z = \mathbb{P}^k$, $k \geq 1$, with probability Fubini–Study forms and a hyperplane D . The positive closed background Θ admits normalized ordinary models $a \leq b$ with

$$\begin{aligned} P_\Theta[a] &= a, & P_\Theta[a]_I &= P_\Theta[b] = P_\Theta[b]_I = b, \\ a &\sim_I b, & a &\not\sim b, \\ \underline{\text{vol}}_\Theta(a) &= \overline{\text{vol}}_\Theta(a) = \underline{\text{vol}}_\Theta(b) = \overline{\text{vol}}_\Theta(b) = 0. \end{aligned}$$

Thus equal singularity volumes of a type and of its ideal model do not imply equality of the envelopes at zero volume.

Proof Use the normalized diffuse polar curve model w of [Example 29.12.2](#) on $\mathbb{P}^1$ with its probability Fubini–Study form. It satisfies $P_\eta[w] = w$ and $P_\eta[w]_I = 0$, and it is unbounded. Take the normalized hyperplane potential on $\mathbb{P}^k$ and put

$$a = \Psi + w \circ p, \quad b = \Psi.$$

The identities for the zero obstacle in [Proposition 15.6.10](#) give all four envelope identities. Both functions have supremum zero, and $w \leq 0$ gives $a \leq b$. Ideal projection preserves the ideal type by [Theorem 15.2.1](#), so $a \sim_I b$. Restriction to $\mathbb{P}^1 \times \{z\}$, for any $z \notin D$, gives the unbounded difference w , so $a \not\sim b$. Finally, [Proposition 15.6.8](#) gives zero extended mass for every ordinary representative of either model, which proves all four volume identities. $\square$

The same failure occurs in a nonclosed background once a second curve factor is added.

Example 15.6.7 In every complex dimension $n \geq 3$, there is a projective manifold with the bounded mass property that admits a smooth positive nonclosed background Θ and normalized ordinary models $a \leq b$ such that

$$\begin{aligned} P_\Theta[a] &= a, & P_\Theta[a]_I &= P_\Theta[b] = P_\Theta[b]_I = b, \\ a &\sim_I b, & a &\not\sim b, \\ \underline{\text{vol}}_\Theta(a) &= \overline{\text{vol}}_\Theta(a) = \underline{\text{vol}}_\Theta(b) = \overline{\text{vol}}_\Theta(b) = 0. \end{aligned}$$

In particular, equality of the upper volumes of a type and of its ideal model does not force equality of the envelopes when the ideal model has zero lower volume.

Proof Let $Y = \mathbb{P}^1 \times \mathbb{P}^1$, with projections π_1, π_2 , and let σ be the probability Fubini–Study form on $\mathbb{P}^1$. Choose a positive nonconstant smooth function f on the first factor and put

$$\beta = \pi_1^* \sigma + (f \circ \pi_1) \pi_2^* \sigma.$$

This form is positive, and $d\beta = \pi_1^*(df) \wedge \pi_2^* \sigma \neq 0$. Let w_0 be the normalized diffuse polar model of [Example 29.12.2](#), and put $w = w_0 \circ \pi_1$. Then $w \in \text{PSH}(Y, \beta)$ and

$$P_\beta[w] = w, \quad P_\beta[w]_I = 0.$$

Indeed, replace an ordinary competitor $v \leq 0$ by $\max(v, w)$. On every horizontal section $y \mapsto (y, z)$, where β restricts to σ , this maximum is a σ -plurisubharmonic function, not identically $-\infty$ since it dominates w_0 , and it is at least as singular as w_0 . Its restriction is therefore at most $P_\sigma[w_0] = w_0$. This proves $v \leq w$ on Y ; the reverse inequality for the envelope holds because w is itself a competitor. All multiplier ideals of w_0 are trivial, so [Lemma 1.16.4](#) shows that the same holds for w . Since β is positive, zero is a competitor for the ideal envelope of w , which proves the second identity.

Set $k = n - 2$ and $M = Y \times \mathbb{P}^k$, with projections p, r . On the second factor take the probability Fubini–Study form κ , a hyperplane D , and its normalized potential ψ with $\kappa + \text{dd}^c \psi = [D]$. Put

$$\Theta = p^* \beta + r^* \kappa, \quad \Psi = \psi \circ r, \quad a = \Psi + w \circ p, \quad b = \Psi.$$

The form Θ is positive and not closed. A sufficiently large multiple of the closed positive product form dominates Θ , so the bounded mass property follows from Stokes’ theorem for that closed form and the metric independence in [Proposition 6.5.1](#).

Apply [Proposition 15.6.8](#) to $p : M \rightarrow Y$ and the divisor $Y \times D$. The induced zero obstacle is zero because $\sup \psi = 0$. The two identities on the base give all four identities upstairs, and both functions have supremum zero. Ideal projection preserves the ideal type, so $a \sim_{\mathcal{I}} b$. Moreover $a \leq b$, while their difference restricts to the unbounded function w on any section outside the divisor, so $a \not\sim b$. Since $\dim Y = 2 < n$, the same proposition gives zero extended mass for every ordinary representative of a or b , which proves the volume assertions. $\square$

We return to the product $M = C \times Z$ and its fixed divisor potential Ψ . All the models $\Psi + q \circ p$ have zero top-degree volumes, but the polar curvature of q on C still distinguishes them.

Definition 15.6.1 For a normalized ordinary model q in background η on C , put

$$\Phi(q) = \Psi + q \circ p, \quad S_\Psi = \{\Phi(q) : P_\eta[q] = q\}.$$

Write $\mu_q = \mathbf{1}_{\{q=-\infty\}}(\eta + \text{dd}^c q)$ for the polar curvature of q , and define

$$\rho_\Psi(\Phi(q_1), \Phi(q_2)) = \|\mu_{q_1} - \mu_{q_2}\|_{\text{TV}}. \quad (15.10)$$

Proposition 15.6.11 *The set $\mathcal{S}_\Psi$ consists of normalized ordinary models in background Θ , and $(\mathcal{S}_\Psi, \rho_\Psi)$ is a complete geodesic metric space. The upper-volume comparison d_Θ of Definition 29.6.1, which is formed from the upper singularity volumes of a , b and $\max(a, b)$, vanishes identically on this set:*

$$d_\Theta(a, b) = 0 \quad (a, b \in \mathcal{S}_\Psi).$$

The ideal models in $\mathcal{S}_\Psi$ form a closed geodesically convex subspace, equal to the ρ_Ψ -closure of the models with analytic singularities. Ideal projection is a 1-Lipschitz retraction onto this subspace and selects the unique nearest ideal model. For $a = \Phi(q)$, the distance from a to this subspace is the mass of the nonatomic part of μ_q . If $\rho_\Psi(a_j, a) \rightarrow 0$, then $a_j \rightarrow a$ in $L^1(M)$ for every smooth positive volume form.

Proof The identities for the zero obstacle in Proposition 15.6.10 give

$$P_\Theta[\Phi(q)] = \Phi(q), \quad P_\Theta[\Phi(q)]_I = \Phi(P_\eta[q]_I).$$

Both summands of $\Phi(q)$ have supremum zero on their respective factors, so $\Phi(q)$ is normalized. Restriction to any section outside D shows that Φ is injective. The classification in Lemma 29.12.1 and the distance formula in Theorem 29.12.1 therefore make Φ an isometry from the space of curve models onto $\mathcal{S}_\Psi$. Completeness and the existence of geodesics follow from Corollary 29.12.1.

By Proposition 15.6.8, every ordinary representative of $\Phi(q)$ has zero extended mass. Moreover,

$$\max(\Phi(q_1), \Phi(q_2)) = \Psi + \max(q_1, q_2) \circ p,$$

and the same proposition, applied to the curve potential $\max(q_1, q_2)$, gives zero upper volume for the maximum. Thus all three upper volumes in the definition of d_Θ vanish.

Under Φ , ideal projection corresponds to taking the atomic part of μ_q . The assertions on closedness, convexity and nearest points therefore follow from Corollary 29.12.1 and Proposition 29.12.1. To prove analytic closure upstairs, approximate an atomic measure by finite atomic measures with rational coefficients and mass less than $\int_C \eta$. By Lemma 18.5.1, their curve models have the corresponding logarithmic poles up to bounded remainders. Adding Ψ preserves an analytic presentation: in the local product monomial, clear the denominators of the rational pole coefficients together with the unit coefficient of D . The resulting models in $\mathcal{S}_\Psi$ converge for ρ_Ψ . Conversely, by Proposition 15.2.3, every ordinary model with analytic singularities in this locus is equal to its ideal projection, so the closure of these models lies in the closed ideal subspace.

Finally, if $\rho_\Psi(\Phi(q_j), \Phi(q)) \rightarrow 0$, then Theorem 29.12.2 gives $q_j \rightarrow q$ in $L^1(C)$. Off the pole sets, which have smooth volume zero, the difference of the two product potentials is $(q_j - q) \circ p$. For a smooth positive volume form dV on M , integration along the compact fibers makes p_*dV a smooth positive density on C , and Fubini's theorem gives

$$\int_M |\Phi(q_j) - \Phi(q)| dV \leq C_{dV} \|q_j - q\|_{L^1(C, \eta)} \longrightarrow 0,$$

where C_{dV} bounds the density of $p_* dV$ with respect to η . $\square$

The same complete metric exists on the corresponding product locus in the nonclosed background of [Example 15.6.7](#).

Corollary 15.6.3 *Let $M = \mathbb{P}^1 \times \mathbb{P}^1 \times \mathbb{P}^k$, $k \geq 1$, with projections h, s, r . Let σ and κ be the probability Fubini–Study forms on $\mathbb{P}^1$ and $\mathbb{P}^k$, respectively, and let f be a positive nonconstant smooth real function on the first factor. Set*

$$\Theta = h^* \sigma + (f \circ h) s^* \sigma + r^* \kappa, \quad \Psi = \psi \circ r,$$

where ψ is the normalized hyperplane potential with $\kappa + dd^c \psi = [D]$. For every normalized ordinary model q on $(\mathbb{P}^1, \sigma)$, put $\Phi_f(q) = \Psi + q \circ h$. Then

$$P_\Theta[\Phi_f(q)] = \Phi_f(q), \quad P_\Theta[\Phi_f(q)]_I = \Phi_f(P_\sigma[q]_I).$$

On $\mathcal{T}_\Psi = \{\Phi_f(q) : P_\sigma[q] = q\}$, define

$$\begin{aligned} \rho_{\Psi, f}(\Phi_f(q_1), \Phi_f(q_2)) &= \|\mu_{q_1} - \mu_{q_2}\|_{TV}, \\ \mu_q &= \mathbf{1}_{\{q=-\infty\}}(\sigma + dd^c q). \end{aligned}$$

All the conclusions of [Proposition 15.6.11](#) hold on this locus: completeness and geodesics, vanishing of the upper-volume comparison, a closed ideal subspace in which analytic models are dense, ideal projection as the nearest-point retraction, and L^1 convergence upstairs.

Proof On $Y = \mathbb{P}^1 \times \mathbb{P}^1$, write π_1, π_2 for the projections and put $\beta = \pi_1^* \sigma + (f \circ \pi_1) \pi_2^* \sigma$. The restriction argument of [Example 15.6.7](#) applies to every normalized ordinary curve model and gives

$$P_\beta[q \circ \pi_1] = q \circ \pi_1.$$

Indeed, the maximum of an ordinary competitor with $q \circ \pi_1$ restricts on every horizontal section to a competitor for $P_\sigma[q] = q$ that is σ -plurisubharmonic and not identically $-\infty$.

Put $q_I = P_\sigma[q]_I$ and let E be the atomic part of μ_q . The Green potential w_E of [Lemma 18.5.1](#) satisfies $q_I \sim w_E$ and $q \sim_I w_E$. Its pullback satisfies

$$dd^c(w_E \circ \pi_1) = \sum_x E(\{x\})[\{x\} \times \mathbb{P}^1] - E(\mathbb{P}^1) \pi_1^* \sigma.$$

The divisor current is closed and has finite mass, and $w_E \circ \pi_1$ is β -plurisubharmonic because $E(\mathbb{P}^1) \leq 1$. By [Corollary 15.2.2](#), its ordinary and ideal envelopes are equal. Multiplier ideals pull back by [Lemma 1.16.4](#), so ordinary equivalence and the ordinary identity just proved give

$$P_\beta[q \circ \pi_1]_I = P_\beta[w_E \circ \pi_1]_I = P_\beta[w_E \circ \pi_1] = q_I \circ \pi_1.$$

This includes the cases $E = 0$ and E with countably many atoms.

Apply [Proposition 15.6.8](#) to $M \rightarrow Y$ and the divisor $Y \times D$, whose induced zero obstacle is zero. The two identities on the base give the asserted identities upstairs. Thus Φ_f identifies the locus isometrically with the whole space of curve models, and ideal projection again takes the atomic part. The metric, nearest-point and analytic-closure arguments of [Proposition 15.6.11](#) apply unchanged; rational atomic coefficients and the unit coefficient of the hyperplane give local analytic monomials. Each pairwise maximum still has the form $\Psi + \max(q_1, q_2) \circ h$, so the fibration proposition makes all three upper volumes zero. Finally, integration of a smooth volume form along the compact fibers of h transfers L^1 convergence on the curve to M , as in that proposition. The background is positive and not closed, and, as in [Example 15.6.7](#), a dominating closed product form gives the bounded mass property. $\square$

The locus and its metric persist when the coefficient f of the second curve factor is allowed to vanish.

Corollary 15.6.4 *Keep $M, h, s, r, \sigma, \kappa, D, \Psi$ from [Corollary 15.6.3](#). For any smooth real function $f \geq 0$ on the first curve, put*

$$\Theta_f = h^*\sigma + (f \circ h)s^*\sigma + r^*\kappa, \quad \Phi(q) = \Psi + q \circ h.$$

For every normalized ordinary curve model q , one has

$$P_{\Theta_f}[\Phi(q)] = \Phi(q), \quad P_{\Theta_f}[\Phi(q)]_I = \Phi(P_\sigma[q]_I).$$

All the metric conclusions of [Corollary 15.6.3](#) hold on the same set $\mathcal{T}_\Psi$, with the same distance given by total variation of polar curvature. The identity map of this set is an isometry between any two of the backgrounds Θ_f and commutes with ideal projection. This includes uniformly convergent families $f_j \rightarrow 0$, whose limiting background Θ_0 is not big.

Proof On $Y = \mathbb{P}^1 \times \mathbb{P}^1$, put $\beta_f = \pi_1^*\sigma + (f \circ \pi_1)\pi_2^*\sigma$. This form is semipositive, and the argument with horizontal sections in [Corollary 15.6.3](#) still gives

$$P_{\beta_f}[q \circ \pi_1] = q \circ \pi_1.$$

Indeed, the pullback of q is β_f -plurisubharmonic, and every horizontal section has background σ , also where f vanishes.

Write $q_I = P_\sigma[q]_I$, let E be the atomic part of μ_q , and set $g = w_E \circ \pi_1$, with the Green potential of the preceding proof. Then g is β_f -plurisubharmonic, $q \circ \pi_1 \sim_I g$, and $g \sim q_I \circ \pi_1$. Its complex Hessian is the same countable divisor current of finite mass minus $E(\mathbb{P}^1)\pi_1^*\sigma$. For every ideal competitor $v \leq 0$ for $q \circ \pi_1$, [Lemma 1.17.4](#) gives $v \preceq g$. Therefore

$$v \leq P_{\beta_f}[g] = P_{\beta_f}[q_I \circ \pi_1] = q_I \circ \pi_1.$$

The last equality uses the ordinary identity just proved, since $q_{\mathcal{I}}$ is an ordinary curve model. Conversely, $q_{\mathcal{I}} \circ \pi_1$ is a normalized β_f -plurisubharmonic ideal competitor, because ideal projection preserves the ideal type on the curve and multiplier ideals pull back. This proves the ideal identity on the base, including the cases $E = 0$ and E with countably many atoms.

Proposition 15.6.8 allows this semipositive background on the base and gives both identities upstairs. Normalization follows because the factors are independent. The metric space is the same isometric copy of the whole space of curve models, and ideal projection, analytic closure, geodesics and L^1 convergence upstairs follow as in the preceding proof. Since the relevant currents are still pulled back from the surface Y , the same proposition gives zero upper volumes, so the upper-volume comparison vanishes. Both $\Phi(q)$ and its polar measure are independent of f , so the stated identifications and the compatibility with ideal projection hold exactly, including at the limiting background. Analytic singularities depend only on the functions, so their closure is also unchanged.

To see that Θ_0 is not big, let $n = k + 2$, and take the smooth closed positive $(n - 1, n - 1)$ -form and the Hermitian form

$$T = h^* \sigma \wedge r^*(\kappa^k), \quad \Omega = h^* \sigma + s^* \sigma + r^* \kappa.$$

One has $\int_M \Theta_0 \wedge T = 0$ and $\int_M \Omega \wedge T = 1$. If $\Theta_0 + \text{dd}^c u \geq \varepsilon \Omega$ for some $u \in \text{QPSH}(M)$ and $\varepsilon > 0$, pairing with T and using Stokes' theorem would give $0 \geq \varepsilon$. Thus Θ_0 is not big, although the model locus keeps its complete metric. $\square$

15.6.7 Several curve factors

A single curve factor produces a model space isometric to the space of models on one curve. Products of several curves give larger complete model spaces at zero volume. The envelopes of a sum of curve models are again computed coordinatewise: the supremum of a competitor over all factors but one is a potential on the remaining curve, and restriction to slices treats the other factors by induction. The sum of the polar distances of the factors is then a complete metric on the induced product models.

Let $C_1, \dots, C_m$ be connected compact curves with smooth positive forms η_i , where $m \geq 2$, and put $A_i = \int_{C_i} \eta_i$. Set

$$Y = \prod_{i=1}^m C_i, \quad \beta = \sum_{i=1}^m \pi_i^* \eta_i,$$

where $\pi_i : Y \rightarrow C_i$ are the projections. For normalized ordinary models q_i on (C_i, η_i) , write

$$w = \sum_{i=1}^m q_i \circ \pi_i, \quad q_{i,\mathcal{I}} = P_{\eta_i}[q_i]_{\mathcal{I}}.$$

Lemma 15.6.2 *The function w is a normalized ordinary model on (Y, β) , and*

$$P_\beta[w]_I = \sum_{i=1}^m q_{i,I} \circ \pi_i.$$

Proof The function w is β -plurisubharmonic and has supremum zero. We prove $P_\beta[w] = w$ by induction on the number of factors, the case of one factor being the identity $P_{\eta_1}[q_1] = q_1$. Let $v \leq 0$ be an ordinary competitor, and replace it by $\max(v, w)$. This preserves $v \preceq w$ and ensures that the restrictions of v to slices are not identically $-\infty$ wherever the corresponding curve potentials are finite.

Write $Y = Y' \times C_m$, and take the regularized partial supremum

$$a(t) = \left(\sup_{y' \in Y'} v(y', t) \right)^*.$$

The restrictions of v to the slices $\{y'\} \times C_m$ are η_m -plurisubharmonic or identically $-\infty$. They are bounded above by zero, and at least one of them is not identically $-\infty$, since $v \geq w$. The local upper-envelope theorem from [Chapter 1](#) therefore makes a an η_m -plurisubharmonic function. The global inequality $v \leq w + C$ gives $a \leq q_m + C$, because the other normalized potentials have supremum zero. Thus a is a competitor for $P_{\eta_m}[q_m]$, and $a \leq P_{\eta_m}[q_m] = q_m$.

For t with $q_m(t)$ finite, the function $v(\cdot, t) - q_m(t)$ is a potential in the product background on Y' , not identically $-\infty$; it is nonpositive and at least as singular as $\sum_{i < m} q_i \circ \pi_i$. The induction hypothesis bounds it by that sum. Hence $v \leq w$ off the poles of q_m . At those poles the original bound $v \leq w + C$ gives the same inequality. Taking the envelope proves the ordinary identity.

For the ideal identity, let E_i be the atomic part of the polar curvature of q_i , and take the Green potentials g_i of [Lemma 18.5.1](#). They satisfy

$$q_i \sim_I g_i, \quad q_{i,I} \sim g_i, \quad \text{dd}^c g_i = E_i - \frac{E_i(C_i)}{A_i} \eta_i.$$

By [Lemmas 1.16.3](#) and [1.16.4](#), $g = \sum_i g_i \circ \pi_i$ is multiplier-ideal equivalent to w . Its complex Hessian is a closed countable sum of the divisors $\pi_i^{-1}(x)$ minus the smooth form $\sum_i E_i(C_i) \pi_i^* \eta_i / A_i$. Each coordinate fiber has constant mass for the product metric, so the divisor part has finite mass. Moreover g is β -plurisubharmonic since $E_i(C_i) \leq A_i$. Therefore [Corollary 15.2.2](#) gives $P_\beta[g]_I = P_\beta[g]$. Since g is ordinarily equivalent to $\sum_i q_{i,I} \circ \pi_i$, the ordinary identity, applied to the models $q_{i,I}$, shows that this envelope is $\sum_i q_{i,I} \circ \pi_i$. As $w \sim_I g$, the ideal envelope of w is the same, which proves the assertion. $\square$

The same coordinatewise computation applies to arbitrary curve potentials, to curve backgrounds that need not be positive, and to smooth obstacles that are sums of functions of the separate coordinates. Keep the curves C_i , the product Y and its projections π_i . Let σ_i be smooth real $(1, 1)$ -forms on C_i with $\text{PSH}(C_i, \sigma_i) \neq \emptyset$, that is, with $\int_{C_i} \sigma_i \geq 0$ by [Lemma 1.8.8](#), and choose $u_i \in \text{PSH}(C_i, \sigma_i)$ and $F_i \in C^\infty(C_i, \mathbb{R})$.

Put

$$\gamma = \sum_i \pi_i^* \sigma_i, \quad u = \sum_i u_i \circ \pi_i, \quad F = \sum_i F_i \circ \pi_i.$$

Proposition 15.6.12 *For the preceding data,*

$$\begin{aligned} P_{\gamma, F}[u] &= \sum_i P_{\sigma_i, F_i}[u_i] \circ \pi_i, \\ P_{\gamma, F}[u]_I &= \sum_i P_{\sigma_i, F_i}[u_i]_I \circ \pi_i. \end{aligned} \tag{15.11}$$

These identities also hold when some of the curve backgrounds have zero area.

Proof Write $e_i = P_{\sigma_i, F_i}[u_i]$. Sums of ordinary competitors in the separate coordinates are ordinary competitors on the product, and their regularized supremum is $\sum_i e_i \circ \pi_i$. This gives the lower bound in the first identity.

For the upper bound we use induction on the number of factors, the case of one factor being trivial. Let $v \leq F$ be an ordinary competitor, so that $v \leq u + C$ for some constant C . Choose a constant K with $u - K \leq F$ and replace v by $\max(v, u - K)$. This preserves both bounds and ensures that the restrictions of v to the slices used below are not identically $-\infty$.

Write $Y = Y' \times C_m$, and on Y' put $u' = \sum_{i < m} u_i \circ \pi_i$ and $F' = \sum_{i < m} F_i \circ \pi_i$. The regularized partial supremum

$$a(t) = \left(\sup_{y' \in Y'} (v(y', t) - F'(y')) \right)^*$$

is σ_m -plurisubharmonic by the local upper-envelope theorem of [Chapter 1](#): the functions $t \mapsto v(y', t) - F'(y')$ have the common upper bound F_m , and at least one of them is not identically $-\infty$, by the lower bound $v \geq u - K$. The bound $v \leq u + C$ gives

$$a \leq u_m + C + \sup_{Y'} (u' - F'), \quad a \leq F_m.$$

Thus a is a competitor for e_m , and $a \leq e_m$. If $u_m(t)$ is finite, so is $e_m(t)$, since a sufficiently low translate of u_m is a competitor for e_m . The function $v(\cdot, t) - e_m(t)$ is then a potential in the product background on Y' , not identically $-\infty$, lying below F' and at least as singular as u' . By induction, $v(\cdot, t) \leq \sum_{i < m} e_i \circ \pi_i + e_m(t)$. At a pole of u_m , the bound $v \leq u + C$ already gives $v = -\infty$. Every competitor is therefore bounded by $\sum_i e_i \circ \pi_i$, and taking the regularized supremum proves the ordinary identity.

For the ideal identity, put $B_i = \int_{C_i} \sigma_i \geq 0$ and $\widehat{\eta}_i = \eta_i / A_i$. By [Lemma 1.8.8](#), choose smooth functions χ_i with

$$\sigma_i = B_i \widehat{\eta}_i + \text{dd}^c \chi_i.$$

Let E_i be the atomic part of $\sigma_i + \text{dd}^c u_i$. If $B_i > 0$, apply [Lemma 18.5.1](#) to $u_i + \chi_i$ in the positive background $B_i \widehat{\eta}_i$. Subtracting χ_i from the resulting atomic Green

potential gives a σ_i -plurisubharmonic function g_i such that

$$\begin{aligned} u_i &\sim_I g_i, & P_{\sigma_i}[u_i]_I &\sim g_i, \\ \text{dd}^c g_i &= E_i - E_i(C_i)\widehat{\eta}_i - \text{dd}^c \chi_i; \end{aligned}$$

the second relation uses the smooth gauge bounds of [Proposition 15.3.1](#). If $B_i = 0$, [Lemma 1.8.8](#) gives $u_i = -\chi_i + c_i$ for a constant c_i , and $E_i = 0$; taking $g_i = -\chi_i$ gives the same conclusions. In either case,

$$\sigma_i + \text{dd}^c g_i = E_i + (B_i - E_i(C_i))\widehat{\eta}_i \geq 0.$$

Put $g = \sum_i g_i \circ \pi_i$. Pullback and addition, [Lemmas 1.16.3](#) and [1.16.4](#), give $g \sim_I u$. The complex Hessian of g is a countable sum of divisor currents supported on coordinate fibers, minus a smooth form. This divisor current has finite mass, because each coordinate fiber has constant mass for a fixed product metric and each E_i has finite mass. Thus [Lemma 1.17.4](#) applies, even when some B_i vanish. Every ideal competitor $v \leq F$ for u therefore satisfies $v \preceq g$, and is bounded by $P_{\gamma, F}[g]$.

Set $r_i = P_{\sigma_i, F_i}[u_i]_I$. Invariance of the ordinary envelope under ordinary equivalence and [Proposition 15.6.6](#) give

$$P_{\sigma_i, F_i}[g_i] = P_{\sigma_i, F_i}[P_{\sigma_i}[u_i]_I] = r_i.$$

By the ordinary identity already proved, applied to g , the ideal envelope of u is therefore at most $\sum_i r_i \circ \pi_i$. Conversely, each r_i lies below F_i and is multiplier-ideal equivalent to u_i , again by [Proposition 15.6.6](#). Their sum is a γ -plurisubharmonic ideal competitor for u below F , which proves the reverse inequality. No strict positivity of the backgrounds is needed in this comparison. $\square$

The proof of [\(15.11\)](#) uses that the obstacle is a sum of functions of the separate coordinates; for an arbitrary smooth obstacle on Y , the coordinatewise bounds are not available. Equality of the two envelopes below such mixed obstacles is treated in [Section 15.6.10](#).

We now return to the positive product background β and the normalized curve models q_i , and add a divisorial factor as in [Section 15.6.6](#). Let Z be a connected compact Kähler manifold of dimension $k \geq 1$, and let $D \subset Z$ be a nonempty smooth reduced divisor, with a Kähler form κ and a normalized potential ψ satisfying $\kappa + \text{dd}^c \psi = [D]$. On $M = Y \times Z$, write p, r for the projections, set $h_i = \pi_i \circ p$, and put

$$\Theta = p^* \beta + r^* \kappa, \quad \Psi = \psi \circ r, \quad \Phi(q_1, \dots, q_m) = \Psi + \sum_i q_i \circ h_i.$$

Let $\mathcal{S}_\Psi^{(m)}$ be the set of these potentials. For the polar curvatures $\mu_i = \mathbf{1}_{\{q_i = -\infty\}}(\eta_i + \text{dd}^c q_i)$ and the analogous measures ν_i of models b_i , define

$$\rho_\Psi^{(m)}(\Phi(q_1, \dots, q_m), \Phi(b_1, \dots, b_m)) = \sum_i \|\mu_i - \nu_i\|_{\text{TV}}. \quad (15.12)$$

Proposition 15.6.13 *The set $\mathcal{S}_\Psi^{(m)}$ consists of normalized ordinary models and is a complete geodesic metric space for $\rho_\Psi^{(m)}$. Its ideal models form a closed geodesically convex subspace, equal to the metric closure of its models with analytic singularities. Ideal projection is the unique nearest-point retraction onto this subspace and is 1-Lipschitz, and the distance to the subspace is the sum of the nonatomic polar masses. Metric convergence implies $L^1(M)$ convergence for every smooth positive volume form. The upper-volume comparison d_Θ vanishes on every pair of points of this locus.*

Proof The preceding lemma and [Proposition 15.6.8](#) give

$$\begin{aligned} P_\Theta[\Phi(q_1, \dots, q_m)] &= \Phi(q_1, \dots, q_m), \\ P_\Theta[\Phi(q_1, \dots, q_m)]_{\mathcal{I}} &= \Phi(q_{1,\mathcal{I}}, \dots, q_{m,\mathcal{I}}), \end{aligned}$$

since the induced zero obstacle is zero; independence of the factors gives normalization. Restricting to sections on which the other potentials are finite shows that if two product potentials are equal, then each coordinate difference is constant, and normalization makes every such constant zero. Thus Φ identifies this locus with the finite product of the spaces of curve models, equipped with the sum of their metrics.

Completeness follows coordinate by coordinate from [Corollary 29.12.1](#). Interpolating all polar measures linearly with the same parameter gives a constant-speed geodesic for the sum metric. Ideal projection takes the atomic part in each coordinate, so the assertions on closedness, convexity, unique nearest points and the Lipschitz bound follow coordinate by coordinate from [Corollary 29.12.1](#) and [Proposition 29.12.1](#), and the distances add. Finite atomic approximations with rational coefficients in each coordinate have local logarithmic coefficients whose denominators, together with the unit coefficient of D , can be cleared in a product monomial. They give analytic models that are dense in the ideal subspace. Conversely, every ordinary model with analytic singularities is its own ideal projection by [Proposition 15.2.3](#), so the closure of these models is exactly the ideal subspace.

By [Theorem 29.12.2](#), metric convergence gives L^1 convergence on each curve. Off the pole sets, the difference of two product potentials is the sum of the pulled-back coordinate differences. Integrating each term along the compact fibers of h_i bounds its L^1 norm on M by a constant times its L^1 norm on the curve, as in [Proposition 15.6.11](#), and the finite sum tends to zero.

Finally, since $\dim Y = m < \dim M$, [Proposition 15.6.8](#) shows that every model in this locus has zero upper singularity volume. A pairwise maximum is still Ψ plus the pullback of a β -plurisubharmonic function on Y , so the same proposition gives zero upper volume for it. All three terms of d_Θ therefore vanish. $\square$

As in [Corollaries 15.6.3](#) and [15.6.4](#), an auxiliary curve factor with a variable coefficient makes the background nonclosed, and lets it degenerate, without changing this metric locus.

Keep Y, β, π_i and Z, κ, D, ψ from above. Let C_0 be another connected compact curve with a smooth positive form τ . On $M = Y \times C_0 \times Z$, write p, s, r for the projections. For a smooth real function $f \geq 0$ on Y , put

$$\Theta_f = p^*\beta + (f \circ p)s^*\tau + r^*\kappa, \quad \Psi = \psi \circ r,$$

and set $\Phi(q_1, \dots, q_m) = \Psi + \sum_i q_i \circ \pi_i \circ p$.

Corollary 15.6.5 *For every tuple of normalized ordinary curve models, one has*

$$\begin{aligned} P_{\Theta_f}[\Phi(q_1, \dots, q_m)] &= \Phi(q_1, \dots, q_m), \\ P_{\Theta_f}[\Phi(q_1, \dots, q_m)]_I &= \Phi(q_{1,I}, \dots, q_{m,I}). \end{aligned}$$

On the locus of these potentials, use the sum of polar distances (15.12). All the metric conclusions of Proposition 15.6.13 hold, and the diameter is $2 \sum_i A_i$. The locus, its metric, ideal projection and the analytic closure are independent of f , including at $f = 0$. The background is positive and not closed when f is positive and nonconstant. The background Θ_0 obtained for $f = 0$ is not big.

Proof On $B = Y \times C_0$, let π, s_0 be the projections and put $\beta_f = \pi^*\beta + (f \circ \pi)s_0^*\tau$. For $w = \sum_i q_i \circ \pi_i$, an ordinary competitor $v \leq 0$ for $w \circ \pi$ may be replaced by its maximum with $w \circ \pi$. Its restriction to every section $Y \times \{z\}$ is then a β -plurisubharmonic competitor for $P_\beta[w] = w$, not identically $-\infty$, by Lemma 15.6.2. Thus

$$P_{\beta_f}[w \circ \pi] = w \circ \pi.$$

Take the atomic Green potentials g_i from the proof of the lemma and put $g = \sum_i g_i \circ \pi_i \circ \pi$. Its complex Hessian is a closed countable divisor current of finite mass minus a smooth form. It is β_f -plurisubharmonic for every $f \geq 0$, and it is multiplier-ideal equivalent to $w \circ \pi$. Put $w_I = \sum_i q_{i,I} \circ \pi_i$. Since $g \sim w_I \circ \pi$, every ideal competitor $v \leq 0$ is bounded above by

$$P_{\beta_f}[g] = P_{\beta_f}[w_I \circ \pi] = w_I \circ \pi.$$

Here Lemma 1.17.4 gives $v \leq g$, and the ordinary identity applies to w_I . Conversely, $w_I \circ \pi$ is a normalized ideal competitor, because ideal projection preserves the ideal type on each curve and the ideal type is compatible with pullback and addition. This computes the ideal envelope on B without requiring β_f to be positive.

Apply Proposition 15.6.8 to $M \rightarrow B$ and the divisor $B \times D$. Its induced zero obstacle is zero, which gives the two identities upstairs and normalization. Restriction to a fixed section of the auxiliary curve identifies this locus isometrically with the finite product of the spaces of curve models. Completeness, geodesics and the nearest-point property of ideal projection therefore follow as in Proposition 15.6.13, and the same rational atomic monomials give analytic density. For $f = 1$, the background is positive and Proposition 15.2.3 shows that every analytic model lies in the ideal subspace. Analytic singularities and the computed ideal projection are independent of f , so this analytic-closure assertion holds for every nonnegative coefficient. Fiber integration, now including the factor C_0 , gives the same L^1 convergence upstairs. Each model and each pairwise maximum is Ψ plus a pullback from B , whose dimension is smaller than that of M , so their upper volumes vanish by Proposition 15.6.8; the upper-volume comparison of Definition 29.6.1 therefore vanishes for every f .

Each polar measure μ_i has mass at most A_i , so the sum distance is at most $2 \sum_i A_i$. By [Lemma 29.12.1](#), this bound is attained by placing mass A_i at two distinct points of each C_i . Hence the diameter does not change, even at the limiting coefficient.

Finally, $d\Theta_f = p^*(df) \wedge s^*\tau$ is nonzero for nonconstant f , and Θ_f is strictly positive when $f > 0$. To see that Θ_0 is not big, put $n = m + 1 + k$ and use the smooth closed positive $(n - 1, n - 1)$ -form T and the Hermitian form Ω given by

$$T = p^* \left(\bigwedge_i \pi_i^* \eta_i \right) \wedge r^*(\kappa^k), \quad \Omega = p^* \beta + s^* \tau + r^* \kappa.$$

Then $\int_M \Theta_0 \wedge T = 0$, whereas $\int_M \Omega \wedge T > 0$. By Stokes' theorem, a lower bound $\Theta_0 + dd^c u \geq \varepsilon \Omega$ with $\varepsilon > 0$ would contradict these identities. Thus the background Θ_0 is not big. $\square$

15.6.8 Varying the curve coefficients

The coefficient f of the auxiliary curve in [Corollary 15.6.5](#) does not affect the metric on the model locus. Scaling the curve forms themselves has a different effect: a positive coefficient rescales the polar distance in its coordinate, whereas a zero coefficient removes the coordinate altogether, so the diameter depends on the remaining curve areas. We describe the resulting family of model spaces and then compare its members.

Keep the product $M = Y \times C_0 \times Z$, its projections and the forms of that corollary. For $a = (a_1, \dots, a_m) \in [0, \infty)^m$ and a smooth function $f \geq 0$ on Y , put

$$J(a) = \{i : a_i > 0\}, \quad \beta_a = \sum_i a_i \pi_i^* \eta_i, \quad \Theta_{a,f} = p^* \beta_a + (f \circ p) s^* \tau + r^* \kappa.$$

The coordinates $i \in J(a)$ are called *active*. For normalized ordinary models q_i in the fixed curve backgrounds η_i , define

$$\Phi_a(q) = \Psi + \sum_{i \in J(a)} a_i q_i \circ \pi_i \circ p, \quad \Psi = \psi \circ r.$$

Terms with zero coefficient are omitted, also on their pole sets, so $\Phi_a(q)$ depends only on the active coordinates. Write $\mathcal{S}_a$ for this locus of potentials, and $q_{i,\mathcal{I}} = P_{\eta_i}[q_i]_{\mathcal{I}}$.

Lemma 15.6.3 *For every a and f as above,*

$$P_{\Theta_{a,f}}[\Phi_a(q)] = \Phi_a(q), \quad P_{\Theta_{a,f}}[\Phi_a(q)]_I = \Phi_a(q_I).$$

Both potentials have supremum zero. In particular, $\mathcal{S}_0 = \{\Psi\}$.

Proof For $a_i > 0$, scaling the ordinary competitors shows that $a_i q_i$ is an ordinary model for $a_i \eta_i$. Its polar curvature is $a_i \mu_i$, where μ_i is the polar curvature of q_i . Taking atomic parts and applying [Theorem 29.13.1](#), we see that its ideal model is $a_i q_{i,I}$.

Put $w_a = \sum_{i \in J(a)} a_i q_i \circ \pi_i$. If there are at least two active factors, [Lemma 15.6.2](#) makes the corresponding sum an ordinary model on the product of the active curves, with its positive product background. For one active factor, this is the identity on the curve. The identity is preserved under pullback to Y , by [Proposition 1.22.1](#): every competitor in the pulled-back background descends, and so do its obstacle bound and its ordinary order, since the projection is surjective. If there are no active factors, the normalized model is zero by the maximum principle. Hence $P_{\beta_a}[w_a] = w_a$ in all cases.

On $B = Y \times C_0$, use the background $\beta_{a,f} = \pi^* \beta_a + (f \circ \pi) s_0^* \tau$. As in [Corollary 15.6.5](#), replace an ordinary competitor by its maximum with $w_a \circ \pi$ and restrict it to each section $Y \times \{z\}$. This gives $P_{\beta_{a,f}}[w_a \circ \pi] = w_a \circ \pi$.

For the ideal identity, take $g_a = \sum_{i \in J(a)} a_i g_i \circ \pi_i \circ \pi$, with the atomic Green potentials g_i of [Lemma 18.5.1](#). Scaling, addition and pullback preserve multiplier-ideal equivalence by [Lemmas 1.16.3](#) and [1.16.4](#). The complex Hessian of g_a is a closed countable divisor current of finite mass minus a smooth form, and g_a is $\beta_{a,f}$ -plurisubharmonic. It is ordinarily equivalent to $w_{a,I} \circ \pi$, where $w_{a,I} = \sum_{i \in J(a)} a_i q_{i,I} \circ \pi_i$. By [Lemma 1.17.4](#), every ideal competitor is an ordinary competitor for g_a , so by the ordinary identity applied to the models $a_i q_{i,I}$ it is bounded by $w_{a,I} \circ \pi$. The latter is itself an ideal competitor, so the ideal envelope equals it. When $J(a)$ is empty, both envelopes on B are zero directly. Finally, [Proposition 15.6.8](#), applied to $M \rightarrow B$ and the divisor $B \times D$ with weight one, gives the identities upstairs, and independence of the factors gives normalization. $\square$

For two tuples $q, \tilde{q}$, let μ_i, ν_i be their polar curvature measures in the fixed backgrounds η_i , and set

$$\rho_a(\Phi_a(q), \Phi_a(\tilde{q})) = \sum_{i \in J(a)} a_i \|\mu_i - \nu_i\|_{\text{TV}}. \quad (15.13)$$

On the singleton $\mathcal{S}_0$ this distance is zero.

Proposition 15.6.14 *For every a , the locus S_a is a complete geodesic metric space for ρ_a , independently of f . Its ideal subspace is closed, geodesically convex and equal to the metric closure of its models with analytic singularities. Ideal projection is the unique nearest-point retraction onto this subspace and is 1-Lipschitz, with distance*

$$\rho_a(\Phi_a(q), \Phi_a(q_I)) = \sum_{i \in J(a)} a_i \mu_i^{\text{na}}(C_i),$$

where μ_i^{na} is the nonatomic part of μ_i . The diameter is $2 \sum_i a_i A_i$, and metric convergence implies $L^1(M)$ convergence for every smooth positive volume form. The upper-volume comparison vanishes on this locus.

If a, b have the same nonempty active set J , the correspondence $T_{ba}\Phi_a(q) = \Phi_b(q)$ is well defined, commutes with ideal projection and satisfies

$$\min_{i \in J} \frac{b_i}{a_i} \rho_a(u, v) \leq \rho_b(T_{ba}u, T_{ba}v) \leq \max_{i \in J} \frac{b_i}{a_i} \rho_a(u, v).$$

For a fixed smooth positive volume form on M , there are constants K_i , independent of a, b and of the normalized model tuple q , such that

$$\|\Phi_a(q) - \Phi_b(q)\|_{L^1(M)} \leq \sum_i K_i |a_i - b_i|.$$

Consequently, as all a_i tend to zero, the diameter tends to zero and every potential in S_a tends to Ψ in $L^1(M)$, uniformly over the normalized model tuples.

Proof Restriction to coordinate sections on which the other potentials are finite determines every active term $a_i q_i$ up to a constant, and normalization makes these constants zero. Thus (15.13) is well defined, and it identifies S_a with the product of the spaces of curve models in the active coordinates, with their distances multiplied by a_i . Coordinates with $a_i = 0$ do not appear, and for $J(a) = \emptyset$ the empty product is a single point.

The completeness, geodesic and atomic-projection results of [Corollary 29.12.1](#) and [Proposition 29.12.1](#) apply coordinate by coordinate, and the weighted distances add; this proves the metric assertions and the distance formula. The diameter bound is attained by choosing polar measures $A_i \delta_{x_i}$ and $A_i \delta_{y_i}$ with $x_i \neq y_i$ on each active curve. Fiber integration and [Theorem 29.12.2](#) give L^1 convergence upstairs. The preceding lemma shows that ideal projection does not depend on f . Since every model and every pairwise maximum is Ψ plus a pullback from B , [Proposition 15.6.8](#) gives zero upper volumes, so the upper-volume comparison vanishes.

For analytic density, approximate the atomic part $a_i \mu_i^{\text{at}}$ of each scaled polar measure, where $\mu_i^{\text{at}} = \mu_i - \mu_i^{\text{na}}$, by finite atomic measures with rational coefficients and mass at most $a_i A_i$. These approximations converge in total variation. Their curve models in the background $a_i \eta_i$ have finitely many logarithmic poles with rational coefficients, whose denominators, together with the unit coefficient of D , can be cleared in local product monomials. They therefore give analytic models in S_a converging to every ideal model. Conversely, suppose that $\Phi_a(q)$ has analytic

singularities. Restrict it to a section along an active curve on which all other potentials are finite and whose Z -coordinate lies outside D . By [Proposition 1.13.1](#), the restriction, which is $a_i q_i$ plus a constant and not identically $-\infty$, has analytic singularities. It is an ordinary model in the positive background $a_i \eta_i$, so [Proposition 15.2.3](#) shows that it equals its ideal projection. The preceding lemma now shows that $\Phi_a(q)$ is an ideal model, and closedness gives the analytic-closure assertion. The argument uses that the scaled poles $a_i q_i$ themselves have rational coefficients; for irrational a_i , the scaled version of an analytic curve model need not be analytic.

For a common active set, the normalized tuple is determined by the potential. The two bounds for T_{ba} follow by comparing each positive weight b_i with a_i , and atomic projection in each coordinate commutes with this correspondence.

Finally, normalized compactness, [Theorem 1.4.1](#), bounds the $L^1(C_i)$ norms of all the q_i uniformly. Integration along the compact fibers of $\pi_i \circ p$ gives constants K_i bounding the $L^1(M)$ norms of their pullbacks. Off the pole sets, which have smooth volume zero, the difference of the two potentials is the sum of the functions $(a_i - b_i)q_i \circ \pi_i \circ p$. The triangle inequality proves the uniform estimate, also when some coefficients vanish. Taking $b = 0$ gives uniform convergence to Ψ , and the diameter formula shows that the diameters tend to zero. $\square$

Thus letting the auxiliary coefficient vanish leaves the metric of [Corollary 15.6.5](#) unchanged, whereas letting a curve coefficient vanish removes its coordinate and decreases the diameter. These computations concern only the specified product loci, not general ordinary models in higher dimension.

15.6.8.1 Comparing bounded model spaces

When the active sets differ, there is no natural map between the spaces $\mathcal{S}_a$, and we compare them as abstract metric spaces. They are bounded, but they are not compact as soon as some coefficient is positive. The Gromov–Hausdorff distance d_{GH} of bounded metric spaces from [Definition 13.18.1](#), together with its estimate through correspondences in [Lemma 13.18.5](#), applies without a compactness hypothesis.

Write $\mathcal{I}_a \subset \mathcal{S}_a$ for the ideal subspace of [Proposition 15.6.14](#), with the restricted metric ρ_a .

Proposition 15.6.15 *For all nonnegative coefficient vectors a, b , including vectors with different active sets,*

$$\left| \sum_i (a_i - b_i) A_i \right| \leq d_{\text{GH}}(\mathcal{S}_a, \mathcal{S}_b) \leq \sum_i |a_i - b_i| A_i. \quad (15.14)$$

The same bounds hold for $d_{\text{GH}}(\mathcal{I}_a, \mathcal{I}_b)$. If $b_i \leq a_i$ for every i , both distances equal $\sum_i (a_i - b_i) A_i$. In particular, the distance from $\mathcal{S}_a$ to the singleton $\mathcal{S}_0 = \mathcal{I}_0 = \{\Psi\}$ equals $\sum_i a_i A_i$.

For $b \leq a$, the map $T_{ba}\Phi_a(q) = \Phi_b(q)$ is a surjective 1-Lipschitz map and commutes with ideal projection. Every fiber has diameter

$$2 \sum_{\{i: a_i > 0, b_i = 0\}} a_i A_i.$$

If some $a_i > 0$, then $\mathcal{S}_a$ and $\mathcal{I}_a$ are not totally bounded, and hence not compact.

Proof Use the correspondence

$$R_{ab} = \{(\Phi_a(q), \Phi_b(q)) : q_i \text{ are normalized ordinary curve models}\}.$$

Every potential in either locus arises from such a tuple, with arbitrary normalized models in its coordinates of zero coefficient, so both projections of R_{ab} are surjective. For any two tuples, put $d_i = \|\mu_i - \nu_i\|_{\text{TV}}$. By (15.13), the difference of their two distances is $\sum_i (a_i - b_i) d_i$, with $0 \leq d_i \leq 2A_i$. Thus the distortion of this correspondence satisfies $\text{dis } R_{ab} \leq 2 \sum_i |a_i - b_i| A_i$, and Lemma 13.18.5 gives the upper bound in (15.14). The diameter formula in Proposition 15.6.14 and the same lemma give the lower bound.

Restricting the correspondence to tuples of ideal curve models, we obtain a correspondence between the two ideal subspaces with the same distortion bound. The atomic measures $A_i \delta_{x_i}$ and $A_i \delta_{y_i}$ show that the ideal subspaces have the same diameters as the full spaces, so the lower bound also holds for them. When $b \leq a$, the upper and lower bounds coincide, including when $b = 0$.

For the transition map, every active coordinate of b is active for a , and uniqueness of the normalized active tuple makes the map well defined. Every b -tuple extends to an a -tuple, so the map is surjective, and $\sum_i b_i d_i \leq \sum_i a_i d_i$ proves the Lipschitz bound. Atomic projection in each coordinate commutes with discarding and rescaling coordinates. In a fiber, every coordinate with $b_i > 0$ is fixed, while the coordinates with $a_i > 0$ and $b_i = 0$ vary freely. The diameter of the fiber is therefore the sum above, by the calculation of the diameter on each curve.

Finally, fix an active coordinate i and all other coordinates at their zero models. Let q_i have polar measure $A_i \delta_x$, with x ranging over infinitely many distinct points of C_i . The resulting potentials are ideal models, and any two of them are at distance $2a_i A_i$. This infinite separated set excludes total boundedness of both spaces. In particular, the comparison above is between complete bounded spaces that are not compact. $\square$

15.6.9 Arbitrary curve backgrounds

Scaling by coefficients is a special case of changing the curve backgrounds. By [Proposition 15.6.12](#), the coordinatewise computation of the envelopes holds for arbitrary smooth curve backgrounds of nonnegative area, so the product metric depends on the areas of the curve backgrounds rather than on their positivity. A curve background of area zero has a unique normalized potential, which is smooth. Its coordinate no longer contributes to the metric, but its smooth potential remains a summand of the product potentials.

Keep $M = Y \times C_0 \times Z$, the projections p, s, r and Ψ from [Corollary 15.6.5](#). On each C_i , choose a smooth real $(1, 1)$ -form σ_i with $\text{PSH}(C_i, \sigma_i) \neq \emptyset$, and put $B_i = \int_{C_i} \sigma_i \geq 0$. For a smooth function $f \geq 0$ on Y , set

$$\gamma_\sigma = \sum_i \pi_i^* \sigma_i, \quad \Theta_{\sigma, f} = p^* \gamma_\sigma + (f \circ p) s^* \tau + r^* \kappa.$$

For normalized ordinary models q_i in the curve backgrounds σ_i , write

$$\Phi_\sigma(q) = \Psi + \sum_i q_i \circ \pi_i \circ p, \quad q_{i, I} = P_{\sigma_i}[q_i]_I,$$

and let $\mathcal{S}_\sigma$ be the locus of these potentials. All coordinates are included: when $B_i = 0$, q_i is the unique normalized potential u_{σ_i} of [Lemma 1.8.8](#), which is smooth.

Lemma 15.6.4 *Every $\Phi_\sigma(q)$ is a normalized ordinary model, and*

$$P_{\Theta_{\sigma, f}}[\Phi_\sigma(q)]_I = \Phi_\sigma(q_I).$$

The background is not big if $f = 0$ or some $B_i = 0$. If $f > 0$ everywhere and all $B_i > 0$, it is big. It is not closed whenever f is nonconstant.

Proof On $B = Y \times C_0$, let π, s_0 be the projections and put

$$\gamma_{\sigma, f} = \pi^* \gamma_\sigma + (f \circ \pi) s_0^* \tau, \quad w = \sum_i q_i \circ \pi_i.$$

The case of the zero obstacle in [Proposition 15.6.12](#) gives $P_{\gamma_\sigma}[w] = w$. Replace an ordinary competitor for $w \circ \pi$ by its maximum with $w \circ \pi$. Its restriction to every section $Y \times \{z\}$ is then a competitor for $P_{\gamma_\sigma}[w]$ that is not identically $-\infty$, so

$$P_{\gamma_{\sigma, f}}[w \circ \pi] = w \circ \pi.$$

Use the atomic Green representatives g_i constructed in the proof of [Proposition 15.6.12](#), which are smooth in the coordinates of zero area. Their sum $g = \sum_i g_i \circ \pi_i \circ \pi$ is $\gamma_{\sigma, f}$ -plurisubharmonic and multiplier-ideal equivalent to $w \circ \pi$, and its complex Hessian is a closed countable divisor current of finite mass minus a smooth form. If $w_I = \sum_i q_{i, I} \circ \pi_i$, then $g \sim w_I \circ \pi$. By [Lemma 1.17.4](#), every ideal competitor is ordinarily dominated by g , hence bounded by

$$P_{\gamma_{\sigma,f}}[g] = P_{\gamma_{\sigma,f}}[w_I \circ \pi] = w_I \circ \pi.$$

Here the last equality holds because each ideal projection $q_{i,I}$ on a curve is an ordinary model, so the argument with sections just given applies to w_I . By pullback and addition, $w_I \circ \pi$ is itself an ideal competitor, which proves the ideal identity on B . Now apply **Proposition 15.6.8** to $M \rightarrow B$ and the divisor $B \times D$ with weight one, whose induced zero obstacle is zero. The two identities upstairs and the independence of the factors give the assertion and normalization.

For the statements on bigness, put $n = m + 1 + k$ and $\Omega = p^*\beta + s^*\tau + r^*\kappa > 0$, with the positive product form β fixed earlier. For $f = 0$, the closed positive test form

$$T_0 = p^* \left(\bigwedge_j \pi_j^* \eta_j \right) \wedge r^*(\kappa^k)$$

satisfies $\int_M \Theta_{\sigma,0} \wedge T_0 = 0$ and $\int_M \Omega \wedge T_0 > 0$. If $B_i = 0$, use instead

$$T_i = p^* \left(\bigwedge_{j \neq i} \pi_j^* \eta_j \right) \wedge s^*\tau \wedge r^*(\kappa^k).$$

Then $\int_M \Theta_{\sigma,f} \wedge T_i = 0$ for every f , since the only nonzero term contains the factor $\int_{C_i} \sigma_i = B_i$, while $\int_M \Omega \wedge T_i > 0$. In either case, Stokes' theorem against the closed test form shows that no current $\Theta_{\sigma,f} + \text{dd}^c u$ with u quasi-plurisubharmonic is bounded below by a positive multiple of Ω , so the background is not big.

Finally, write $\sigma_i = B_i \eta_i / A_i + \text{dd}^c \chi_i$ by **Lemma 1.8.8**. The smooth potential $-\sum_i \chi_i \circ \pi_i \circ p$ has strictly positive current when every $B_i > 0$ and $f > 0$, which proves bigness in that case. The identity $\text{d}\Theta_{\sigma,f} = p^*(\text{d}f) \wedge s^*\tau$ shows that the background is not closed for nonconstant f . $\square$

For the polar curvatures μ_i of q_i and ν_i of another tuple $\tilde{q}$, taken in the backgrounds σ_i , set

$$\rho_{\sigma}(\Phi_{\sigma}(q), \Phi_{\sigma}(\tilde{q})) = \sum_i \|\mu_i - \nu_i\|_{\text{TV}}. \quad (15.15)$$

Write $\mathcal{I}_{\sigma} \subset \mathcal{S}_{\sigma}$ for the ideal subspace and μ_i^{na} for the nonatomic part of μ_i .

Proposition 15.6.16 *The metric space (S_σ, ρ_σ) is complete and geodesic, with diameter $2 \sum_i B_i$. The ideal subspace is closed, geodesically convex and equal to the metric closure of the models with analytic singularities. Ideal projection is the unique nearest-point retraction onto it and is 1-Lipschitz, and the distance to the subspace is $\sum_i \mu_i^{\text{na}}(C_i)$. Metric convergence implies $L^1(M)$ convergence for every smooth positive volume form. These assertions are independent of f , and the upper-volume comparison vanishes on this locus.*

Let σ'_i be another tuple of smooth real forms with $\text{PSH}(C_i, \sigma'_i) \neq \emptyset$, with areas B'_i . Then

$$\left| \sum_i (B_i - B'_i) \right| \leq d_{\text{GH}}(S_\sigma, S_{\sigma'}) \leq \sum_i |B_i - B'_i|. \quad (15.16)$$

The same bounds hold for the ideal subspaces. If $B'_i \leq B_i$ for every i , both distances equal $\sum_i (B_i - B'_i)$. In this case, rescaling the polar measures by the area ratios, with the unique normalized potential in each target coordinate of zero area, gives a surjective 1-Lipschitz map that commutes with ideal projection. Its fibers have diameter $2 \sum_{\{i: B_i > 0, B'_i = 0\}} B_i$.

Both S_σ and I_σ are noncompact if some $B_i > 0$. If all $B_i = 0$, they coincide with the singleton $\{\Psi + \sum_i u_{\sigma_i} \circ \pi_i \circ p\}$.

Proof Restriction to coordinate sections on which the other potentials are finite determines each q_i up to a constant, and normalization fixes that constant. The preceding lemma and [Proposition 29.13.1](#) therefore identify the locus with the finite product of the spaces of curve models, with the sum of their polar metrics; factors of zero area are single points. Completeness, geodesics and the diameter formula follow coordinatewise. Under this identification, [Corollary 29.12.1](#) and [Proposition 29.12.1](#) give closedness, geodesic convexity and the unique nearest-point retraction onto the ideal subspace, and the distances add. Fiber integration transfers L^1 convergence on the curves to M .

For analytic density, approximate each atomic polar measure by finite atomic measures with rational coefficients and mass at most B_i . By the atomic Green construction and transport under smooth gauge changes, their models in background σ_i have the corresponding finitely many poles with rational coefficients, up to bounded remainders. Coordinates of zero area are smooth. Together with the unit coefficient of D , the poles in the coordinates of positive area allow the denominators to be cleared in local product monomials, which gives analytic models in the locus. They converge for the metric (15.15). Conversely, by [Proposition 1.13.1](#), a product model with analytic singularities restricts, on every coordinate curve section on which the other potentials are finite and whose Z -coordinate lies outside D , to a function with analytic singularities that is not identically $-\infty$. Each q_i therefore has polar curvature with finitely many atoms, and it is an ideal model by the classification of curve models. Closedness proves the analytic-closure assertion.

By [Proposition 15.6.8](#), applied to the divisor $B \times D$ with weight one, every model and every pairwise maximum in this locus has zero upper volume; for a maximum, use Ψ plus the pullback of the maximum of the two potentials on B . Thus all three

terms of the upper-volume comparison vanish, even in the backgrounds that are not big by the lemma.

To compare different backgrounds, put $a_i = B_i/A_i$, and for a positive polar measure μ on C_i of mass at most B_i write $p_{\sigma_i}(\mu)$ for the ordinary model in background σ_i with polar curvature μ , as in [Proposition 29.13.1](#). Sending a curve model for η_i with polar measure μ_i , of mass at most A_i , to $p_{\sigma_i}(a_i\mu_i)$, which for $a_i = 0$ is the unique normalized potential, defines an isometry from the weighted locus $\mathcal{S}_a$ of [Proposition 15.6.14](#) onto $\mathcal{S}_\sigma$ that maps the ideal subspaces onto each other. Applying [Proposition 15.6.15](#) with $a_i = B_i/A_i$ and $b_i = B'_i/A_i$ gives (15.16), the exact value for ordered areas, the contractions and the diameters of their fibers. In curve coordinates the contraction is

$$p_{\sigma_i}(\mu) \mapsto \begin{cases} p_{\sigma'_i}((B'_i/B_i)\mu), & B_i > 0, \\ p_{\sigma'_i}(0), & B_i = 0. \end{cases}$$

In the second case $B'_i = 0$, because $B'_i \leq B_i$. Atomic projection commutes with both operations. As in [Theorem 29.13.1](#), irrational area ratios need not preserve individual analytic models, but the ideal subspaces are preserved for every ratio.

If $B_i > 0$, the models with polar measure $B_i\delta_x$ for infinitely many distinct points $x \in C_i$, with all other coordinates fixed at their models with zero polar curvature, form an infinite set of ideal product models with mutual distances $2B_i$. This excludes total boundedness of both loci. If all areas are zero, every curve coordinate is fixed at its unique normalized smooth potential, which proves the last assertion. $\square$

Corollary 15.6.6 *For each i , let $\sigma_{i,j}$ be smooth real forms on C_i of nonnegative area that converge uniformly, as $j \rightarrow \infty$, to a smooth form $\sigma_{i,0}$ of area zero, and write $\sigma_j = (\sigma_{1,j}, \dots, \sigma_{m,j})$. For any nonnegative smooth auxiliary coefficients f_j , the diameters of $\mathcal{S}_{\sigma_j}$ tend to zero. For every fixed smooth positive volume form on M , the potentials in $\mathcal{S}_{\sigma_j}$ converge in $L^1(M)$ to*

$$\Psi + \sum_i u_{\sigma_{i,0}} \circ \pi_i \circ p,$$

uniformly over all normalized model tuples.

Proof The areas $B_{i,j}$ tend to zero, so the diameter formula applies. By [Theorem 1.8.1](#), all normalized $\sigma_{i,j}$ -plurisubharmonic potentials converge in $L^1(C_i)$ to $u_{\sigma_{i,0}}$, uniformly over this family. Integration along the fixed compact fibers bounds each pulled-back norm by a constant times the norm on the curve, and the finite sum gives the asserted uniform limit on M . The auxiliary coefficients do not enter these potentials or their metrics. $\square$

Thus the metric comparison sees only the areas of the curve backgrounds, while the limiting potential still records their smooth gauges. These statements concern the separated product locus; extending the metric to general ordinary models is part of [Problem 15.6.1](#).

15.6.10 Equality below all obstacles on separated products

We return to the question raised in [Section 15.6.4](#): does equality of the two envelopes below zero imply their equality below every smooth obstacle? For sums of curve potentials the answer is yes, even for obstacles that mix the coordinates. By [Proposition 15.6.6](#), membership in the relative envelope class of the ideal model implies equality below every obstacle, and this membership can be tested coordinatewise, because stretching competitors can be added before any obstacle is imposed.

Lemma 15.6.5 *Let $N \geq 1$, let X_j , $1 \leq j \leq N$, be connected compact complex manifolds with smooth real $(1, 1)$ -forms θ_j , and let $u_j, \varphi_j \in \text{PSH}(X_j, \theta_j)$. On $X = \prod_j X_j$, with projections pr_j , put*

$$\vartheta = \sum_j \text{pr}_j^* \theta_j, \quad u = \sum_j u_j \circ \text{pr}_j, \quad \varphi = \sum_j \varphi_j \circ \text{pr}_j.$$

Then

$$u \in \mathcal{E}_{\text{env}}(X, \vartheta, \varphi) \iff u_j \in \mathcal{E}_{\text{env}}(X_j, \theta_j, \varphi_j) \text{ for every } j.$$

Proof The ordinary order between the sums is equivalent to the ordinary order in each coordinate. Indeed, the latter follows from the former by fixing the other coordinates at points where their potentials are finite and restricting the inequality, and the converse follows by adding the coordinate inequalities.

Suppose that each u_j belongs to its relative class. For $b > 1$, choose stretching competitors h_j as in [Definition 12.4.1](#). The sum $h = \sum_j h_j \circ \text{pr}_j$ is ϑ -plurisubharmonic and satisfies

$$b^{-1}h + (1 - b^{-1})\varphi \leq u.$$

This convex inequality is meaningful at poles. For $b = 1$, use $h = u$. Thus u belongs to the relative class on the product.

Conversely, fix $b > 1$ and a stretching competitor h on the product. Choose a point $x = (x_1, \dots, x_N)$ at which h and all the coordinate potentials are finite; such points have full smooth volume. For each j , let $h^{(j)}$ be the restriction of h to the slice through x in the j th factor. It is θ_j -plurisubharmonic and not identically $-\infty$, since it is finite at x_j . Put

$$c_j = \sum_{\ell \neq j} u_\ell(x_\ell), \quad d_j = \sum_{\ell \neq j} \varphi_\ell(x_\ell).$$

Restricting the product inequality to the slice gives

$$b^{-1}(h^{(j)} - bc_j + (b - 1)d_j) + (1 - b^{-1})\varphi_j \leq u_j.$$

This gives a stretching competitor in the j th coordinate for every $b > 1$. Together with the ordinary order and the competitor u_j for $b = 1$, it proves the converse. $\square$

Keep the curves C_i and the smooth forms σ_i with $\text{PSH}(C_i, \sigma_i) \neq \emptyset$ from [Section 15.6.9](#), and choose arbitrary $u_i \in \text{PSH}(C_i, \sigma_i)$. Put

$$u = \sum_i u_i \circ \pi_i, \quad q_i = P_{\sigma_i}[u_i], \quad r_i = P_{\sigma_i}[u_i]_I, \quad Q = \sum_i r_i \circ \pi_i.$$

Write μ_i and E_i for the polar and the atomic parts of the positive curvature measure $\sigma_i + \text{dd}^c u_i$, respectively.

Proposition 15.6.17 *For these data, $Q = P_{\gamma_\sigma}[u]_I$. The following are equivalent:*

$$\begin{aligned} P_{\gamma_\sigma}[u] &= P_{\gamma_\sigma}[u]_I, & \mu_i &= E_i \text{ for every } i, \\ & & u &\in \mathcal{E}_{\text{env}}(Y, \gamma_\sigma, Q), \\ P_{\gamma_\sigma, F}[u] &= P_{\gamma_\sigma, F}[u]_I \text{ for every smooth real } F \text{ on } Y. \end{aligned}$$

The obstacle in the last condition may mix the curve coordinates. Curve backgrounds of zero area are allowed, and the models may have zero volume.

Proof For the zero obstacle, [Proposition 15.6.12](#) identifies the two envelopes with $\sum_i q_i \circ \pi_i$ and Q , respectively. Since the coordinates are independent and all these functions have supremum zero, the two sums are equal if and only if $q_i = r_i$ for every i . By [Corollary 29.13.1](#), this is equivalent to $\mu_i = E_i$, and also to $u_i \in \mathcal{E}_{\text{env}}(C_i, \sigma_i, r_i)$, for every i , including backgrounds of zero area. The preceding lemma identifies these memberships with membership in the relative class on the product. Finally, [Proposition 15.6.6](#) gives equality below every smooth obstacle, and taking $F = 0$ gives the reverse implication. This proves all four equivalences. $\square$

Corollary 15.6.7 *On $M = Y \times C_0 \times Z$ with the background $\Theta_{\sigma, f}$, for any smooth $f \geq 0$, put $U = \Psi + u \circ p$. Then*

$$\begin{aligned} P_{\Theta_{\sigma, f}}[U] &= \Psi + \sum_i q_i \circ \pi_i \circ p, \\ P_{\Theta_{\sigma, f}}[U]_I &= \Psi + Q \circ p. \end{aligned}$$

The following are equivalent: equality of these two envelopes; $\mu_i = E_i$ for every i ; $U \in \mathcal{E}_{\text{env}}(M, \Theta_{\sigma, f}, \Psi + Q \circ p)$; and equality of the ordinary and ideal envelopes of U below every smooth real obstacle on M . These statements include the case $f = 0$ and curve backgrounds of zero area.

Proof On $B = Y \times C_0$, with projection π to Y , use the background $\gamma_{\sigma, f}$ of the proof of [Lemma 15.6.4](#). Sums of ordinary competitors in the separate coordinates give $P_{\gamma_{\sigma, f}}[u \circ \pi] \geq \sum_i q_i \circ \pi_i \circ \pi$. For the reverse inequality, replace an ordinary competitor by its maximum with a sufficiently low translate of $u \circ \pi$. Its restriction to every section $Y \times \{z\}$ is then not identically $-\infty$, nonpositive and at least as singular as u , so the separation for the zero obstacle bounds it by $\sum_i q_i \circ \pi_i$. The reduction of [Proposition 15.6.8](#), applied to the divisor $B \times D$ with weight one, proves the ordinary identity upstairs.

By [Proposition 15.2.1](#), each q_i has the multiplier ideals of u_i , so pullback and addition give $U \sim_I \Phi_\sigma(q)$. These two potentials therefore have the same ideal envelope, which [Lemma 15.6.4](#) identifies with $\Psi + Q \circ p$.

If $\mu_i = E_i$ for every i , then $u_i \in \mathcal{E}_{\text{env}}(C_i, \sigma_i, r_i)$ by [Corollary 29.13.1](#), and we choose stretching competitors in these curve classes. The sum of their pullbacks plus Ψ is $\Theta_{\sigma, f}$ -plurisubharmonic: its current is the sum of the pulled-back positive curve currents, the form $(f \circ p)s^*\tau$ and the current of the divisor with weight one. Adding the stretching inequalities gives the one for U relative to $\Psi + Q \circ p$, also at poles, and the ordinary order follows in the same way. Thus U belongs to that relative class, and [Proposition 15.6.6](#) gives equality below all obstacles. Taking the zero obstacle and using the two identities above recovers $q_i = r_i$, hence $\mu_i = E_i$. This closes the chain of equivalences. $\square$

These criteria concern sums of curve potentials and their extensions to the product M . They give neither coordinatewise formulas for the envelopes below mixed obstacles nor the implication for general potentials of zero volume.

15.6.11 Auxiliary compact complex factors

So far, the auxiliary factor that makes the background nonclosed has been a curve. The arguments only used that the auxiliary term in the background is semipositive and vanishes on the slices parallel to the curve product. The auxiliary factor can therefore be any compact complex manifold of positive dimension, Kähler or not, and the potentials and their polar metric still depend only on the curve coordinates and the fixed divisor of weight one.

Keep Y , σ_i , B_i and γ_σ , as well as the data (Z, κ, D, ψ) of the divisor of weight one. Let T be a connected compact complex manifold of dimension $\ell \geq 1$, and put $B = Y \times T$, with projections π to Y and pr_T to T . Choose a smooth semipositive real $(1, 1)$ -form α on B whose restriction to every slice $Y \times \{t\}$ is zero. By semipositivity, the tangent spaces of these slices lie in the kernel of α , so in product coordinates α has only coefficients in the T -directions. On $M = B \times Z$, let ϖ, r be the projections, and put $p = \pi \circ \varpi$ and

$$\Gamma_\alpha = \pi^* \gamma_\sigma + \alpha, \quad \Theta_\alpha = \varpi^* \Gamma_\alpha + r^* \kappa, \quad \Psi = \psi \circ r.$$

We assume neither that α is closed nor that M has the bounded mass property.

Lemma 15.6.6 For $u_i \in \text{PSH}(C_i, \sigma_i)$ put

$$u = \sum_i u_i \circ \pi_i, \quad U = \Psi + u \circ p, \quad q_i = P_{\sigma_i}[u_i], \quad r_i = P_{\sigma_i}[u_i]_I.$$

Then

$$P_{\Theta_\alpha}[U] = \Psi + \sum_i q_i \circ \pi_i \circ p,$$

$$P_{\Theta_\alpha}[U]_I = \Psi + \sum_i r_i \circ \pi_i \circ p.$$

Every ordinary representative of either of these envelopes has zero extended mass, so their upper and lower singularity volumes are zero.

Proof On B , sums of ordinary competitors on the curves give the lower bound $P_{\Gamma_\alpha}[u \circ \pi] \geq \sum_i q_i \circ \pi_i \circ \pi$. For the upper bound, replace a competitor by its maximum with a sufficiently low translate of $u \circ \pi$. Its restriction to every slice $Y \times \{t\}$ is then not identically $-\infty$, and since α restricts to zero there, it is a γ_σ -plurisubharmonic ordinary competitor for u . The case of the zero obstacle in [Proposition 15.6.12](#) bounds it by $\sum_i q_i \circ \pi_i$. This proves the identity for the ordinary envelope on B .

Take the atomic Green representatives g_i of the proof of [Proposition 15.6.12](#). The pullback g of their sum to B belongs to $\text{PSH}(B, \Gamma_\alpha)$, is multiplier-ideal equivalent to $u \circ \pi$, and is ordinarily equivalent to $\sum_i r_i \circ \pi_i \circ \pi$. Its complex Hessian is a countable current of divisors along coordinate fibers, minus a smooth form; this divisor current has finite mass, as one sees with a fixed product Hermitian metric and the finite atomic masses on the curves. By [Lemma 1.17.4](#), every ideal competitor is therefore at least as singular as g ; if the divisor current is zero, g is smooth and this is immediate by compactness. Thus every such competitor is bounded by $P_{\Gamma_\alpha}[g] = P_{\Gamma_\alpha}[\sum_i r_i \circ \pi_i \circ \pi]$, which equals $\sum_i r_i \circ \pi_i \circ \pi$ by the ordinary identity just proved and $P_{\sigma_i}[r_i] = r_i$. This sum is itself an ideal competitor, which proves the identity for the ideal envelope on B .

Apply [Proposition 15.6.8](#) to $M \rightarrow B$ and the divisor $B \times D$ with weight one. Its induced zero obstacle is zero because $\sup_Z \psi = 0$, which gives both identities upstairs. The mass assertion of the same proposition, applied to each of the two envelopes, shows that every representative of its ordinary type has zero mass, so both singularity volumes are zero. $\square$

For normalized ordinary curve models q_i , write

$$\Phi_\alpha(q) = \Psi + \sum_i q_i \circ \pi_i \circ p,$$

let $\mathcal{S}_\alpha$ be the locus of these potentials, and give it the metric

$$\rho_\alpha(\Phi_\alpha(q), \Phi_\alpha(\tilde{q})) = \sum_i \|\mu_i - \tilde{\mu}_i\|_{\text{TV}},$$

where $\mu_i, \tilde{\mu}_i$ are the polar curvatures of $q_i, \tilde{q}_i$.

Proposition 15.6.18 *The map $\Phi_\alpha(q) \mapsto \Phi_\sigma(q)$ is an isometry from $\mathcal{S}_\alpha$ onto the locus $\mathcal{S}_\sigma$ of [Proposition 15.6.16](#), and it maps the ideal subspaces and the models with analytic singularities onto each other. Consequently $\mathcal{S}_\alpha$ is complete and geodesic, with diameter $2 \sum_i B_i$. Its ideal subspace is closed, geodesically convex and equal to the metric closure of the models with analytic singularities. Ideal projection is the unique nearest-point retraction onto this subspace and is 1-Lipschitz, and the distance to the subspace is the sum of the nonatomic polar masses.*

Changing T or α does not change this abstract metric space. All the area comparisons and the contractions commuting with ideal projection of [Proposition 15.6.16](#) hold, even for different auxiliary data. The upper-volume comparison vanishes on the locus, and metric convergence implies $L^1(M)$ convergence for every smooth positive volume form. If T and Z are fixed and the curve backgrounds converge uniformly to backgrounds of zero area, then, for any choice of the semipositive terms α , the potentials converge in $L^1(M)$, uniformly over the model tuples, to the sum of Ψ and the pullbacks of the normalized smooth potentials of the limiting curve backgrounds, as in [Corollary 15.6.6](#).

Proof Applied to model tuples, the lemma shows that every $\Phi_\alpha(q)$ is a normalized ordinary model and computes its ideal projection coordinatewise. Restrictions to curve sections on which the other potentials are finite determine the tuple up to constants, and the normalization of the coordinates determines these constants. Thus the map is well defined and bijective, and the formulas for the polar curvatures make it an isometry preserving ideal projection.

Each potential in either locus is pulled back from $Y \times Z$. Analytic presentations pull back under the projection that forgets the auxiliary factor. Conversely, by [Proposition 1.13.1](#), the restriction of a potential with analytic singularities to a section with fixed auxiliary coordinate has analytic singularities and is not identically $-\infty$. Hence a potential in either locus has analytic singularities exactly when the common potential on $Y \times Z$ does, and the isometry maps the analytic models onto each other. The statements on the complete metric, the ideal closure, geodesics, nearest points and area comparisons now follow from [Proposition 15.6.16](#).

A pairwise maximum is Ψ plus the pullback of the maximum of two Γ_α -plurisubharmonic functions on B . The reduction along the divisor of weight one gives zero upper volume for it and for both models, so the upper-volume comparison vanishes. For L^1 convergence, integration along the fixed compact fibers bounds the norm of each pulled-back curve potential by a constant times its norm on the curve. The same estimate and [Theorem 1.8.1](#) give the asserted uniform limit at zero area. Neither estimate involves α . $\square$

Corollary 15.6.8 *For the arbitrary curve potentials u_i of the lemma, put $R = \Psi + \sum_i r_i \circ \pi_i \circ p$. The following are equivalent: $P_{\Theta_\alpha}[U] = P_{\Theta_\alpha}[U]_T$; for each i , the polar part of the curvature measure of u_i equals its atomic part; $U \in \mathcal{E}_{\text{env}}(M, \Theta_\alpha, R)$; and the ordinary and ideal envelopes of U agree below every smooth real obstacle on M .*

Proof By the lemma and the normalization of the coordinates, equality of the envelopes below zero is equivalent to $q_i = r_i$ for every i . By [Corollary 29.13.1](#), this is equivalent to equality of the polar and atomic measures, and in that case $u_i \in \mathcal{E}_{\text{env}}(C_i, \sigma_i, r_i)$. Choose stretching competitors in these curve classes. The sum of their pullbacks plus Ψ has positive current, since the contributions of the curves, the form $\varpi^*\alpha$ and the current of the divisor are all positive. Adding the convex stretching inequalities, which is possible also at poles, gives a stretching competitor relative to R for every finite stretch, and adding the ordinary bounds gives $U \preceq R$. Thus $U \in \mathcal{E}_{\text{env}}(M, \Theta_\alpha, R)$, and [Proposition 15.6.6](#) gives equality below every smooth obstacle. Taking the zero obstacle recovers the first condition, which proves the equivalence. $\square$

Corollary 15.6.9 *If $\alpha = 0$ or some $B_i = 0$, the background Θ_α is not big. If all $B_i > 0$ and α is positive on every nonzero vector tangent to the factor T , it is big. In particular, for a Hermitian form ω_T on T and a positive nonconstant smooth function h on Y , the choice $\alpha = (h \circ \pi) \text{pr}_T^* \omega_T$ gives a big background that is not closed whenever all $B_i > 0$.*

Proof For $\alpha = 0$, the background is pulled back from $Y \times Z$, and by [Proposition 1.22.1](#) every potential in it descends to $Y \times Z$. The corresponding currents have no component in the T -directions, so they cannot dominate a positive multiple of a Hermitian form on M . Thus the background is not big.

If $B_i = 0$, choose any Hermitian form ω_T on T and write $s : M \rightarrow T$ for the projection. The positive $(m + \ell + k - 1, m + \ell + k - 1)$ -form

$$L_i = p^* \left(\bigwedge_{j \neq i} \pi_j^* \eta_j \right) \wedge s^*(\omega_T^\ell) \wedge r^*(\kappa^k)$$

is closed, because ω_T^ℓ has top degree on T . Its pairing with Θ_α is zero, since the only possible contribution contains the integral of σ_i , whereas its pairing with a positive product Hermitian form is strictly positive. By Stokes' theorem, no current in the background is bounded below by a positive multiple of a Hermitian form.

When all areas are positive, write $\sigma_i = B_i \eta_i / A_i + \text{dd}^c \chi_i$. Subtracting the smooth pullback of $\sum_i \chi_i \circ \pi_i$ gives the current $p^* \sum_i (B_i / A_i) \pi_i^* \eta_i + \varpi^* \alpha + r^* \kappa$. Positivity of α in the T -directions makes this form strictly positive, which proves bigness. For the stated choice of α , the exterior derivative of Θ_α has the component $dh \wedge \omega_T$, with one direction in Y and two in T . It is nonzero for nonconstant h and cannot be canceled by the component with three directions in T . Hence $d\Theta_\alpha \neq 0$. $\square$

The proofs use no bound on the ambient masses, so the auxiliary manifold may fail the bounded mass property; an explicit example follows. The complete metric and the criterion for all obstacles concern only the specified product locus.

15.6.12 A polar metric in a background with unbounded mass

Taking the Hopf threefold of [Theorem 8.0.1](#) as the auxiliary factor makes the ambient masses unbounded, while the complete metric on the product models is unchanged. Letting the coefficient of the Hopf factor vary over the curve product also makes the background nonclosed.

Example 15.6.8 There is a compact complex sixfold with a smooth positive background Θ that is not closed and has infinite upper mass $v_+(\Theta) = +\infty$ in the sense of [Definition 6.5.1](#), while the locus of separated product models of [Proposition 15.6.18](#), along a divisor of weight one, has a complete geodesic polar metric of diameter 4. The ideal subspace is closed and is the metric closure of the models with analytic singularities, and ideal projection is the unique nearest-point retraction onto it and is 1-Lipschitz. The upper-volume comparison vanishes on this locus. The locus contains distinct ideal models with analytic singularities at polar distance 1.

Proof Take $Y = C_1 \times C_2$ with $C_1 = C_2 = \mathbb{P}^1$ and normalized Fubini–Study forms ω_i of area one, and write $\pi_i : Y \rightarrow C_i$ for the projections. Let (T, ω_T, V_j) be the Hopf threefold, its Gauduchon form and the smooth potentials of [Theorem 8.0.1](#). Take $Z = \mathbb{P}^1$ with its normalized Fubini–Study form κ , a point D and its normalized potential ψ satisfying $\kappa + \text{dd}^c \psi = [D]$. On $M = Y \times T \times Z$, write p, s, r for the projections. Choose a positive nonconstant smooth function h on Y and put

$$\Theta = p^*(\pi_1^* \omega_1 + \pi_2^* \omega_2) + (h \circ p)s^* \omega_T + r^* \kappa, \quad \Psi = \psi \circ r.$$

This form is strictly positive. The component $dh \wedge \omega_T$ of its exterior derivative, with one direction in Y and two in T , is nonzero and cannot be canceled by the component with three directions in T . Thus Θ is not closed.

Put $c = \min_Y h > 0$. The smooth functions $W_j = cV_j \circ s$ are strictly Θ -plurisubharmonic, since their current in the T -directions is

$$h\omega_T + c\text{dd}^c V_j = c(\omega_T + \text{dd}^c V_j) + (h - c)\omega_T > 0.$$

Only the part of degree three in the T -directions contributes to the top-degree product. The three curve forms have integral one, so positivity of smooth mixed products and Fubini’s theorem give

$$\begin{aligned} \int_M (\Theta + \text{dd}^c W_j)^6 &= 120 \int_Y \pi_1^* \omega_1 \wedge \pi_2^* \omega_2 \int_T (h(y)\omega_T + c\text{dd}^c V_j)^3 \\ &\geq 120c^3 \int_T (\omega_T + \text{dd}^c V_j)^3 \longrightarrow +\infty. \end{aligned}$$

The factor $120 = 6!/3!$ counts the ways of choosing one factor for each curve direction and three for T . Each W_j is bounded, so [Definition 6.5.1](#) gives $\nu_+(\Theta) = +\infty$, and the bounded mass property fails.

Apply [Proposition 15.6.18](#) to this product, with both curve areas equal to one. On the locus of potentials $\Psi + q_1 \circ \pi_1 \circ p + q_2 \circ \pi_2 \circ p$, where each q_i ranges over the ordinary ω_i -models with supremum zero, it gives a complete metric ρ of diameter 4, the analytic closure of the ideal subspace, the nearest-point retraction and the vanishing of the upper-volume comparison. These conclusions use no bound on the ambient masses.

For $x \in C_1$, let g_x be the normalized Green potential of the point x , with $\omega_1 + \text{dd}^c g_x = [x]$. By [Lemma 15.6.6](#), the potentials

$$\Phi_0 = \Psi, \quad \Phi_x = \Psi + g_x \circ \pi_1 \circ p$$

are ordinary and ideal models, and their divisorial poles with coefficient one give analytic singularities. Their tuples of polar curvatures are $(0, 0)$ and $(\delta_x, 0)$, so $\rho(\Phi_0, \Phi_x) = \|\delta_x\|_{\text{TV}} = 1$. Nevertheless, by the same lemma, every representative of either ordinary type has zero extended mass; in particular, all their upper and lower singularity volumes are zero. $\square$

15.6.13 Complete model topologies

We now compare the complete metrics obtained so far and ask how they might extend to all ordinary models. On a curve, the total variation of polar curvature is a complete metric on ordinary models, ideal projection keeps the atomic part of the polar curvature, and the distance to the closure of the analytic models is exactly the diffuse polar mass, by [Corollary 29.12.1](#) and [Proposition 29.12.1](#). This topology is stronger than $\tau_{\omega,0}$ on ordinary models: [Proposition 29.12.2](#) exhibits a concentration of diffuse polar curvature that is lost in the latter topology.

Adding the smooth curve background as a further coordinate gives the complete space of [Theorem 29.14.1](#). Its analytic closure is the locus of ideal models, also over backgrounds of zero area, and metric convergence controls the normalized potentials in L^1 and in capacity. This construction keeps the positive-volume topology but imposes a different Cauchy condition at the zero-volume boundary.

For a smooth big background with bounded mass, [Theorem 29.11.1](#) gives a complete topology on ordinary models of positive lower volume. Its locus of ideal models is the completion of the analytic models of positive volume, by [Corollary 29.11.1](#).

At zero volume, the product constructions of the preceding subsections keep information that top-degree mass cannot detect. A fixed divisor with unit coefficient forces every ordinary representative of the induced models to have zero mass, while polar curvature on the curve factors still distinguishes these models and gives a complete metric whose analytic closure is exactly the locus of ideal models, with

ideal projection as the unique nearest-point retraction. These conclusions hold on the product loci of [Propositions 15.6.11](#) and [15.6.18](#), including the nonclosed background with unbounded ambient mass in [Example 15.6.8](#).

Changing the curve areas rescales the polar distances, and a zero area removes the corresponding coordinate. The comparisons in [Proposition 15.6.15](#) quantify this change even when different sets of coordinates survive. If the curve backgrounds converge uniformly to forms of area zero, the diameters tend to zero and the potentials converge in L^1 , uniformly over the model tuples, and the limit still contains the normalized smooth potentials of the limiting backgrounds, by [Corollary 15.6.6](#). These loci thus describe explicit degenerations beyond the positive-volume theory.

We do not know how to extend the complete topology to general ordinary models while keeping analytic closure and compatibility across backgrounds. Since polar curvature is the coordinate that achieves this on a curve, it is natural to test polar curvature on all modifications in higher dimension. The rest of this subsection shows that this candidate fails in three ways: the first polar current misses isolated poles unless a modification exposes them; normalizing polar traces by Gauduchon forms makes the topology depend on the chosen forms; and diffuse poles of product type are invisible to polar curvature on every modification, although they lower the volume.

15.6.13.1 Polar curvature in higher dimension

On a curve, the polar curvature records every logarithmic pole. In higher dimension, the restriction of the curvature current to the pole set no longer does: it vanishes for an isolated logarithmic pole, although such a pole changes the multiplier ideals. The curve metric therefore cannot be extended simply by replacing the polar measure with this restricted current.

Here X has dimension $n \geq 2$, and ω is a Hermitian form on X . For $p \in \text{PSH}(X, \omega)$, the *first polar current* of p is

$$\text{Pol}_1(p) = \mathbf{1}_{\{p=-\infty\}}(\omega + \text{dd}^c p),$$

where the restriction to the pole set is applied to the coefficient measures of the positive current. In the notation of [Proposition 1.25.3](#), $\text{Pol}_1(p) = \text{Pol}_\omega(p)$; it is a closed positive current.

Proposition 15.6.19 *For every $x \in X$, there is $a_0 > 0$ such that, for each rational $a \in (0, a_0)$, there is an ideal model p_a with analytic singularities and pole set $\{x\}$ satisfying*

$$p_a = a \log |z|^2 + O(1) \quad \text{near } x, \quad \text{Pol}_1(p_a) = 0.$$

The models p_a are pairwise ordinarily inequivalent and have pairwise distinct families of multiplier ideals $\mathcal{I}(tp_a)$, $t > 0$, whereas also $\text{Pol}_1(0) = 0$. More precisely, with $\mathfrak{m}_x$ the maximal ideal at x ,

$$\mathcal{I}(tp_a)_x = \mathfrak{m}_x^{\max\{[ta]-n+1, 0\}} \quad (t > 0). \quad (15.17)$$

Proof Choose the cutoff potentials u_a of [Lemma 1.16.2](#) for the single point x , with a_0 smaller than the reciprocal of the constant in that lemma, and put $p_a = P_\omega[u_a]$. By [Proposition 15.2.3](#), p_a is an ideal model with analytic singularities, ordinarily equivalent to u_a . It is locally bounded away from x , and its only pole has the stated logarithmic coefficient. Distinct coefficients give unbounded differences near x . Formula (15.17) follows from [Lemma 1.16.1](#) with codimension n , and its exponents distinguish any two coefficients at sufficiently large weights.

It remains to show that the current has no coefficient mass at x . In coordinates centered at x , let $\beta = \text{dd}^c|z|^2$ and let

$$\nu = (\omega + \text{dd}^c p_a) \wedge \beta^{n-1}.$$

This is a positive measure. Choose smooth cutoff functions $0 \leq \chi_\varepsilon \leq 1$, equal to one on the ball of radius ε and supported in the ball of radius 2ε , with $-C\varepsilon^{-2}\beta \leq \text{dd}^c \chi_\varepsilon \leq C\varepsilon^{-2}\beta$; their complex Hessians are supported in the annulus between the two balls. Since β is closed, distributional integration by parts gives

$$\int \chi_\varepsilon d\nu = \int \chi_\varepsilon \omega \wedge \beta^{n-1} + \int p_a \text{dd}^c \chi_\varepsilon \wedge \beta^{n-1}.$$

The logarithmic bound for p_a on the annulus and the Euclidean volume of the annulus therefore give

$$0 \leq \nu(\{x\}) \leq \int \chi_\varepsilon d\nu \leq C_a(\varepsilon^{2n} + \varepsilon^{2n-2}(1 + |\log \varepsilon|)) \longrightarrow 0.$$

This is where $n \geq 2$ is used. By positivity, the coefficient measures of $\omega + \text{dd}^c p_a$ are bounded by its trace measure ν , so they have no mass at x . Hence the restriction to the pole set is zero, as asserted. The zero potential is an ordinary and an ideal model because $\omega > 0$, and its pole set is empty. $\square$

Consequently, no comparison that depends only on the fixed background and on Pol_1 separates these analytic ideal models, and a complete topology in higher dimension must involve singularity data of higher codimension.

A modification can turn the isolated pole into a divisor. For a modification $\pi : Y \rightarrow X$, pullback maps $\text{PSH}(X, \omega)$ to $\text{PSH}(Y, \pi^*\omega)$ by [Proposition 1.22.2](#), and we define

$$\text{Pol}_\pi(p) = \mathbf{1}_{\{p \circ \pi = -\infty\}}(\pi^* \omega + \text{dd}^c(p \circ \pi)).$$

Corollary 15.6.10 *Fix x and the models p_a of [Proposition 15.6.19](#). Let $\pi : Y \rightarrow X$ be the blowup at x , with exceptional divisor E , and let η be a Hermitian form on Y . Then*

$$\text{Pol}_\pi(p_a) = a[E].$$

For $\mu_a = \text{Pol}_\pi(p_a) \wedge \eta^{n-1}$ and any two admissible coefficients a, b ,

$$\|\mu_a - \mu_b\|_{\text{TV}} = |a - b| \int_E \eta^{n-1}.$$

Proof On relatively compact blowup charts, with $z = (s, sw)$, one has $p_a \circ \pi = a \log |s|^2 + O(1)$ along $E = \{s = 0\}$. Thus the pole set is E and the generic Lelong number along it is a . Add a local smooth function ρ with $\text{dd}^c \rho \geq \pi^* \omega$. By the argument of [Lemma 1.17.1](#), the restriction of the closed positive current $\text{dd}^c(p_a \circ \pi + \rho)$ to E is $a[E]$, and subtracting the smooth correction does not change the coefficient mass on E . Consequently $\mu_a = a[E] \wedge \eta^{n-1}$. The positive measure $[E] \wedge \eta^{n-1}$ has mass $\int_E \eta^{n-1} > 0$, which proves the formula for the total variation. $\square$

A fixed modification detects isolated poles only over the set where it is not an isomorphism, so countably many modifications still miss the poles at all points outside a countable union of nowhere dense analytic sets.

Corollary 15.6.11 *For every countable family of modifications $\pi_j : Y_j \rightarrow X$ between connected compact complex manifolds, there are pairwise ordinarily inequivalent ideal ω -models p_a with analytic singularities and with pairwise distinct families of multiplier ideals, such that*

$$\text{Pol}_{\pi_j}(p_a) = 0 \quad \text{for every } j \text{ and every } a.$$

Proof For each j , choose a proper closed analytic subset $S_j \subset X$ over whose complement π_j is an isomorphism. Each S_j is nowhere dense, so the Baire category theorem gives a point $x \notin \bigcup_j S_j$. Apply [Proposition 15.6.19](#) at this point.

Each π_j is biholomorphic near the unique pole y_j of $p_a \circ \pi_j$, and the pulled-back potential has the same logarithmic coefficient there. Its smooth background and positive curvature current satisfy the trace estimate in the proof of [Proposition 15.6.19](#), which does not use strict positivity of the background. Thus the coefficient measures have no mass at y_j , and their restriction to the pole set is zero. The same proposition gives the ordinary inequivalence and the distinct multiplier ideals. $\square$

15.6.13.2 Gauduchon polar trace comparisons

To use polar currents on all modifications at once, their sizes must be normalized compatibly. Pairing with Gauduchon forms does this: for a Gauduchon form η on a modification, the total η -trace of the curvature current does not depend on the

potential. Taking the supremum, over a family of modifications, of the normalized total variations of the polar traces gives a comparison that separates analytic models without any bound on top-degree mass. The space of all possible values of these coordinates is complete; whether its limit points are realized by ordinary models is a separate question.

Here X again has arbitrary dimension $n \geq 1$, and ω is a Hermitian form on X . Fix a set $\mathcal{R}$ of smooth modifications $\pi : Y_\pi \rightarrow X$ that contains the identity and, for any two analytic singularity types, a common log resolution. On each Y_π , choose a Gauduchon form η_π , that is, a Hermitian form with $\text{dd}^c(\eta_\pi^{n-1}) = 0$ as in [Definition 4.1.1](#). For $u \in \text{PSH}(X, \omega)$, set

$$\mu_\pi(u) = \mathbf{1}_{\{u \circ \pi = -\infty\}} (\pi^* \omega + \text{dd}^c(u \circ \pi)) \wedge \eta_\pi^{n-1},$$

where the restriction is applied to the coefficient measures of the current, and define

$$\begin{aligned} A_\pi &= \int_{Y_\pi} \pi^* \omega \wedge \eta_\pi^{n-1}, \\ \delta_\omega^{\text{pol}}(u, v) &= \sup_{\pi \in \mathcal{R}} \frac{\|\mu_\pi(u) - \mu_\pi(v)\|_{\text{TV}}}{A_\pi}. \end{aligned} \tag{15.18}$$

The Gauduchon forms are part of the data. Multiplying one of them by a positive constant does not change the corresponding term in the supremum.

Proposition 15.6.20 *Every A_π is positive. The comparison (15.18) is a pseudometric on $\text{PSH}(X, \omega)$, bounded by two, and its restriction to normalized ordinary models with analytic singularities is a metric. If X is a curve, then for all ordinary models p, q ,*

$$\delta_\omega^{\text{pol}}(p, q) = \frac{\|\mu_{\text{id}_X}(p) - \mu_{\text{id}_X}(q)\|_{\text{TV}}}{\int_X \omega},$$

so $\delta_\omega^{\text{pol}}$ induces the complete topology of the polar metric on curve models, in which the closure of the analytic models is exactly the set of ideal models.

Let f be a smooth real function and $\omega' = \omega + \text{dd}^c f$. If $\delta_{\omega'}^{\text{pol}}$ is defined by the same formula with the same Gauduchon forms, then its denominators are positive and

$$\delta_{\omega'}^{\text{pol}}(u - f, v - f) = \delta_\omega^{\text{pol}}(u, v) \quad (u, v \in \text{PSH}(X, \omega)).$$

Proof The form $\pi^* \omega$ is semipositive, and it is positive on the nonempty open set where π is an isomorphism, so $A_\pi > 0$. By [Proposition 1.22.2](#), $u \circ \pi \in \text{PSH}(Y_\pi, \pi^* \omega)$. Since $\text{dd}^c(\eta_\pi^{n-1}) = 0$, distributional Stokes gives

$$\int_{Y_\pi} (\pi^* \omega + \text{dd}^c(u \circ \pi)) \wedge \eta_\pi^{n-1} = A_\pi.$$

Thus $\mu_\pi(u)$ is a positive measure of mass at most A_π , and the normalized total variation distance of two such measures is at most two. Symmetry and the triangle inequality persist under the supremum, which proves the pseudometric assertion.

Let p, q be ordinary models with analytic singularities, choose a common log resolution π in $\mathcal{R}$, and suppose that $\delta_\omega^{\text{pol}}(p, q) = 0$. Then their measures in this coordinate agree. Let E_i be the prime components of the resolved ideals on Y_π , and a_i, b_i the coefficients of p and q along them. The divisorial restriction argument of [Lemma 1.17.1](#) gives

$$\mu_\pi(p) = \sum_i a_i [E_i] \wedge \eta_\pi^{n-1}, \quad \mu_\pi(q) = \sum_i b_i [E_i] \wedge \eta_\pi^{n-1}.$$

Indeed, a smooth local correction makes the complex Hessian closed and positive without changing its coefficient mass on a divisor. Distinct components do not share trace mass on their intersections, and each component has strictly positive trace mass. Equality of these measures therefore implies $a_i = b_i$ for every i . The criterion of [Lemma 1.17.9](#), which uses only the finitely many divisors E_i , applied in both directions gives $p \sim q$. An ordinary model is the ordinary envelope of every potential of its type, so ordinary models with the same type are equal. This proves separation.

On a curve, every smooth modification is an isomorphism and $\eta_\pi^{n-1} = 1$. Hence $A_\pi = \int_X \omega$, and pullback preserves the total variation of polar curvature. The formula on curves and the assertions following it are therefore consequences of [Corollary 29.12.1](#) and [Proposition 29.12.1](#).

Finally, $u - f$ has, in background ω' , the same pulled-back curvature current and the same pole set as u in background ω , and Stokes' theorem gives $A_{\pi, \omega'} = A_{\pi, \omega}$. The gauge formula follows. It holds for the potentials themselves, before any ordinary projection. $\square$

The coordinates $\mu_\pi(u)$ take values in a complete space. For each π , let $\mathcal{B}_\pi$ be the set of positive finite Borel measures on Y_π of mass at most A_π .

Proposition 15.6.21 *The space $\prod_{\pi \in \mathcal{R}} \mathcal{B}_\pi$ is complete for the metric*

$$\widehat{\delta}((\lambda_\pi), (\nu_\pi)) = \sup_{\pi \in \mathcal{R}} \frac{\|\lambda_\pi - \nu_\pi\|_{\text{TV}}}{A_\pi}.$$

The map $u \mapsto (\mu_\pi(u))_\pi$ takes values in this space and preserves the comparison $\delta_\omega^{\text{pol}}$.

Proof The metric is finite, bounded by two, and separates points. A Cauchy sequence is Cauchy in total variation in each coordinate, and completeness of the space of finite signed measures gives a limit there; positivity and the mass bound pass to the limit. Given $\varepsilon > 0$, choose N such that every normalized coordinate distance is at most ε for all $j, k \geq N$. Letting k tend to infinity separately in each coordinate preserves this inequality, and taking the supremum proves convergence for $\widehat{\delta}$. The last assertion follows from the definition and the mass bound proved above. $\square$

By [Proposition 1.25.1](#), the coordinates μ_π are invariant under bounded changes of the potential. This allows the gauge identity of [Proposition 15.6.20](#), which concerns the potentials themselves, to be transferred to normalized ordinary models.

Corollary 15.6.12 *The comparison $\delta_\omega^{\text{pol}}$ descends to ordinary classes. For a smooth real function f and $\omega' = \omega + \text{dd}^c f$, the map*

$$G_f(p) = P_{\omega'}[p - f]$$

is a bijection between the normalized ordinary models in the two backgrounds, with inverse $q \mapsto P_\omega[q + f]$. If the same Gauduchon forms are used in both backgrounds, G_f preserves $\delta_\omega^{\text{pol}}$, analytic models and ideal models.

Proof Boundedly equivalent potentials have boundedly equivalent pullbacks on every modification, with the same pole set. **Proposition 1.25.1** therefore gives equality of their polar currents and of their measures μ_π in every coordinate, which proves descent to ordinary classes.

If $p = P_\omega[p]$, the version of **Proposition 15.3.1** for ordinary envelopes gives

$$p + \min_X f \leq G_f(p) + f \leq p + \max_X f.$$

Thus $G_f(p) \sim p - f$. Since ordinary envelopes depend only on the ordinary type, $P_{\omega'}[G_f(p)] = P_{\omega'}[p - f] = G_f(p)$, and similarly $P_\omega[G_f(p) + f] = P_\omega[p] = p$. The same argument applied to models in background ω' proves surjectivity and the formula for the inverse. Invariance of the polar coordinates and the gauge identity of **Proposition 15.6.20** now give

$$\delta_{\omega'}^{\text{pol}}(G_f(p), G_f(q)) = \delta_\omega^{\text{pol}}(p, q).$$

Subtraction of a smooth function and bounded equivalence preserve analytic singularities. If $p = P_\omega[p]_{\mathcal{I}}$, the gauge estimate for ideal envelopes gives $P_{\omega'}[p - f]_{\mathcal{I}} \sim p - f \sim G_f(p)$. By **Proposition 15.2.1**, this ideal envelope is an ordinary model, and two ordinary models of the same ordinary type coincide. Hence it equals $G_f(p)$, which shows that G_f maps ideal models to ideal models; the inverse map gives the converse. $\square$

The traces μ_π determine the whole polar currents, because these currents are closed by the local cutoff argument of **Proposition 1.25.3**, which also applies when the pole set is not closed.

Corollary 15.6.13 *Let $u, v \in \text{PSH}(X, \omega)$. For every $\pi \in \mathcal{R}$, the polar curvature currents of $u \circ \pi$ and $v \circ \pi$, defined by coefficientwise restriction, are closed, and they agree if and only if $\mu_\pi(u) = \mu_\pi(v)$. Consequently, $\delta_\omega^{\text{pol}}(u, v) = 0$ exactly when all these polar currents agree.*

Proof By **Proposition 1.22.2**, the pullbacks belong to $\text{PSH}(Y_\pi, \pi^*\omega)$, and **Proposition 1.25.3**, applied with background $\pi^*\omega$, shows that their polar currents are closed and positive. Both currents are carried by the union of the two Borel pole sets, which has Lebesgue measure zero. Equality of their η_π -traces therefore gives equality of the currents by **Lemma 1.25.3**, and the converse is immediate. Since every A_π is positive, the last assertion follows. $\square$

For a sequence that is Cauchy for $\delta_\omega^{\text{pol}}$, total-variation convergence of the traces keeps the limiting polar mass on the union of the pole sets of the sequence, and the recovery from traces then gives compatible limits of the full polar currents.

Proposition 15.6.22 *Let (p_j) be normalized ordinary ω -models forming a Cauchy sequence for $\delta_\omega^{\text{pol}}$. For every $\pi \in \mathcal{R}$, their polar currents on Y_π converge weakly to a unique closed positive current R_π , with*

$$R_\pi \wedge \eta_\pi^{n-1} = \lim_{j \rightarrow \infty} \mu_\pi(p_j) \quad \text{in total variation.}$$

If $g : Y_{\pi'} \rightarrow Y_\pi$ is a modification with $\pi' = \pi \circ g$ and $\pi, \pi' \in \mathcal{R}$, then $g_ R_{\pi'} = R_\pi$. There is $h \in \text{PSH}(X, \omega)$ such that every R_π is carried coefficientwise by $\{h \circ \pi = -\infty\}$.*

Proof Fix π . By [Proposition 15.6.21](#), the measures $\mu_\pi(p_j)$ converge in total variation to a positive measure λ_π . Put

$$B_\pi = \bigcup_{j \geq 1} \{p_j \circ \pi = -\infty\}.$$

This is a Borel set of Lebesgue measure zero. Every measure $\mu_\pi(p_j)$ vanishes on its complement, so $\lambda_\pi(Y_\pi \setminus B_\pi) = 0$. The polar currents are closed and positive by [Corollary 15.6.13](#), and their η_π -trace masses are at most A_π . By compactness of positive currents of bounded mass, a subsequence converges weakly. Its limit R is closed and positive, and $R \wedge \eta_\pi^{n-1} = \lambda_\pi$. Since positivity bounds all coefficient measures by the Hermitian trace, R is carried by B_π . Any two subsequential limits have the same null carrier and the same trace, so they agree by [Lemma 1.25.3](#). As every subsequence has a further convergent subsequence, the whole sequence of currents converges weakly to this unique limit R_π .

Apply [Proposition 1.25.2](#) to g , with background $\pi^* \omega$ and potential $p_j \circ \pi$. It gives $g_* \text{Pol}_{\pi'}(p_j) = \text{Pol}_\pi(p_j)$. Proper pushforward is weakly continuous, since a smooth test form downstairs pulls back to a smooth test form upstairs, and passing to the limit proves compatibility. The limits are constructed separately in each coordinate, so no diagonal subsequence over $\mathcal{R}$ is needed.

To obtain one pole carrier, put $h_m = \sum_{j=1}^m 2^{-j} p_j$. These functions decrease, and they are ω -plurisubharmonic because the coefficients have sum at most one and $\omega > 0$. Normalized compactness, [Theorem 1.4.1](#), bounds their L^1 norms uniformly, so [Corollary 1.4.1](#) gives a limit $h \in \text{PSH}(X, \omega)$. Since all summands are nonpositive, each pole set of a p_j is contained in the pole set of h . Hence $B_\pi \subset \{h \circ \pi = -\infty\}$, which gives the last assertion. $\square$

The common pole carrier does not identify R_π with the polar current of h . We do not know whether all the limits R_π are the polar currents of a single ordinary model.

The topology defined by $\delta_\omega^{\text{pol}}$ also depends on the choice of the Gauduchon forms. On a surface, a Gauduchon form close to the pullback of a Kähler form assigns little trace mass to exceptional curves, so choosing the forms independently on the different modifications can make a sequence of moving point poles of fixed strength

converge to zero. We compare $\delta_\omega^{\text{pol}}$ with the upper-volume comparison d_ω and with the sets $\mathcal{M}_\delta(\omega)$ of ordinary models of lower volume at least δ , both introduced in [Definition 29.6.1](#).

Proposition 15.6.23 *Let $X = \mathbb{P}^2$ and let ω be the Fubini–Study form normalized by $\int_X \omega^2 = 1$. For every set $\mathcal{R}$ as above and every rational $a \in (0, 1)$, there are Gauduchon forms η_π and ideal models p_j with analytic singularities, whose pole sets are pairwise distinct single points with logarithmic coefficient a , such that*

$$\delta_\omega^{\text{pol}}(p_j, 0) \leq \frac{1}{j}, \quad d_\omega(p_j, 0) = a^2.$$

All p_j and 0 belong to $\mathcal{M}_{(1-a^2)/2}(\omega)$. Thus, for these choices of the Gauduchon forms, $\delta_\omega^{\text{pol}}$ does not induce the topology of [Theorem 29.11.1](#) on models of positive volume.

Proof At $x = [1 : 0 : 0]$, put

$$u_x([Z_0 : Z_1 : Z_2]) = a \log \frac{|Z_1|^2 + |Z_2|^2}{|Z_0|^2 + |Z_1|^2 + |Z_2|^2}.$$

The homogeneous quotient defines a global nonpositive potential. Its curvature is positive, since $\log(|Z_1|^2 + |Z_2|^2)$ is plurisubharmonic in a local trivialization and the remaining background is $(1-a)\omega$. Its only pole is x , where it is $a \log |z|^2 + O(1)$. By [Proposition 15.2.3](#), $p_x = P_\omega[u_x]$ is an ideal model with analytic singularities, ordinarily equivalent to u_x . Unitary projective automorphisms preserve ω and commute with its envelopes for the zero obstacle. Transporting this construction to pairwise distinct points x_j , we obtain models p_j .

Fix $\pi : Y_\pi \rightarrow X$ and some Gauduchon form γ_π on Y_π . The closed polar current of $p_j \circ \pi$ is supported on the analytic fiber over x_j . The divisorial restriction in [Lemma 1.17.1](#) and the support theorem, [[Dem12](#), Chapter III, Corollaries 2.11 and 2.14, pp. 141–143], give

$$\text{Pol}_\pi(p_j) = \sum_{E \mapsto x_j} b_{E,j}[E], \quad b_{E,j} = a \text{ord}_E(\mathfrak{m}_{x_j} \mathcal{O}_{Y_\pi}),$$

where the sum runs over the irreducible curves $E \subset Y_\pi$ with $\pi(E) = x_j$. Indeed, [Corollary 15.6.13](#) shows that the polar current is closed, and after the curve components are removed, the remaining closed current of order zero is supported at finitely many points and therefore vanishes. The sum is finite. Every such curve is contracted by π , so the restriction of $\pi^*\omega$ to it is zero. Put

$$C_{\pi,j} = \sum_{E \mapsto x_j} b_{E,j} \int_E \gamma_\pi, \quad J_\pi = \{j : C_{\pi,j} > 0\}.$$

A modification of a surface has finitely many exceptional curves, so there are only finitely many points over which π has exceptional curves. Since the points x_j are

distinct, J_π is finite. Choose $\varepsilon_\pi > 0$ with $\varepsilon_\pi C_{\pi,j} \leq 1/j$ for every $j \in J_\pi$; if J_π is empty, take $\varepsilon_\pi = 1$. Now fix

$$\eta_\pi = \pi^* \omega + \varepsilon_\pi \gamma_\pi.$$

This form is positive and Gauduchon, since on a surface the Gauduchon equation is $\text{dd}^c \eta_\pi = 0$. Moreover

$$A_\pi = 1 + \varepsilon_\pi \int_{Y_\pi} \pi^* \omega \wedge \gamma_\pi \geq 1, \quad \|\mu_\pi(p_j)\|_{\text{TV}} = \varepsilon_\pi C_{\pi,j} \leq \frac{1}{j}.$$

These forms are fixed for the whole sequence, and the estimate holds for every modification. Since $\mu_\pi(0) = 0$, taking the supremum gives the asserted convergence.

To compute the singularity volumes, let $\rho : Y \rightarrow X$ be the blowup at x , with exceptional curve E , and let $F : Y \rightarrow \mathbb{P}^1$ be the morphism resolving the pencil $[Z_1 : Z_2]$. Write ω_1 for the normalized Fubini–Study form on $\mathbb{P}^1$. Then

$$\rho^* \omega + \text{dd}^c(u_x \circ \rho) = a[E] + H_a, \quad H_a = (1 - a)\rho^* \omega + aF^* \omega_1.$$

For every $v \sim u_x$, divisorial removal gives $H_a + \text{dd}^c w \geq 0$, where $w = v \circ \rho - u_x \circ \rho$ is bounded after extension across E . The bounded product of [Proposition 1.7.1](#) assigns no mass to E , so change of variables off E identifies the non-pluripolar mass of v with $\int_Y (H_a + \text{dd}^c w)^2$. Since H_a is closed, integration by parts for bounded potentials gives

$$\int_Y (H_a + \text{dd}^c w)^2 = \int_Y H_a^2 = 1 - a^2.$$

For the last equality, note that H_a represents the class $H - aE$, where $H = \rho^*[\omega]$, and that $H^2 = 1$, $H \cdot E = 0$ and $E^2 = -1$. Hence both singularity volumes of p_x , and by unitary transport those of every p_j , are equal to $1 - a^2$. The zero model has both volumes equal to one. Since $p_j \leq 0$, [Definition 29.6.1](#) gives $d_\omega(p_j, 0) = 1 - (1 - a^2) = a^2$. This also proves the common positive lower bound for the volumes and the incompatibility of the topologies. $\square$

Thus compatibility with the positive-volume topology, even on analytic models, requires a coordinated choice of the Gauduchon forms. The obstruction in the next part is of a different kind: it applies to every choice of the forms, on general ordinary models. The normalization by A_π also excludes backgrounds of zero curve area, for which $A_\pi = 0$.

15.6.13.3 Diffuse product poles

Even polar currents on all modifications, with any choice of Gauduchon forms, miss some ordinary models. A maximum of diffuse polar potentials on the factors of a polydisk has a joint pole set of Hausdorff dimension zero, so all its first polar currents vanish. Nevertheless, its bounded truncations keep a fixed positive amount

of top-degree mass near that set. The non-pluripolar product loses this mass, so the volume of the model drops, although the polar comparison does not see any pole.

Lemma 15.6.7 *Let $\Delta \subset \mathbb{C}$ be the unit disk. There are a compact set $K \Subset \Delta$ of Hausdorff dimension zero and a negative subharmonic function g on Δ , smooth and harmonic off K , with*

$$\{g = -\infty\} = K, \quad v(g, a) = 0 \quad (a \in \Delta), \quad g|_{\partial\Delta} = 0.$$

For $n \geq 2$, put $D = \Delta^n$, $S = K^n$ and

$$h(z) = \max_{1 \leq j \leq n} g(z_j), \quad h_L = \max\{h, -L\} \quad (L > 0).$$

The function h is locally Lipschitz off S , and its bounded local Monge–Ampère measure $(dd^c h)^n$ vanishes there. The measures $(dd^c h_L)^n$ all have the same finite mass $M > 0$. Their supports are compact and converge to S as $L \rightarrow \infty$, in the sense that they lie in any given neighborhood of S for all large L .

Proof Use the binary Cantor set and the nonatomic probability measure σ of [Example 29.12.2](#), placed in a small real interval in Δ . Its intervals of level k have length $r_k = \exp(-4^{k+1})$ and mass 2^{-k} . For every $s > 0$,

$$2^k r_k^s \rightarrow 0, \quad 2^{nk} (\sqrt{n} r_k)^s \rightarrow 0.$$

Covering K by its 2^k intervals of level k , and S by the 2^{nk} products of such intervals, which have diameter at most $\sqrt{n} r_k$, shows that K and S have Hausdorff dimension zero. Define the Green potential of the disk

$$g(z) = \int_{\Delta} \log \left| \frac{z-y}{1-\bar{y}z} \right|^2 d\sigma(y).$$

Then $dd^c g = \sigma$, with the normalization of dd^c fixed in the conventions. The Green kernel is nonpositive, vanishes on the boundary and is smooth away from its pole. On a fixed smaller disk it is at most $\log |z-y|^2 + C$. For $z \in K$, integration over the interval of level k containing z , together with nonpositivity of the kernel elsewhere, gives

$$g(z) \leq 2^{-k} (2 \log r_k + C) \rightarrow -\infty.$$

Outside K the potential is finite, smooth and harmonic. Its Lelong number at a is $\sigma(\{a\}) = 0$. Since K stays away from the boundary, g is smooth near the boundary and tends uniformly to zero there.

Near a point off S , some coordinate z_j lies outside K , and the finite value $g(z_j)$ locally exceeds all branches $g(z_i)$ with z_i near K . Hence h is locally the maximum of at most n pluriharmonic functions, and in particular it is locally Lipschitz. For $m \leq n$ pluriharmonic functions a_j , use the smooth approximations

$$\varepsilon \log \sum_{j=1}^m e^{a_j/\varepsilon},$$

which decrease to $\max_j a_j$ as $\varepsilon \downarrow 0$. Their complex Hessian is a positive multiple of the weighted covariance of the forms ∂a_j , with probability weights proportional to $e^{a_j/\varepsilon}$. The centered forms satisfy one weighted linear relation, so this Hessian has rank at most $m - 1 < n$, and its n th power vanishes. Bounded decreasing convergence in [Theorem 1.6.1](#) gives the same conclusion for the maximum.

The bounded truncation h_L is continuous, since near a pole of any curve potential the corresponding branch lies below the constant $-L$. The same argument, applied to the $n + 1$ branches $g(z_1), \dots, g(z_n), -L$, shows that $(\text{dd}^c h_L)^n$ is carried by

$$Q_L = \{z : g(z_j) = -L \text{ for every } j\}.$$

Indeed, off Q_L one branch lies strictly below the maximum. Discarding it, together with any branches near poles, leaves at most n pluriharmonic branches locally, so the measure vanishes there. Since Q_L is compact, the Chern–Levine–Nirenberg estimate (1.2) gives finite mass.

For $L, L' > 0$, the functions h_L and $h_{L'}$ agree near ∂D , since h tends uniformly to zero there. Integration by parts for bounded potentials gives

$$(\text{dd}^c h_L)^n - (\text{dd}^c h_{L'})^n = \text{dd}^c \left((h_L - h_{L'}) \sum_{j=0}^{n-1} (\text{dd}^c h_L)^j \wedge (\text{dd}^c h_{L'})^{n-1-j} \right).$$

The current on the right has compact support, so its integral is zero. To see that the common mass M is positive, fix L and choose $\varepsilon > 0$ so small that

$$U = \{h_L < \varepsilon(|z|^2 - n - 1)\}$$

is nonempty. This set is relatively compact in D , because h_L tends to zero at the boundary while the quadratic function is strictly negative on $\overline{D}$. The comparison (1.4) for bounded potentials gives

$$0 < \int_U (\varepsilon \text{dd}^c |z|^2)^n \leq \int_U (\text{dd}^c h_L)^n \leq M.$$

Finally, g is bounded on compact subsets of $\overline{\Delta} \setminus K$. Its sublevel sets $\{g \leq -L\}$ therefore converge to K as $L \rightarrow \infty$, and Q_L converges to S . $\square$

For a separable maximum, the full top-degree product of [Theorem 1.6.3](#) can be computed exactly. Its restriction to the pole set, which we call the *residual measure*, depends only on the product of the weights of the branches, so different positive weights can give the same residual measure and different singularity types.

Lemma 15.6.8 *Use the Green potential g , the probability measure σ and the sets $D = \Delta^n$, $S = K^n$ of [Lemma 15.6.7](#). For $s, L > 0$ and $a = (a_1, \dots, a_n) \in (0, +\infty)^n$, put*

$$\mu_s = \text{dd}^c \max(g, -s), \quad h_a(z) = \max_j a_j g(z_j),$$

and $h_{a,L} = \max(h_a, -L)$. Each μ_s is a nonatomic probability measure supported on $\{g = -s\}$, and $\mu_s \rightarrow \sigma$ weakly as $s \rightarrow \infty$. The bounded products satisfy

$$(\text{dd}^c h_{a,L})^n = \left(\prod_{j=1}^n a_j \right) \mu_{L/a_1} \otimes \cdots \otimes \mu_{L/a_n}.$$

The function h_a has pole set S , is locally Lipschitz off S , and has zero bounded top-degree product there. Its full product in the sense of [Theorem 1.6.3](#) is

$$(\text{dd}^c h_a)_{\text{full}}^n = \left(\prod_{j=1}^n a_j \right) \sigma^{\otimes n}.$$

In particular, the common mass M in [Lemma 15.6.7](#) is 1.

Proof The truncation $\max(g, -s)$ agrees with g near the boundary of Δ . Their difference is a compactly supported integrable function, so its complex Hessian has integral zero, and $\mu_s(\Delta) = \sigma(\Delta) = 1$. The truncation is constant near K and harmonic off K wherever $g \neq -s$, which proves the support assertion. Since the truncation is bounded, μ_s has no point masses, by [Theorem 1.6.1](#). Decreasing local L^1 convergence to g gives $\mu_s \rightarrow \text{dd}^c g = \sigma$; for large s , the supports lie in one fixed compact subset of Δ .

The rank argument of [Lemma 15.6.7](#) applies with the weights a_j . Away from S , the finite branches dominate the branches near poles, so h_a is locally a Lipschitz maximum of at most n pluriharmonic functions, with zero top-degree product. For the bounded maximum with the constant branch $-L$, the same argument shows that its top-degree product is supported on

$$Q_{a,L} = \{z : a_j g(z_j) = -L \text{ for every } j\}.$$

Indeed, off this set one branch lies strictly below the maximum, leaving at most n active pluriharmonic branches; this also applies near branches with poles, which lie below the constant branch.

Near a point of $Q_{a,L}$ at which all the differentials $dg(z_j)$ are nonzero, set $x_j = a_j g(z_j) + L$. Each x_j is the real part of a local holomorphic coordinate in its own factor. For $\varepsilon > 0$, smooth the maximum locally by

$$f_\varepsilon(x) = \varepsilon \log \left(1 + \sum_{j=1}^n e^{x_j/\varepsilon} \right),$$

with weights

$$w_0 = \frac{1}{1 + \sum_j e^{x_j/\varepsilon}}, \quad w_j = e^{x_j/\varepsilon} w_0.$$

Then $-L + f_\varepsilon$ decreases to $h_{a,L}$. The Hessian matrix of f_ε in the variables x_j is $\varepsilon^{-1}(\text{diag}(w_j) - (w_j w_k)_{j,k})$, whose determinant is $\varepsilon^{-n} w_0 \prod_j w_j$. Hence

$$(\text{dd}^c f_\varepsilon)^n = n! \varepsilon^{-n} w_0 \prod_{j=1}^n w_j \bigwedge_{j=1}^n (dx_j \wedge d^c x_j).$$

The scalar kernel on $\mathbb{R}^n$ is an approximate identity of mass 1. To check the constant, write $y = x/\varepsilon$. The map

$$y \mapsto \left(\frac{e^{y_j}}{1 + \sum_k e^{y_k}} \right)_{j=1}^n$$

is a diffeomorphism onto the open simplex $\{w_j > 0, \sum_j w_j < 1\}$, with Jacobian $w_0 \prod_j w_j$. The simplex has volume $1/n!$, so the kernel above has integral 1. Integrability of the fixed kernel in y gives concentration at $x = 0$ as $\varepsilon \downarrow 0$.

Bounded decreasing convergence of products therefore identifies the local limit with the tensor product of the one-variable level measures. In the j th factor, the chain rule for $\max(x_j, 0)$ gives

$$\delta_0(x_j) dx_j \wedge d^c x_j = a_j \text{dd}^c \max(g, -L/a_j),$$

where the Dirac notation denotes the level measure in the real normal coordinate x_j . The critical points of the nonconstant harmonic function g off K are isolated. In each coordinate neighborhood, their inverse images are analytic hypersurfaces, hence pluripolar. The bounded top-degree product gives them zero mass by [Theorem 1.6.1](#), and so does the candidate tensor measure, because each μ_{L/a_j} has no point masses. Thus the formula extends across these points and, together with the support assertion, holds on all of D .

Tensor products of the curve probabilities converge to $\sigma^{\otimes n}$: this follows first for products of continuous functions of one variable, and then for all continuous test functions by uniform approximation on a common compact product. Finally, $h_{a,L} \downarrow h_a$, whose unbounded locus is the closed set S of Hausdorff dimension zero. By [Theorem 1.6.3](#), the weak limit is the full top-degree product of h_a . Taking $a_j = 1$ proves $M = 1$. $\square$

Proposition 15.6.24 *Let X be a connected compact Kähler manifold of dimension $n \geq 2$, with Kähler form ω . There are a normalized ordinary model $p \neq 0$ and $\delta > 0$ such that $p, 0 \in \mathcal{M}_\delta(\omega)$, all multiplier ideals of p are trivial, and*

$$\mathbf{1}_{\{p \circ \pi = -\infty\}} (\pi^* \omega + \text{dd}^c(p \circ \pi)) = 0$$

for every smooth modification $\pi : Y \rightarrow X$. Consequently, for every family of modifications and every choice of Gauduchon forms as in [Section 15.6.13.2](#),

$$\delta_\omega^{\text{pol}}(p, 0) = 0, \quad d_\omega(p, 0) > 0.$$

Thus the polar comparison does not separate ordinary models of positive lower volume, and the closure of the analytic models for this comparison contains the model p , which is not an ideal model.

Proof Place the polydisk of [Lemma 15.6.7](#) in a holomorphic coordinate chart of X . Choose a smooth cutoff function $0 \leq \chi \leq 1$, compactly supported in that polydisk and equal to one on a neighborhood of S , and extend $H = \chi h$ by zero. Then H is quasi-plurisubharmonic and not identically $-\infty$. Indeed, outside S the gradients of h are locally bounded, so the terms containing derivatives of χ in

$$\text{dd}^c(\chi h) = \chi \text{dd}^c h + h \text{dd}^c \chi + d\chi \wedge d^c h + dh \wedge d^c \chi$$

have bounded coefficients on their compact support, while the first term is positive. Hence $\text{dd}^c H \geq -C\omega$ for some $C > 0$. Take $0 < t < 1/C$ and put $u = tH$. Then $u \leq 0$, $\sup_X u = 0$, the pole set of u is S , and

$$\omega + \text{dd}^c u \geq (1 - tC)\omega.$$

Set $u_k = \max(u, -k)$. By Stokes' theorem in the closed background, the bounded currents $\omega + \text{dd}^c u_k$ have total Monge–Ampère mass $A = \int_X \omega^n$. Near S , where $\chi = 1$,

$$(\omega + \text{dd}^c u_k)^n = (\omega + t \text{dd}^c h_{k/t})^n \geq t^n (\text{dd}^c h_{k/t})^n.$$

For large k , the whole support of the measure on the right lies in this neighborhood; these measures have mass $t^n M$ and their supports converge to S . Take a subsequence along which both these local measures and the global measures $(\omega + \text{dd}^c u_k)^n$ converge weakly. The global limit has mass at least $t^n M$ on S . Off S , the function u is locally bounded, and $u_k = u$ eventually on every compact set, so there the global limit is the non-pluripolar measure of u . It follows that

$$(1 - tC)^n A \leq \int_X \text{MA}_\omega(u) \leq A - t^n M < A.$$

The lower bound follows from the current inequality above and bounded local products off the Lebesgue-null set S .

In a closed Kähler background, bounded changes of a potential do not change its non-pluripolar mass. Both singularity volumes of u therefore equal this positive

number. By [Theorem 29.3.2](#), $p = P_\omega[u]$ is a normalized ordinary model with the same volumes. In particular $p \neq 0$, and $d_\omega(p, 0) = A - \overline{\text{vol}}_\omega(p) > 0$. Taking for δ half the lower volume of p puts both models in $\mathcal{M}_\delta(\omega)$. Also $u \leq p \leq 0$, so the pole set of p is contained in S .

Fix a smooth modification π , and let E_i be the irreducible divisorial components of its exceptional locus, away from which π is an isomorphism. The polar current R of $p \circ \pi$ is closed and positive by [Proposition 1.25.3](#). On the set where π is an isomorphism, R is carried by the inverse image of S , which has Hausdorff dimension zero in each relatively compact chart; by [Corollary 1.13.1](#), R vanishes there. The support theorem for closed positive currents therefore gives

$$R = \sum_i b_i [E_i], \quad b_i \geq 0;$$

see [\[Dem12, Chapter III, Corollaries 2.11 and 2.14, pp. 141–143\]](#). Components of codimension at least two carry no closed $(1, 1)$ -current of order zero, and the sum is finite by compactness. Since $R \leq \pi^* \omega + \text{dd}^c(p \circ \pi)$, its coefficients satisfy $b_i \leq \nu(p \circ \pi, E_i)$.

If $\pi(E_i)$ is not contained in S , some regular point of E_i maps outside S . Near such a point $u \circ \pi$, and hence $p \circ \pi$, is bounded below, so the generic Lelong number of $p \circ \pi$ along E_i vanishes and $b_i = 0$. Every remaining image $\pi(E_i)$ is an irreducible analytic set contained in the set S of Hausdorff dimension zero, hence a point $a = (a_1, \dots, a_n)$. Near that point, $u = t \max_j g(z_j)$. At a general point of E_i , with a local equation ζ of E_i , the first coordinate satisfies

$$z_1 \circ \pi - a_1 = \zeta^m f, \quad m \geq 1, \quad f \neq 0.$$

A local holomorphic m th root of the unit f turns this expression into ζ'^m for another local equation ζ' of E_i . Taking circular means gives

$$\nu(g(a_1 + \zeta'^m), E_i) = m\nu(g, a_1) = 0.$$

Since $p \circ \pi \geq u \circ \pi \geq t g(z_1 \circ \pi)$ there, again $b_i = 0$. Thus $R = 0$ for every modification.

The same local comparison gives zero Lelong numbers for u , and hence for $p \geq u$, at every point. Skoda's local integrability theorem, recalled in [\[Xia\]](#), then makes e^{-sp} locally integrable for every $s > 0$, so all multiplier ideals of p are trivial. The ideal envelope of p is therefore the zero model, and since $p \neq 0$, p is not an ideal model. The zero model has analytic singularities, and $\delta_\omega^{\text{pol}}(p, 0) = 0$ puts p in the closure of the analytic models for the polar comparison. This proves the final assertions. $\square$

The lost top-degree mass also measures distances along the scaled family. Closed positive currents of lower degree cannot charge the pole set, which has Hausdorff dimension zero, so they cause no further loss of volume.

Corollary 15.6.14 Fix $H = \chi h$, $S = K^n$, $C > 0$ and $M > 0$ from the construction in [Proposition 15.6.24](#), and put $A = \int_X \omega^n$. Choose $0 < t_0 < 1/C$. For $0 < t \leq t_0$ set

$$u_t = tH, \quad p_t = P_\omega[u_t],$$

and define $u_0 = p_0 = 0$ separately. Both singularity volumes of p_t equal

$$V(p_t) = A - Mt^n, \quad 0 \leq t \leq t_0.$$

For all $s, t \in [0, t_0]$,

$$d_\omega(p_s, p_t) = M|s^n - t^n|, \quad \delta_\omega^{\text{pol}}(p_s, p_t) = 0.$$

Thus this family, with the restriction of d_ω , is a complete ordered interval, isometric to $[0, Mt_0^n]$. Every p_t with $t > 0$ is not an ideal model and has trivial multiplier ideals. For any prescribed $0 < \delta < A$, one can choose $t_0 > 0$ so that the whole interval lies in $\mathcal{M}_\delta(\omega)$.

Proof Fix $t > 0$. Let $u_{t,k} = \max(tH, -k)$ and $\Theta_k = \omega + \text{dd}^c u_{t,k}$. These bounded closed positive currents satisfy, for $1 \leq j \leq n$,

$$\int_X \Theta_k^j \wedge \omega^{n-j} = A.$$

Indeed, subtract ω^j , write the difference as a telescoping sum of mixed products, and integrate $\text{dd}^c(u_{t,k} \sum_{i=0}^{j-1} \Theta_k^i \wedge \omega^{j-1-i}) \wedge \omega^{n-j}$ by parts for bounded potentials.

Choose an open neighborhood U of S on which $\chi = 1$. There $\Theta_k = \omega + t \text{dd}^c h_{k/t}$, so positivity gives

$$t^j (\text{dd}^c h_{k/t})^j \wedge \omega^{n-j} \leq \Theta_k^j \wedge \omega^{n-j}.$$

For the finitely many $1 \leq j < n$, take a common subsequence along which the local closed positive currents $(\text{dd}^c h_{k/t})^j$ converge weakly on U , with limits R_j ; the inequalities above give the required local bounds on their traces. Along a further subsequence, the global measures Θ_k^n and the local top-degree measures also converge weakly. By [Lemma 15.6.7](#), the latter have mass M and supports eventually contained in a fixed compact subset of U and converging to S . Their extensions by zero therefore converge, along a further subsequence, to a measure ρ supported on S with $\rho(S) = M$.

Since S has Hausdorff dimension zero, [Corollary 1.13.1](#) shows that every R_j , $j < n$, has coefficient measures vanishing on S . The smooth measure ω^n also gives S zero mass. On U we expand

$$\Theta_k^n = \sum_{j=0}^n \binom{n}{j} t^j (\text{dd}^c h_{k/t})^j \wedge \omega^{n-j}.$$

If η is the chosen global weak limit, this expansion gives $\eta(S) = t^n \rho(S) = Mt^n$, while $\eta(X) = A$. Off S , the function u_t is locally bounded and its truncations eventually agree with it on each compact set, so there η agrees with $\text{MA}_\omega(u_t)$. The

non-pluripolar measure gives S zero mass, which proves

$$\int_X \text{MA}_\omega(u_t) = A - Mt^n.$$

This argument uses only a weak subsequential limit in top degree; it does not define an unbounded Bedford–Taylor product on S .

The current inequality $\omega + \text{dd}^c u_t \geq (1 - Ct)\omega$ gives $A - Mt^n \geq (1 - Ct_0)^n A > 0$. Invariance of non-pluripolar mass under bounded changes in the closed background and [Theorem 29.3.2](#) now give the formula for both singularity volumes of the normalized ordinary model p_t . Since $H \leq 0$, monotonicity of the ordinary envelope gives $p_s \geq p_t$ for $s \leq t$, and the zero endpoint satisfies the same order. Thus $\max(p_s, p_t) = p_s$, and the formula for ordered pairs in [\(29.6\)](#) gives $d_\omega(p_s, p_t) = M(t^n - s^n)$. Hence $p_t \mapsto Mt^n$ is an isometry onto $[0, Mt_0^n]$, and the interval is complete.

The proof of [Proposition 15.6.24](#) applies to every $0 < t \leq t_0$: all first polar currents vanish on all modifications, and all multiplier ideals are trivial. The polar currents also vanish for $p_0 = 0$, so the polar comparison vanishes on the family. For $t > 0$, the strict volume deficit makes $p_t \neq 0$, and its trivial ideals then show that it is not an ideal model. Finally, choose $t_0 < 1/C$ so small that $(1 - Ct_0)^n A > \delta$; the uniform lower bound for the volumes puts every p_t in $\mathcal{M}_\delta(\omega)$. $\square$

In a nonclosed background, the mass of a potential also involves the terms with derivatives of the background in the mass expansion [\(2.1\)](#). Bounded cutoff approximations separate these lower-degree terms from the loss of top-degree mass on S .

Proposition 15.6.25 *Let X be a connected compact complex manifold of dimension $n \geq 2$, with Hermitian form ω . Place the polydisk of [Lemma 15.6.7](#) in a coordinate chart. Choose a smooth function $0 \leq \chi \leq 1$, compactly supported there and equal to one near $S = K^n$, and extend $H = \chi h$ and $H_L = \chi h_L$ by zero. There is $C > 0$ such that $\text{dd}^c H \geq -C\omega$ and $\text{dd}^c H_L \geq -C\omega$ for all sufficiently large L . Put $A = \int_X \omega^n$. The limits*

$$c_j = \lim_{L \rightarrow \infty} \int_X H_L (\text{dd}^c H_L)^{j-1} \wedge \text{dd}^c (\omega^{n-j}), \quad 1 \leq j < n,$$

exist and are finite, and, for $0 < t < 1/C$,

$$\int_X \text{MA}_\omega(tH) = A + \sum_{j=1}^{n-1} \binom{n}{j} c_j t^j - Mt^n.$$

If $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$, this mass is $A - Mt^n$. On a surface the formula is

$$\int_X \text{MA}_\omega(tH) = A + 2t \int_X H \text{dd}^c \omega - Mt^2.$$

Proof Outside a fixed neighborhood of S , the truncations h_L eventually agree with h on every compact set, in particular on the supports of the derivatives of χ . The cutoff calculation in [Proposition 15.6.24](#) therefore gives a lower bound $-C\omega$ for $\text{dd}^c H_L$ and $\text{dd}^c H$, uniform in L .

Let $\kappa = \text{dd}^c |z|^2$ on the coordinate polydisk D , and choose $B > 0$ so that $T_L = B\kappa + \text{dd}^c H_L$ is positive and closed on D . The potentials of T_L are locally bounded. Since H_L has compact support, integration by parts for bounded potentials gives, for $1 \leq j \leq n$,

$$\int_D T_L^j \wedge \kappa^{n-j} = B^j \int_D \kappa^n.$$

Indeed, every nonconstant term of the binomial expansion is the complex Hessian of a compactly supported current built from bounded products, wedged with a closed power of κ . Thus the traces in all degrees are bounded independently of L .

For $j < n$, every subsequential weak limit of T_L^j has coefficient measures vanishing on S , by [Corollary 1.13.1](#). Off S , local boundedness and eventual equality identify it with $(B\kappa + \text{dd}^c H)^j$. These two properties determine the limit uniquely. Expanding $(T_L - B\kappa)^j$ therefore shows that $(\text{dd}^c H_L)^j$ converges weakly to a finite signed current W_j with no coefficient mass on S . It vanishes near ∂D and extends by zero to X . Integration by parts for bounded potentials gives

$$\int_X (\text{dd}^c H_L)^j \wedge \omega^{n-j} = \int_X H_L (\text{dd}^c H_L)^{j-1} \wedge \text{dd}^c (\omega^{n-j}).$$

The left side converges to $\int_X W_j \wedge \omega^{n-j}$, which proves that c_j exists and is finite.

Fix $0 < t < 1/C$. The positive measures $(\omega + t\text{dd}^c H_L)^n$ have uniformly bounded mass, by their local expansion in powers of T_L and smooth forms. Their total masses satisfy

$$\int_X (\omega + t\text{dd}^c H_L)^n = A + \sum_{j=1}^{n-1} \binom{n}{j} t^j \int_X (\text{dd}^c H_L)^j \wedge \omega^{n-j},$$

since the top power $(\text{dd}^c H_L)^n$ integrates to zero by Stokes' theorem for bounded potentials. Let η be a weak subsequential limit. Its total mass is $A + \sum_{j=1}^{n-1} \binom{n}{j} c_j t^j$.

Near S , where $\chi = 1$, expand $(\omega + t\text{dd}^c h_L)^n$. All the limits of lower degree give S zero mass, while the top-degree measures have mass M and supports converging to S , by [Lemma 15.6.7](#). Hence $\eta(S) = Mt^n$. Off S , eventual equality with the locally bounded function tH identifies η with the non-pluripolar measure of tH . Subtracting the mass on S proves the formula.

If $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$, every c_j is zero. For $n = 2$, dominated L^1 convergence $H_L \rightarrow H$ gives $c_1 = \int_X H \text{dd}^c \omega$, which proves the formula on surfaces. These formulas give the masses of the potentials tH themselves. Passing to singularity volumes in a nonclosed background requires control of the masses of all potentials ordinarily equivalent to tH . $\square$

When $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$, this control is available. The residual measure on the pole set is unchanged under bounded perturbations by [Lemma 1.6.5](#), while all bounded global truncations have the same total mass by mass invariance.

Corollary 15.6.15 *Let ω be a Hermitian form on a connected compact complex manifold X of dimension $n \geq 2$, and assume*

$$\text{dd}^c(\omega^q) = 0, \quad 1 \leq q < n.$$

For the cutoff H of [Proposition 15.6.25](#) and $0 < t < 1/C$, every $v \in \text{PSH}(X, \omega)$ with $v \sim tH$ satisfies

$$\int_X \text{MA}_\omega(v) = A - Mt^n, \quad A = \int_X \omega^n.$$

Consequently, all conclusions of [Corollary 15.6.14](#) hold in this background: the ordinary models have both volumes equal to $A - Mt^n$, they form a complete ordered interval with distances $M|s^n - t^n|$, and their first polar currents vanish on all modifications, so their polar comparison vanishes. For any $0 < \delta < A$, the interval can be chosen inside $\mathcal{M}_\delta(\omega)$. The models with positive parameter are not ideal models, and their multiplier ideals are trivial.

In particular, these conclusions hold on every connected compact complex surface equipped with a Gauduchon form.

Proof By [Theorem 2.2.2](#), every bounded ω -plurisubharmonic potential has mass A . Thus $v_+(\omega) = A$ for the upper mass of [Definition 6.5.1](#), and X has the bounded mass property by [Proposition 6.5.1](#).

Fix $v \sim tH$. Its pole set is S , and it is locally bounded off S . In a coordinate neighborhood of S , choose a smooth local correction q such that $a = v + q$ is plurisubharmonic. Since $\chi = 1$ there, $a - th$ is bounded near S . By [Theorem 1.6.3](#), the full product of h is the weak limit of the measures $(\text{dd}^c h_L)^n$, and the support and mass assertions of [Lemma 15.6.7](#) show that this limit is supported on S with total mass M . The invariance of residual measures in [Lemma 1.6.5](#) therefore gives

$$(\text{dd}^c a)_{\text{full}}^n(S) = Mt^n.$$

Set $v_k = \max(v, -k)$. After each fixed local smooth correction, these functions decrease to a plurisubharmonic function whose unbounded locus lies in S . The theorem on full local products and the expansion (1.10) identify the weak limit of $(\omega + \text{dd}^c v_k)^n$ with a global positive measure T_v of total mass A ; the local expressions agree on overlaps because they are limits of the same bounded global measures. By [Corollary 1.13.1](#), every closed positive power $(\text{dd}^c a)_{\text{full}}^j$ with $j < n$ has coefficient measures vanishing on S , and smooth forms also give S zero mass. Hence only the top-degree power contributes on S , and $T_v(S) = Mt^n$. Off S , the truncations eventually agree with v on each compact set, so there T_v equals the non-pluripolar measure of v . Removing the mass on S proves the formula for every representative $v \sim tH$.

Both singularity volumes of tH thus equal $A - Mt^n$. The current inequality $\omega + \text{dd}^c(tH) \geq (1 - Ct)\omega$ shows that this volume is positive, uniformly for $0 < t \leq t_0 < 1/C$. By [Theorem 29.3.2](#), ordinary projection preserves both volumes and gives the normalized models. Their order and distances follow as in [Corollary 15.6.14](#), with the zero endpoint defined separately.

The support and Lelong-number argument in the proof of [Proposition 15.6.24](#) uses that the background is smooth and that its polar restriction is closed, but not that the background is closed. It therefore gives vanishing first polar currents on all modifications and trivial multiplier ideals at all weights in the present setting as well. The strict volume deficit shows that every model with positive parameter is not an ideal model. Choosing t_0 small enough puts the interval in $\mathcal{M}_\delta(\omega)$. Finally, on a surface the only condition is $\text{dd}^c\omega = 0$, which is the Gauduchon condition, and Gauduchon forms exist by [Theorem 4.1.1](#). $\square$

In an arbitrary Hermitian background, bounded equivalence still preserves the loss of top-degree mass on the pole set. The total mass of the limit of the truncations, however, can vary with the representative, through the terms with derivatives of the background.

Proposition 15.6.26 *Let ω be a Hermitian form on a connected compact complex manifold X of dimension $n \geq 2$. Fix the cutoff H , the constant C and the mass M of [Proposition 15.6.25](#), and $0 < t < 1/C$. For every $v \in \text{PSH}(X, \omega)$ with $v \sim tH$, put $v_k = \max(v, -k)$. The limits*

$$c_j(v) = \lim_{k \rightarrow \infty} \int_X v_k (\text{dd}^c v_k)^{j-1} \wedge \text{dd}^c(\omega^{n-j}), \quad 1 \leq j < n,$$

exist and are finite, and

$$\int_X \text{MA}_\omega(v) = A + \sum_{j=1}^{n-1} \binom{n}{j} c_j(v) - Mt^n, \quad A = \int_X \omega^n.$$

In particular, with the lower and upper masses $v_\pm(\omega)$ of [Definition 6.5.1](#),

$$v_-(\omega) - Mt^n \leq \int_X \text{MA}_\omega(v) \leq v_+(\omega) - Mt^n.$$

On a surface this mass is $A + 2 \int_X v \text{dd}^c \omega - Mt^2$.

Proof The pole set of v is S , and v is locally bounded off S . On each relatively compact coordinate neighborhood, choose a fixed smooth local correction q such that $v + q$ and every $v_k + q$ are plurisubharmonic. By [Theorem 1.6.3](#), all closed powers of $\text{dd}^c(v_k + q)$ converge weakly to finite currents of order zero. Expanding $\text{dd}^c v_k = \text{dd}^c(v_k + q) - \text{dd}^c q$ gives weak convergence of $(\text{dd}^c v_k)^j$ in every degree j . The local limits patch together, because the bounded currents $(\text{dd}^c v_k)^j$ are global; write W_j for the limits.

Integration by parts for bounded potentials gives

$$\int_X (\mathrm{dd}^c v_k)^j \wedge \omega^{n-j} = \int_X v_k (\mathrm{dd}^c v_k)^{j-1} \wedge \mathrm{dd}^c (\omega^{n-j});$$

this follows by uniformly bounded decreasing regularization, as in [Theorems 1.11.1](#) and [2.2.1](#). Pairing W_j with the smooth form ω^{n-j} shows that $c_j(v)$ exists and is finite. The top power $(\mathrm{dd}^c v_k)^n$ has zero integral for every k , by Stokes' theorem for bounded potentials. Expanding the positive bounded measures $(\omega + \mathrm{dd}^c v_k)^n$ therefore gives a global positive weak limit T_v of finite total mass $A + \sum_{j=1}^{n-1} \binom{n}{j} c_j(v)$.

Near S , compare $a = v + q$ with th ; their difference is bounded there. The full top-degree product of h has mass M and is supported on S , by [Theorem 1.6.3](#) and [Lemma 15.6.7](#). Hence [Lemma 1.6.5](#) gives $(\mathrm{dd}^c a)_{\mathrm{full}}^n(S) = Mt^n$. Every closed power of lower degree has zero coefficient mass on S , by [Corollary 1.13.1](#). In the expansion with the smooth form $\omega - \mathrm{dd}^c q$, only the top power therefore contributes to $T_v(S)$, and $T_v(S) = Mt^n$. Off S , the truncations eventually agree with v , so T_v is the non-pluripolar measure of v there. Subtracting the mass on S proves the formula.

Each measure $(\omega + \mathrm{dd}^c v_k)^n$ has total mass between $v_-(\omega)$ and $v_+(\omega)$. Passing to the weak limit and subtracting Mt^n gives the two bounds, the upper one in the extended real sense. In dimension two, L^1 convergence of v_k to v gives $c_1(v) = \int_X v \mathrm{dd}^c \omega$, which proves the formula on surfaces. $\square$

Corollary 15.6.16 *On a connected compact complex surface with Hermitian form ω , fix the preceding cutoff and $0 < t < 1/C$. The non-pluripolar mass is constant on the ordinary type of $u = tH$ if and only if ω is Gauduchon. More precisely, for every smooth real f and every sufficiently small real ε ,*

$$\int_X \mathrm{MA}_\omega(u + \varepsilon f) - \int_X \mathrm{MA}_\omega(u) = 2\varepsilon \int_X f \mathrm{dd}^c \omega.$$

Proof By the current inequality $\omega + \mathrm{dd}^c u \geq (1 - Ct)\omega$, the potential $u + \varepsilon f$ is ω -plurisubharmonic for both signs of ε , provided $|\varepsilon|$ is small: choose $c_f > 0$ with $-c_f \omega \leq \mathrm{dd}^c f \leq c_f \omega$ and take $|\varepsilon| < (1 - Ct)/c_f$. These potentials differ boundedly from u , so [Proposition 15.6.26](#) gives the stated difference.

If $\mathrm{dd}^c \omega = 0$, the same proposition gives mass $A - Mt^2$ for every potential ordinarily equivalent to u . Conversely, write $\mathrm{dd}^c \omega = \rho \omega^2$ with ρ smooth and real. If this form is not zero, choose $f = \rho$. Then $\int_X f \mathrm{dd}^c \omega = \int_X \rho^2 \omega^2 > 0$, so the masses of the smooth perturbations above vary. Thus constancy of the mass forces $\mathrm{dd}^c \omega = 0$, which is the Gauduchon condition on a surface. $\square$

When the background has both the bounded mass property and positive lower mass, the bounds in [Proposition 15.6.26](#) still give a definite volume gap between these models and zero. This extends the obstruction for first polar currents beyond backgrounds with invariant mass.

Proposition 15.6.27 *Let X be a connected compact complex manifold of dimension $n \geq 2$, with a Hermitian form ω satisfying*

$$0 < v_-(\omega) \leq v_+(\omega) < +\infty.$$

Fix H, C, M from Proposition 15.6.25. For $0 < t < 1/C$ with $Mt^n < v_-(\omega)$, the normalized ordinary model $p_t = P_\omega[tH]$ satisfies

$$\begin{aligned} 0 < v_-(\omega) - Mt^n &\leq \underline{\text{vol}}_\omega(p_t) \leq \overline{\text{vol}}_\omega(p_t) \\ &\leq v_+(\omega) - Mt^n. \end{aligned}$$

Its first polar currents vanish on every smooth modification, all its multiplier ideals are trivial, and

$$d_\omega(p_t, 0) \geq Mt^n > 0, \quad \delta_\omega^{\text{pol}}(p_t, 0) = 0$$

for every family of modifications and every choice of Gauduchon forms. Thus p_t is not an ideal model, and it belongs to the closure of the analytic models for the polar comparison. For any $0 < \delta < v_-(\omega)$, all sufficiently small positive parameters give $p_t, 0 \in \mathcal{M}_\delta(\omega)$.

In particular, these conclusions apply to every Hermitian form on every connected compact complex surface.

Proof Taking the infimum and the supremum in Proposition 15.6.26 gives the bounds for the singularity volumes of tH . The lower volume is positive, so by Theorem 29.3.2 ordinary projection preserves both volumes. Since $tH \leq p_t \leq 0$ and $\sup_X tH = 0$, the model is normalized.

The type of zero consists of the bounded potentials, so its upper volume is $v_+(\omega)$. Since $p_t \leq 0$, (29.6) gives $d_\omega(p_t, 0) = v_+(\omega) - \overline{\text{vol}}_\omega(p_t) \geq Mt^n$. In particular $p_t \neq 0$.

The part of the proof of Proposition 15.6.24 that uses supports and Lelong numbers applies to this model: its pole set lies in S , its polar restriction is closed and positive, and every exceptional divisor whose image lies in S maps to a point. Since the curve potential g has zero Lelong numbers, every divisorial coefficient vanishes. The lower bound $p_t \geq tH$ and Skoda's integrability theorem give trivial multiplier ideals at all weights. Hence the ideal envelope of p_t is the zero model, while $p_t \neq 0$. All first polar comparisons with zero vanish, which proves that p_t is not an ideal model and lies in the closure of the analytic models.

Given $0 < \delta < v_-(\omega)$, choose $t_0 < 1/C$ with $Mt_0^n < v_-(\omega) - \delta$. The lower bound for the volume then puts zero and every p_t with $0 < t \leq t_0$ in $\mathcal{M}_\delta(\omega)$.

On a compact complex surface, a Gauduchon form has finite upper mass by Theorems 2.2.2 and 4.1.1. By the metric independence in Proposition 6.5.1, every Hermitian form then has finite upper mass, and Corollary 25.17.1 gives positive lower mass. $\square$

The residual measure distinguishes the parameters of the family p_t even after ordinary projection. Volume addition controls the volumes over the whole range

$0 < t < 1/C$, so the ordered family is still a complete interval in a general Hermitian background, where the terms $c_j(v)$ of [Proposition 15.6.26](#) need not vanish.

Corollary 15.6.17 *Assume $0 < v_-(\omega) \leq v_+(\omega) < +\infty$, as in [Proposition 15.6.27](#), and fix $0 < t_0 < 1/C$. Set $p_t = P_\omega[tH]$ for $0 < t \leq t_0$, define $p_0 = 0$ separately, and write*

$$L(t) = \underline{\text{vol}}_\omega(p_t), \quad U(t) = \overline{\text{vol}}_\omega(p_t).$$

For $0 \leq t \leq t_0$,

$$(1 - Ct)^n v_-(\omega) \leq L(t) \leq U(t) \leq v_+(\omega) - Mt^n.$$

The models are pairwise distinct, and $p_s \geq p_t$ for $s \leq t$. For either $V = L$ or $V = U$, and $0 \leq s < t \leq t_0$,

$$\left(\frac{1 - Ct}{1 - Cs} \right)^n V(s) \leq V(t) \leq V(s).$$

Consequently

$$d_\omega(p_s, p_t) = |U(s) - U(t)| \leq \frac{nCv_+(\omega)}{1 - Ct_0} |s - t|, \quad \delta_\omega^{\text{pol}}(p_s, p_t) = 0.$$

With the restriction of d_ω , the family is a complete ordered interval, isometric to $[0, v_+(\omega) - U(t_0)]$. Every model with positive parameter is not an ideal model and has trivial multiplier ideals. For any $0 < \delta < v_-(\omega)$, t_0 can be chosen so that the whole interval lies in $\mathcal{M}_\delta(\omega)$.

Proof Put $u_t = tH$ for $t > 0$ and $u_0 = 0$. For $0 < t < 1/C$, the potential u_t is $Ct\omega$ -plurisubharmonic. Adding it to the zero potential in the background $(1 - Ct)\omega$, [Proposition 29.1.1](#) and homogeneity show that either singularity volume of u_t is at least $(1 - Ct)^n$ times the corresponding volume of zero. In particular, the lower volume of u_t is positive on the whole range $0 < t < 1/C$, and ordinary projection preserves both volumes by [Theorem 29.3.2](#). The upper bound follows from [Proposition 15.6.26](#), and the zero endpoint has $L(0) = v_-(\omega)$ and $U(0) = v_+(\omega)$.

Near S , one has $u_t = th$. After a fixed smooth local correction, invariance of residual measures and [Lemma 15.6.7](#) show that u_t has residual measure of mass Mt^n , and by [Theorem 29.3.3](#) so does p_t . Zero has residual measure zero, since its corrected top-degree measure is smooth. Thus two models of the family coincide only if their parameters are equal.

For $s < t$, set $c = (1 - Ct)/(1 - Cs)$. Then $0 < c < 1$ and

$$u_t = cu_s + (t - cs)H, \quad C(t - cs) = 1 - c.$$

The second summand is $(1 - c)\omega$ -plurisubharmonic. Addition and homogeneity give $V(t) \geq c^n V(s)$, whereas monotonicity gives $V(t) \leq V(s)$. The same computation holds for $s = 0$, with the separately defined zero potential. Monotonicity of the envelope gives $p_s \geq p_t$, so [\(29.6\)](#) gives $d_\omega(p_s, p_t) = U(s) - U(t)$. Since $U(s) \leq v_+(\omega)$, the Lipschitz bound follows from

$$1 - c^n \leq n(1 - c) = \frac{nC(t - s)}{1 - Cs} \leq \frac{nC(t - s)}{1 - Ct_0}.$$

By this bound, U is continuous. Distinct ordinary models of positive lower volume are separated by [Proposition 29.6.1](#), so U is strictly decreasing. Thus $t \mapsto v_+(\omega) - U(t)$ identifies the family isometrically with the closed interval in the statement, which proves completeness.

The support and Lelong-number argument in the proof of [Proposition 15.6.24](#) applies on the whole range $0 < t < 1/C$: all first polar currents vanish and all multiplier ideals are trivial. The deficit Mt^n of the upper volume separates every positive parameter from zero, which proves that the models with positive parameter are not ideal models and that their polar comparisons vanish. Finally, choose $t_0 < 1/C$ with $(1 - Ct_0)^n v_-(\omega) > \delta$ to place the whole interval in $\mathcal{M}_\delta(\omega)$. $\square$

The residual measure distinguishes the parameters of one ordered family, but its total mass alone cannot distinguish poles placed in different regions. Cutoffs with disjoint supports give a pair whose maximum is exactly zero, so that the volume comparison remains explicit.

Proposition 15.6.28 *Let ω be a Hermitian form on a connected compact complex manifold X of dimension $n \geq 2$, with $0 < v_-(\omega) \leq v_+(\omega) < +\infty$. Fix $0 < \delta < v_-(\omega)$. For every sufficiently small $r > 0$, there are distinct normalized ordinary models $p_1, p_2 \in \mathcal{M}_\delta(\omega)$ and disjoint compact sets S_1, S_2 of Hausdorff dimension zero such that the full Monge–Ampère measures Φ_{p_i} of [Theorem 29.3.3](#), the weak limits of the Monge–Ampère measures of the bounded truncations, satisfy*

$$R_i := \mathbf{1}_{S_1 \cup S_2} \Phi_{p_i}, \quad R_i(X) = r, \quad \text{supp } R_i \subset S_i.$$

Both models are not ideal models, all their multiplier ideals are trivial, and their first polar currents vanish on every smooth modification. Moreover,

$$\max(p_1, p_2) = 0, \quad d_\omega(p_1, p_2) \geq 2r, \quad \delta_\omega^{\text{pol}}(p_1, p_2) = 0.$$

If $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$, both singularity volumes of both models equal $A - r$, where $A = \int_X \omega^n$, and their distance is exactly $2r$. Thus the first polar currents together with the total residual mass do not separate ordinary models, and when $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$, they still do not separate them after both singularity volumes are added.

Proof Choose two disjoint coordinate polydisks, and in each apply the construction of [Proposition 15.6.25](#), obtaining a cutoff H_i with pole set S_i , curvature constant $C_i > 0$ and truncation mass $M_i > 0$. For small $r > 0$ put

$$t_i = (r/M_i)^{1/n}, \quad u_i = t_i H_i, \quad p_i = P_\omega[u_i].$$

Choose r so small that $C_i t_i < 1$ and $(1 - C_i t_i)^n v_-(\omega) > \delta$ for both i . By [Corollary 15.6.17](#), the p_i are normalized ordinary models in $\mathcal{M}_\delta(\omega)$; they are not ideal

models, their multiplier ideals are trivial and their first polar currents vanish. Their upper volumes U_i satisfy $U_i \leq v_+(\omega) - r$.

The full top-degree product of h in the i th chart is a positive measure ρ_i supported on S_i , of mass M_i . Near S_i one has $u_i = t_i h$, so invariance of residual measures under bounded changes and [Theorem 29.3.3](#) give $\mathbf{1}_{S_i} \Phi_{p_i} = t_i^n \rho_i$, extended by zero outside that chart. Outside the compact support of H_i , the bounds $u_i \leq p_i \leq 0$ force $p_i = 0$. In particular p_i is smooth near S_j for $j \neq i$, and its full measure there is ω^n , which gives S_j zero mass. Hence $R_i = t_i^n \rho_i$. These measures have the same total mass $r > 0$ and disjoint supports, so they differ.

Since the cutoffs have disjoint supports, at every point at least one p_i vanishes, and both are nonpositive; this proves $\max(p_1, p_2) = 0$. By [Definition 29.6.1](#),

$$d_\omega(p_1, p_2) = 2v_+(\omega) - U_1 - U_2 \geq 2r.$$

All first polar coordinates of both models are zero, so their polar comparison vanishes. When $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$, [Corollary 15.6.15](#) gives both volumes equal to $A - M_i t_i^n = A - r$, and $v_+(\omega) = A$. Substituting these values gives the exact distance $2r$ and the final assertion. $\square$

Knowing the location and the size of the whole residual measure still does not determine the model. For anisotropic maxima on the same pole set, the residual measure depends only on the product of the weights, whereas the volume of the maximum of two such potentials detects the individual weights. On a compact box of positive weights, this comparison has an explicit metric interpretation.

Proposition 15.6.29 *Let ω be a Hermitian form on a connected compact complex manifold X of dimension $n \geq 2$, with $\text{dd}^c(\omega^q) = 0$ for $1 \leq q < n$. Put $A = \int_X \omega^n$, fix $0 < \delta < A$ and $0 < \alpha < \beta$, and write $B = [\alpha, \beta]^n$. There are a compact set $S \subset X$ of Hausdorff dimension zero, a nonatomic probability measure ρ supported on S , and $t_0 > 0$ with the following properties. For each fixed $0 < t \leq t_0$, normalized ordinary models $p_a \in \mathcal{M}_\delta(\omega)$ are defined for all $a \in B$ and satisfy*

$$\mathbf{1}_S \Phi_{p_a} = t^n \left(\prod_j a_j \right) \rho, \quad \underline{\text{vol}}_\omega(p_a) = \overline{\text{vol}}_\omega(p_a) = A - t^n \prod_j a_j.$$

For $a, b \in B$, set $c_j = \min(a_j, b_j)$. Then

$$d_\omega(p_a, p_b) = t^n \left(\prod_j a_j + \prod_j b_j - 2 \prod_j c_j \right).$$

The restriction of d_ω to this family is a metric, and

$$t^n \alpha^{n-1} \max_j |a_j - b_j| \leq d_\omega(p_a, p_b) \leq t^n \beta^{n-1} \sum_j |a_j - b_j|.$$

Thus $a \mapsto p_a$ identifies B homeomorphically with a compact complete metric space. Every model in the family is not an ideal model, all its multiplier ideals are trivial, and its first polar currents vanish on every smooth modification. For $\alpha^n < P < \beta^n$, the subfamily defined by $\prod_j a_j = P$ is complete and homeomorphic to a convex polytope of real dimension $n - 1$. Throughout this subfamily, the residual measure on S is $Pt^n\rho$ and both singularity volumes are $A - Pt^n$. Hence these data, even together with all multiplier ideals and the first polar currents on all modifications, do not separate ordinary models.

Proof Place the polydisk D of [Lemma 15.6.8](#) in a coordinate chart, and use one cutoff function $0 \leq \chi \leq 1$, compactly supported there and equal to one near $S = K^n$. For $a \in B$, extend $H_a = \chi h_a$ by zero and put $u_a = tH_a$. We first prove a curvature bound that is uniform in a .

Choose a compact neighborhood Σ of the supports of the derivatives of χ , disjoint from S . The isotropic maximum $\max_j g(z_j)$ is bounded below on Σ by $-B_0$, for some $B_0 > 0$. Since $g \leq 0$ and $a_j \leq \beta$, it follows that $-\beta B_0 \leq h_a \leq 0$ there. If the j th branch $a_j g(z_j)$ attains the maximum, then $a_j g(z_j) \geq -\beta B_0$, so $g(z_j) \geq -\beta B_0/\alpha$. Within the fixed compact range of the coordinates, this sublevel set stays away from K , and g and its gradient are bounded on a neighborhood of it. Thus all maximizing branches have uniformly bounded gradients, and the maxima h_a satisfy one local Lipschitz bound on Σ , independent of $a \in B$.

In the distributional product rule for $\text{dd}^c(\chi h_a)$, the term $\chi \text{dd}^c h_a$ is positive. The remaining terms contain derivatives of χ together with h_a or its first derivatives, so the preceding bounds control their coefficients uniformly. The cutoff argument of [Proposition 15.6.25](#) therefore gives one $C > 0$ with $\text{dd}^c H_a \geq -C\omega$ for every $a \in B$. Choose $t_0 < 1/C$ with $t_0^n \beta^n < A - \delta$. Then all u_a , $0 < t \leq t_0$, are normalized and satisfy $\omega + \text{dd}^c u_a \geq (1 - Ct)\omega$.

By [Theorem 2.2.2](#), all bounded ω -plurisubharmonic functions have mass A , so $v_-(\omega) = v_+(\omega) = A$. For any $v \sim u_a$, the global limit of the measures of the truncations has total mass A , as in the proof of [Corollary 15.6.15](#). Near S , the difference between v plus a smooth local correction and th_a is bounded. By [Lemmas 1.6.5](#) and [15.6.8](#), the residual measure of v is

$$t^n \left(\prod_j a_j \right) \rho, \quad \rho = \sigma^{\otimes n},$$

extended by zero from the chart. Every corrected closed power of lower degree gives S zero coefficient mass, so this is also the restriction to S of the global limit of the truncations. Off S that limit equals the non-pluripolar measure, which proves that every such representative has mass

$$V(u_a) = A - t^n \prod_j a_j > \delta.$$

Hence, by [Theorem 29.3.2](#), ordinary projection preserves both singularity volumes, and by [Theorem 29.3.3](#) it preserves the residual measure. Setting $p_a = P_\omega[u_a]$

proves the formulas for the residual measure and the volumes simultaneously for all $a \in B$.

For $a, b \in B$ and $c_j = \min(a_j, b_j)$, positivity of the weights and $g \leq 0$ give, pointwise and also at the poles,

$$\max(h_a, h_b) = h_c, \quad \max(u_a, u_b) = u_c.$$

The invariance of the comparison under ordinary projection in [Proposition 29.6.1](#) and the definition of the comparison give

$$\begin{aligned} d_\omega(p_a, p_b) &= d_\omega(u_a, u_b) \\ &= t^n \left(\prod_j a_j + \prod_j b_j - 2 \prod_j c_j \right). \end{aligned}$$

For the boxes $R_a = \prod_j [0, a_j] \subset \mathbb{R}^n$ and Lebesgue measure λ , the last expression is $t^n \lambda(R_a \triangle R_b)$, since $R_a \cap R_b = R_c$; equivalently, it is $t^n \|\mathbf{1}_{R_a} - \mathbf{1}_{R_b}\|_{L^1(\lambda)}$. This proves the triangle inequality within the family. A slab in the coordinate where $|a_j - b_j|$ is largest, with every other coordinate in $[0, \alpha]$, lies in the symmetric difference up to its boundary, and its volume gives the lower bound. The symmetric difference is covered by the n coordinate slabs between a_j and b_j , with every other coordinate in $[0, \beta]$, and their total volume gives the upper bound. In particular, the distance separates the parameters, and the two estimates show that it induces the Euclidean topology of B . A sequence that is Cauchy for the distance has Cauchy weights in the Euclidean sense, whose limit lies in B , and the upper bound gives convergence for the distance. Compactness follows from the same bounds.

The support and Lelong-number argument in the proof of [Proposition 15.6.24](#) applies for every positive weight vector. Every exceptional divisor mapping into S maps to a point, and comparison with $ta_1 g(z_1 \circ \pi)$ shows that the generic Lelong number along it is zero. Thus every first polar current is zero. The same comparison gives zero Lelong numbers at all points and trivial multiplier ideals at all weights. The strict volume deficit $t^n \prod_j a_j$ shows that $p_a \neq 0$, whereas the ideal envelope of p_a is zero, so p_a is not an ideal model.

Finally, the constraint $\prod_j a_j = P$ defines a closed subset of B , so the subfamily is complete. Taking logarithms coordinatewise identifies it with

$$[\log \alpha, \log \beta]^n \cap \left\{ x \in \mathbb{R}^n : \sum_j x_j = \log P \right\}.$$

For $\alpha^n < P < \beta^n$, this convex polytope meets the interior of the cube at the point with $x_j = (\log P)/n$ for all j , and it has dimension $n - 1$. The formulas for the volume and the residual measure are constant on it, while the distance separates its members. For example, taking $\alpha = 1/2$, $\beta = 2$, $P = 1$, $a = (2, 1/2, 1, \dots, 1)$ and $b = (1, 1, 1, \dots, 1)$ gives two models with common residual measure $t^n \rho$, both volumes equal to $A - t^n$, and distance t^n . $\square$

Finally, even the full residual measure on the pole set can miss anisotropy. In **Proposition 15.6.29**, distinct ordinary models of positive volume have the same residual measure, the same singularity volumes, the same multiplier ideals and the same first polar currents on every modification, while their volume comparison is positive. A general extension must therefore record more than these data.

Problem 15.6.1 Extend the complete topology of **Theorem 29.11.1** to ordinary models of zero lower volume and to backgrounds without bounded mass, in such a way that the closure of the analytic models is exactly the locus of ideal models. The extension should recover the curve topology of **Corollary 29.12.1** and the background compatibility of **Sections 29.9** and **29.10**, including higher-dimensional limits that lose bigness or positive lower volume.

Part IV
Interpolation and restriction

Chapter 16

Perron interpolation and the geodesic equation

Let X be a connected compact complex manifold of dimension $n \geq 1$, and let θ be a smooth real $(1, 1)$ -form. Fix a smooth positive volume form dV for the $L^1(X)$ topology.

This part studies two operations on singular potentials: interpolation between two potentials along an auxiliary real parameter, and restriction to a complex submanifold. A one-parameter family of θ -plurisubharmonic functions can be regarded as a single function on the product of X with a strip in $\mathbb{C}$, and positivity of its curvature current on the product is a convexity condition in the parameter. The largest such family with prescribed endpoints, the Perron envelope, interpolates between two potentials; in Kähler geometry it gives the weak geodesics of the space of potentials. A Legendre transform in the parameter relates rays made of Perron segments to concave decreasing families of envelope fixed points, the test curves of [Chapter 17](#). Restriction behaves differently: the restriction of a potential to a submanifold can acquire poles that are invisible to its multiplier ideals, and [Chapter 18](#) works instead with the information carried by the restricted multiplier ideals. All these constructions use only positivity of currents, so they apply to nonclosed backgrounds.

In Kähler geometry, the smooth geodesic equation for the Mabuchi L^2 metric on potentials is a homogeneous Monge–Ampère equation on such a product. Positivity on the product still defines Perron interpolation for a nonclosed background, but the two constructions can now differ: integration by parts in the L^2 action produces torsion terms. Even a smooth Perron segment given by translation by constants can fail to be stationary for that action.

The Perron construction itself rests on convexity and barriers. Convexity in the parameter bounds every admissible path by the chord between its endpoints, while a lower barrier ensures that the envelope attains the endpoints. For two potentials of the same ordinary singularity type, two affine barriers suffice and give a Lipschitz bound in the parameter. Maximality on each finite subinterval is the property that links Perron segments with Legendre duality in [Chapter 17](#).

16.1 Subgeodesics and endpoint bounds

As in [Lemma 1.20.1](#), for a nonempty open interval $I \subset \mathbb{R}$ write

$$S_I = \{z \in \mathbb{C} : \operatorname{Re} z \in I\}, \quad \pi : X \times S_I \longrightarrow X,$$

where π is the projection. A family $u_t \in \operatorname{PSH}(X, \theta)$, $t \in I$, is a *subgeodesic* if its complexification $U(x, z) = u_{\operatorname{Re} z}(x)$ is quasi-plurisubharmonic and satisfies $\pi^*\theta + \operatorname{dd}^c U \geq 0$ on $X \times S_I$. For finite $a < b$ and $u_a, u_b \in \operatorname{PSH}(X, \theta)$, a subgeodesic on (a, b) runs from u_a to u_b if $u_t \rightarrow u_a$ in $L^1(X)$ as $t \downarrow a$ and $u_t \rightarrow u_b$ as $t \uparrow b$.

The elementary operations below produce lower barriers. Convexity in t , given by [Lemma 1.20.1](#), and the minimum principle of [Section 1.20](#) then give the continuity and upper bounds needed for the Perron envelope.

Proposition 16.1.1 *Subgeodesics are preserved by adding an affine function of t , by a positive affine reparametrization of time, by finite maxima, and by convex combinations. For $h \in C^\infty(X, \mathbb{R})$, replacing θ by $\theta + \operatorname{dd}^c h$ and u_t by $u_t - h$ also preserves them.*

Proof Affine functions of $\operatorname{Re} z$ have zero complex Hessian, and a positive affine change of time is induced by a holomorphic affine change of the strip coordinate. Convex combinations preserve the inequality between currents, and the change $(\theta, u_t) \mapsto (\theta + \operatorname{dd}^c h, u_t - h)$ preserves the current itself. Maxima are covered by [Lemma 1.3.1](#). $\square$

Proposition 16.1.2 *A subgeodesic is continuous in $L^1(X)$ on the interior of its parameter interval. If the interval is (a, b) with $a < b$ finite, and the subgeodesic runs from u_a to u_b , where $u_a, u_b \in \operatorname{PSH}(X, \theta)$, then*

$$u_t \leq \frac{b-t}{b-a}u_a + \frac{t-a}{b-a}u_b, \quad a < t < b. \quad (16.1)$$

Moreover, the following upper limits, taken jointly in space and time, hold at the endpoints:

$$\limsup_{\substack{y \rightarrow x \\ t \downarrow a}} u_t(y) \leq u_a(x), \quad \limsup_{\substack{y \rightarrow x \\ t \uparrow b}} u_t(y) \leq u_b(x).$$

Proof For a compact interval $J \Subset I$, choose $a' < \inf J \leq \sup J < b'$ in I . By [Lemma 1.20.1](#), the path lies below the chord through $u_{a'}$ and $u_{b'}$, hence below a constant on J , and by [Proposition 1.20.1](#) the function $\inf_{a' < t < b'} u_t$ is an integrable lower bound. For almost every x , the function $t \mapsto u_t(x)$ is finite and convex, hence continuous, and dominated convergence proves continuity in L^1 on J .

For the chord bound, choose sequences of times tending to a and b along which the assumed L^1 convergence holds almost everywhere. Applying convexity between these times and passing to the limit proves (16.1) almost everywhere in x , for each t , and hence everywhere by [Lemma 1.3.3](#).

For the joint upper limit at a , note that in (16.1) the coefficient of u_a tends to one, while the term involving u_b has a vanishing coefficient and a uniform upper bound.

Upper semicontinuity of u_a gives the assertion when $u_a(x)$ is finite. At a pole of u_a , bound u_a near x above by an arbitrary real number, take the joint upper limit, and let that number tend to $-\infty$. The argument at b is the same. $\square$

16.2 Perron segments

The chord bound survives taking a regularized supremum, and a single competitor attaining the endpoints bounds that supremum from below and forces the same endpoint limits. Fix $u_0, u_1 \in \text{PSH}(X, \theta)$ and call a subgeodesic on $(0, 1)$ *admissible* if its joint upper limits at $t = 0$ and $t = 1$, in the sense of [Proposition 16.1.2](#), are at most u_0 and u_1 , respectively. Define the *Perron envelope*

$$U = (\sup\{V : V \text{ is an admissible complexification}\})^*,$$

where the upper semicontinuous regularization is taken on $X \times S_{(0,1)}$, and denote the slices of U by u_t^P . When these slices form a subgeodesic running from u_0 to u_1 , they define the *Perron segment* from u_0 to u_1 , and we set $u_0^P = u_0$ and $u_1^P = u_1$. An affine change of parameter gives the same construction on any finite interval.

Proposition 16.2.1 *If an admissible subgeodesic exists, the Perron envelope is the largest admissible subgeodesic. If some admissible subgeodesic runs from u_0 to u_1 , so does the envelope, which is then the Perron segment. In that case, for every $[a, b] \subset [0, 1]$ with $a < b$, its restriction to $[a, b]$ is the Perron segment between u_a^P and u_b^P .*

Proof Convexity in t and the upper limits at the endpoints bound every competitor by $(1-t)u_0 + tu_1$. This bound is jointly upper semicontinuous on the interior and locally bounded above, so it persists after regularization. The local envelope theorem of [Section 1.19](#) shows that U is quasi-plurisubharmonic with $\pi^*\theta + \text{dd}^c U \geq 0$, and U is still independent of $\Im z$. Since it dominates an admissible competitor, each slice belongs to $\text{PSH}(X, \theta)$. The chord bound gives the joint upper limits at the endpoints, by the argument at the end of the proof of [Proposition 16.1.2](#). The envelope therefore belongs to its defining family and is its largest member.

If a competitor w_t runs from u_0 to u_1 , then

$$w_t \leq u_t^P \leq (1-t)u_0 + tu_1.$$

In particular, almost everywhere,

$$|u_t^P - u_0| \leq |w_t - u_0| + t|u_1 - u_0|,$$

which proves $u_t^P \rightarrow u_0$ in L^1 as $t \downarrow 0$. The argument at $t = 1$ is the same.

For $0 \leq a < b \leq 1$, let v_t be the Perron envelope on (a, b) between u_a^P and u_b^P . The original path restricted to (a, b) runs between these endpoints and is admissible

by **Proposition 16.1.2**. Thus v_t also runs between them and dominates u_t^P . The joint upper limits of v_t at a and b allow us to glue its complexification to U outside the smaller strip, by **Lemma 1.3.2**; if $a = 0$ or $b = 1$, the same upper limits show that the glued family is still admissible for u_0, u_1 . The resulting competitor cannot exceed U , which proves $v_t = u_t^P$ on (a, b) . $\square$

When the endpoints differ by a bounded function, an explicit lower barrier is available.

Theorem 16.2.1 *Suppose that $u_0 \sim u_1$, and choose $C \geq 0$ with $u_0 - C \leq u_1 \leq u_0 + C$. Then the Perron segment from u_0 to u_1 exists, every slice has the ordinary singularity type of u_0 and u_1 , and*

$$u_0 - Ct \leq u_t^P \leq u_0 + Ct, \quad u_1 - C(1-t) \leq u_t^P \leq u_1 + C(1-t).$$

Moreover, away from the common pole set,

$$|u_t^P - u_s^P| \leq C|t - s|, \quad 0 \leq s, t \leq 1.$$

Proof Consider the barrier

$$w_t = \max\{u_0 - Ct, u_1 - C(1-t)\}.$$

It is a subgeodesic by **Proposition 16.1.1**, and the bounded difference gives $w_0 = u_0$ and $w_1 = u_1$. Upper semicontinuity gives the joint upper limits at the endpoints. Off the common poles, $|w_t - u_0| \leq Ct$ and $|w_t - u_1| \leq C(1-t)$, so w_t runs from u_0 to u_1 , and **Proposition 16.2.1** applies.

The lower bounds follow from $w_t \leq u_t^P$, and the upper bounds from the chord estimate; together they give the asserted singularity type. Off the common poles, put $f(t) = u_t^P(x)$. For $0 < s < t < 1$, monotonicity of the slopes of secants of the convex function f gives

$$-C \leq \frac{f(s) - f(0)}{s} \leq \frac{f(t) - f(s)}{t - s} \leq \frac{f(1) - f(t)}{1 - t} \leq C.$$

The two-sided estimates at the endpoints cover the cases $s = 0$ and $t = 1$, which proves the Lipschitz bound on $[0, 1]$. $\square$

For endpoints of different types, a common lower potential still gives an admissible constant path, so the envelope exists. Attaining the endpoints requires a barrier approaching the prescribed values; **Proposition 16.2.1** separates this requirement from the existence of the envelope.

16.3 The smooth product equation

For a smooth path, positivity on the product compares the acceleration with the spatial gradient of the velocity. Let u_t be smooth in $(x, t) \in X \times I$, suppose that $\eta_t = \theta + dd^c u_t > 0$, and write, in local holomorphic coordinates $(x_1, \dots, x_n)$,

$$\theta = \frac{i}{2\pi} \sum_{i,j=1}^n g_{i\bar{j}} dx_i \wedge d\bar{x}_j, \quad H = (g_{i\bar{j}} + \partial_i \partial_{\bar{j}} u), \quad \xi = (\partial_i \dot{u})_{i=1}^n.$$

Here dots denote derivatives in t , ξ is a column vector, and ξ^* is its conjugate transpose. Since $t = \operatorname{Re} z$, the form $\pi^* \theta + dd^c U$ on the product has, in the coordinates $(x_1, \dots, x_n, z)$, the coefficient matrix

$$\begin{pmatrix} H & \frac{1}{2}\xi \\ \frac{1}{2}\xi^* & \frac{1}{4}\ddot{u} \end{pmatrix}.$$

Proposition 16.3.1 *The form $\pi^* \theta + dd^c U$ is semipositive exactly when*

$$\ddot{u} \geq \xi^* H^{-1} \xi.$$

Its $(n+1)$ st power vanishes exactly when equality holds. Equivalently, the homogeneous Monge–Ampère equation on the product is

$$\ddot{u} \eta_t^n = n d\dot{u} \wedge d^c \dot{u} \wedge \eta_t^{n-1}. \quad (16.2)$$

Proof The Schur complement of H in the block matrix is $(\ddot{u} - \xi^* H^{-1} \xi)/4$. Since $H > 0$, the block matrix is semipositive exactly when this complement is nonnegative, and its determinant, which is $\det H$ times the complement, vanishes exactly when the complement vanishes.

To rewrite the equation in terms of forms, note that

$$d\dot{u} \wedge d^c \dot{u} = \frac{i}{2\pi} \partial \dot{u} \wedge \bar{\partial} \dot{u}, \quad n \frac{d\dot{u} \wedge d^c \dot{u} \wedge \eta_t^{n-1}}{\eta_t^n} = \operatorname{tr}(H^{-1} \xi \xi^*) = \xi^* H^{-1} \xi.$$

Multiplying the second identity by $\eta_t^n > 0$ gives (16.2). $\square$

This calculation identifies the homogeneous equation for smooth paths. Whether nonsmooth Perron segments solve a weak form of this equation is a separate question, which we do not address.

16.4 The L^2 action and torsion

The homogeneous equation on the product involves the spatial form η_t only pointwise. In the L^2 action, integration by parts also differentiates the powers of η_t , which produces terms absent from that equation. Fix a Hermitian form ω , write $\omega_u = \omega + \text{dd}^c u$, and recall from [Chapter 2](#) the space $\mathcal{H}_\omega$ of smooth real functions u with $\omega_u > 0$. On $\mathcal{H}_\omega$ consider the Riemannian metric

$$G_u(v, w) = \int_X v w \omega_u^n, \quad v, w \in C^\infty(X, \mathbb{R}).$$

For a smooth path $u_t \in \mathcal{H}_\omega$, $0 \leq t \leq 1$, its action is

$$\mathcal{S}(u) = \frac{1}{2} \int_0^1 \int_X \dot{u}_t^2 \omega_{u_t}^n dt.$$

Stationarity under smooth variations fixing both endpoints is the formal geodesic equation of this metric.

Theorem 16.4.1 *Let $u_t \in \mathcal{H}_\omega$, $0 \leq t \leq 1$, be a smooth path, and put $\eta_t = \omega_{u_t}$ and $T_t = \eta_t^{n-1}$. The path is stationary for $\mathcal{S}$ if and only if*

$$\begin{aligned} \ddot{u}_t \eta_t^n &= n \dot{u}_t \wedge \text{d}^c \dot{u}_t \wedge T_t \\ &\quad + n \dot{u}_t (\text{d} \dot{u}_t \wedge \text{d}^c T_t - \text{d}^c \dot{u}_t \wedge \text{d} T_t) + \frac{n}{2} \dot{u}_t^2 \text{dd}^c T_t. \end{aligned} \quad (16.3)$$

All differentials on the right act only in the X variable.

Proof Vary the path as $u_t + s v_t$, where v_t is smooth in (x, t) and $v_0 = v_1 = 0$, and put $f = \dot{u}_t$. Differentiating the action at $s = 0$, using $\partial_s (\omega_{u_t + s v_t}^n)|_{s=0} = n \text{dd}^c v_t \wedge T_t$, gives

$$\delta \mathcal{S} = \int_0^1 \left(\int_X f \dot{v}_t \eta_t^n + \frac{n}{2} \int_X f^2 \text{dd}^c v_t \wedge T_t \right) dt.$$

We integrate by parts in t in the first term, using $\partial_t (\eta_t^n) = n \text{dd}^c f \wedge T_t$, and on X in the second, using [Lemma 2.1.1](#) with the whole form $f^2 T_t$. Thus

$$\delta \mathcal{S} = \int_0^1 \int_X v_t \left(-\ddot{u}_t \eta_t^n - n f \text{dd}^c f \wedge T_t + \frac{n}{2} \text{dd}^c (f^2 T_t) \right) dt.$$

The product rule gives

$$\begin{aligned} \text{dd}^c (f^2 T_t) &= 2 f \text{dd}^c f \wedge T_t + 2 \text{d} f \wedge \text{d}^c f \wedge T_t \\ &\quad + 2 f (\text{d} f \wedge \text{d}^c T_t - \text{d}^c f \wedge \text{d} T_t) + f^2 \text{dd}^c T_t. \end{aligned}$$

After the term $n f \text{dd}^c f \wedge T_t$ cancels, the integrand is v_t times the difference between the right-hand and left-hand sides of [\(16.3\)](#). Since $\eta_t > 0$ on the compact set $X \times [0, 1]$,

every smooth v_t gives an admissible variation for small $|s|$, and the fundamental lemma of the calculus of variations gives both implications. $\square$

For a Kähler background, $dT_t = d^c T_t = 0$, and the equation reduces to (16.2). The Gauduchon condition $dd^c T_t = 0$ on η_t removes only the last term. Translations by constants isolate that term and give an exact test for stationarity.

Corollary 16.4.1 *Fix $u \in \mathcal{H}_\omega$ and a nonzero constant a . The path $u_t = u + at$, $0 \leq t \leq 1$, is a Perron segment and solves the homogeneous equation (16.2). It is stationary for the L^2 action if and only if*

$$dd^c(\omega_u^{n-1}) = 0.$$

For $n \geq 2$, this means that ω_u is a Gauduchon metric.

Proof The path is admissible and equals the chord between its endpoints, so by the chord bound no admissible competitor can be larger; it is therefore the Perron segment. Its acceleration and the spatial derivatives of its velocity vanish, which proves (16.2). In (16.3), the only remaining term is $\frac{n}{2}a^2 dd^c(\omega_u^{n-1})$, which vanishes exactly under the stated condition. $\square$

The three-dimensional torus in Example 4.7.1 carries a Gauduchon form ω and a smooth potential $u \in \mathcal{H}_\omega$ for which ω_u is not Gauduchon. Thus $u_t = u + t$ is a smooth Perron segment that is not stationary for the L^2 action. On a surface, the Gauduchon condition persists under perturbation of the potential by Proposition 4.7.2, but it does not cancel the terms in (16.3) involving first derivatives of T_t . We do not know how to relate Perron interpolation to a complete metric on singularity types in the Hermitian setting.

Chapter 17

Test curves and Legendre duality

Let X be a connected compact complex manifold of dimension $n \geq 1$, and let θ be a smooth real $(1, 1)$ -form. Fix $\varphi \in \text{PSH}(X, \theta)$ with $P_\theta[\varphi] = \varphi$, where $P_\theta[\cdot]$ is the ordinary singularity envelope of [Definition 1.19.1](#); thus $\varphi \leq 0$ and $\sup_X \varphi = 0$. A fixed smooth positive volume form defines the $L^1(X)$ topology.

Legendre duality in the parameter exchanges two maximality conditions: each member of a test curve is a fixed point of the singularity envelope, while every finite segment of the corresponding ray is a Perron segment in the sense of [Chapter 16](#). Replacing a finite segment of the ray by the Perron segment with the same endpoints changes each inverse transform only by a bounded amount, so the envelope condition forces Perron maximality. Conversely, comparison with affine paths built from obstacle envelopes shows that the inverse transforms of a ray of Perron segments are envelope fixed points. The argument uses only convexity, the minimum principle and the Perron construction, and therefore applies to nonclosed backgrounds as well as to Kähler forms.

The transforms are the pointwise Legendre transforms of [Section 1.20.1](#), and the proofs follow the envelope arguments for the Ross–Witt Nyström correspondence in [\[Xia\]](#).

17.1 Envelope test curves and rays

The members of a test curve become more singular as the parameter increases. The cutoff of the curve becomes the slope of the transformed ray, while its limit as the parameter tends to $-\infty$ gives the initial potential.

Definition 17.1.1 An *envelope test curve* with initial potential φ consists of a real number c and potentials $\Gamma_\tau \in \text{PSH}(X, \theta)$ for $\tau < c$ such that

- (1) $\tau \mapsto \Gamma_\tau$ is pointwise concave and decreasing;
- (2) $P_\theta[\Gamma_\tau] = \Gamma_\tau$ for every $\tau < c$;
- (3) $(\sup_{\tau < c} \Gamma_\tau)^* = \varphi$.

Its cutoff is c . We extend it by

$$\Gamma_c = \lim_{\tau \uparrow c} \Gamma_\tau, \quad \Gamma_\tau \equiv -\infty \quad (\tau > c).$$

Each Γ_τ is an envelope fixed point and hence has supremum zero, so [Theorem 1.4.1](#) and [Corollary 1.4.1](#) give $\Gamma_c \in \text{PSH}(X, \theta)$.

Definition 17.1.2 An *envelope ray* with initial potential φ and slope c is a subgeodesic $u_t, t > 0$, such that

- (1) $u_t \rightarrow \varphi$ in $L^1(X)$ as $t \downarrow 0$, and, with $u_0 = \varphi$, the restriction of the ray to every interval (a, b) with $0 \leq a < b < \infty$ is the Perron segment from u_a to u_b ;
- (2) $P_\theta[u_t] = \varphi$ for every $t > 0$;
- (3) $\sup_X u_t = ct$ for every $t > 0$.

For an envelope test curve, write U_t for its forward transform [\(1.38\)](#), the pointwise supremum of $\Gamma_\tau + t\tau$ over $\tau < c$. For a family $(u_t)_{t>0}$, write $\widehat{u}_t$ for its inverse transform [\(1.39\)](#), the pointwise infimum of $u_t - t\tau$ over $t > 0$. The forward transform is a subgeodesic by [Theorem 1.20.1](#); it remains to show that its finite segments are Perron segments.

17.2 Perron maximality

The slope and the singularity envelope of the transformed ray follow directly from the normalization of the test curve. To prove Perron maximality, we replace the transform on a finite interval by the Perron segment with the same endpoints. The estimate [\(17.1\)](#) keeps each inverse transform in its original ordinary singularity type, where the envelope condition forces equality.

Theorem 17.2.1 *The forward transform of an envelope test curve with cutoff c is an envelope ray with the same initial potential and slope c . Moreover, $U_t - ct$ decreases as t increases.*

Proof By [Theorem 1.20.1](#), U_t is a subgeodesic. The inequalities

$$\Gamma_\tau + t\tau \leq U_t \leq \varphi + ct$$

give $\sup_X U_t \geq t\tau$ for each $\tau < c$, since $\sup_X \Gamma_\tau = 0$, and $\sup_X U_t \leq ct$. Letting $\tau \uparrow c$ proves $\sup_X U_t = ct$. The formula

$$U_t - ct = \sup_{\tau < c} (\Gamma_\tau - t(c - \tau))$$

shows that $U_t - ct$ is decreasing in t .

Since $\Gamma_\tau \preceq U_t \preceq \varphi$, monotonicity of the singularity envelope gives

$$\Gamma_\tau = P_\theta[\Gamma_\tau] \leq P_\theta[U_t] \leq P_\theta[\varphi] = \varphi.$$

Taking the regularized supremum in τ proves $P_\theta[U_t] = \varphi$.

The local envelope theorem in [Section 1.19](#) gives $\sup_{\tau < c} \Gamma_\tau = \varphi$ almost everywhere, and at those points the bounds $\Gamma_\tau + t\tau \leq U_t \leq \varphi + ct$ imply $U_t \rightarrow \varphi$ as $t \downarrow 0$. For any fixed $\tau_0 < c$ and $0 < t \leq 1$, they also give

$$\Gamma_{\tau_0} - |\tau_0| \leq U_t \leq \varphi + |c|.$$

Both bounds are integrable, so dominated convergence gives $U_t \rightarrow \varphi$ in L^1 as $t \downarrow 0$.

It remains to prove Perron maximality. Fix $0 \leq a < b$ and replace U_t on (a, b) by the Perron segment from U_a to U_b , with $U_0 = \varphi$ when $a = 0$; it exists by [Proposition 16.2.1](#), because the restriction of U_t itself runs between these endpoints. The joint upper limits of the Perron segment at a and b allow gluing by [Lemma 1.3.2](#) and [Proposition 16.1.2](#). The resulting subgeodesic v_t dominates U_t and equals it outside (a, b) , where therefore $v_t \leq ct$. On (a, b) , the chord bound [\(16.1\)](#) together with $U_a \leq ca$ and $U_b \leq cb$ gives $v_t \leq ct$ as well.

For $\tau < c$, put $\chi_\tau = \inf_{t>0} (v_t - t\tau)$. Since $v_t - t\tau \geq U_t - t\tau \geq \Gamma_\tau$, [Proposition 1.20.1](#) gives $\chi_\tau \in \text{PSH}(X, \theta)$. We claim that

$$\Gamma_\tau \leq \chi_\tau \leq \Gamma_\tau + (b-a)(c-\tau). \quad (17.1)$$

The first inequality was just noted. For the second, let $s > 0$. If $s \in [a, b]$, then $v_b = U_b$, and since $U_t - ct$ is decreasing,

$$\chi_\tau \leq U_b - b\tau \leq U_s - s\tau + (b-s)(c-\tau).$$

If $s \notin [a, b]$, then $\chi_\tau \leq v_s - s\tau = U_s - s\tau$. In both cases $\chi_\tau \leq U_s - s\tau + (b-a)(c-\tau)$. Taking the infimum over $s > 0$ and using [Lemma 1.20.3](#) proves [\(17.1\)](#).

Moreover, $v_t \leq ct$ gives $\chi_\tau \leq t(c-\tau)$ for every $t > 0$, hence $\chi_\tau \leq 0$. By [\(17.1\)](#), χ_τ has the ordinary type of Γ_τ , so it is a competitor for $P_\theta[\Gamma_\tau] = \Gamma_\tau$. Thus $\chi_\tau = \Gamma_\tau$. Recovering v_t from its inverse transforms by [Lemma 1.20.2](#) gives $v_t = U_t$, which proves Perron maximality on every finite interval. $\square$

17.3 Recovering the singularity envelopes

The minimum principle shows that the inverse transforms are θ -plurisubharmonic, but their envelope property uses the whole ray. For an inverse transform g and $C > 0$, the envelope $P_\theta(g + C, 0)$ of the obstacle $\min(g + C, 0)$ gives an admissible affine path on every interval $[0, M]$, lying below the ray translated by an affine function of t . Letting the length M vary, and then letting the relative time t/M tend to zero, removes the additive constant C .

Theorem 17.3.1 *If u_t is an envelope ray of slope c with initial potential φ , its inverse transform is an envelope test curve with cutoff c and initial potential φ . The forward and inverse transforms are mutually inverse bijections between the envelope test*

curves of [Definition 17.1.1](#) and the envelope rays of [Definition 17.1.2](#) with initial potential φ .

Proof By [Lemma 1.20.1](#), for each x the function $t \mapsto u_t(x) - ct$ is either finite and convex or identically $-\infty$. It is bounded above by zero, so it is decreasing. Since $\sup_X(u_t - ct) = 0$, [Theorem 1.4.1](#) and [Corollary 1.4.1](#) give

$$\widehat{u}_c = \inf_{t>0} (u_t - ct) \in \text{PSH}(X, \theta).$$

For $\tau < c$, we have $\widehat{u}_c \leq \widehat{u}_\tau \leq u_1 - \tau$, so [Proposition 1.20.1](#) gives $\widehat{u}_\tau \in \text{PSH}(X, \theta)$. Also

$$\widehat{u}_\tau \leq \inf_{t>0} t(c - \tau) = 0 \quad (\tau \leq c),$$

while the bound $\widehat{u}_\tau \leq t(c - \tau)$ with $t \rightarrow \infty$ shows $\widehat{u}_\tau \equiv -\infty$ for $\tau > c$. Concavity and monotonicity in τ hold because $\widehat{u}_\tau$ is an infimum of affine functions of τ with negative slopes $-t$.

Fix $\tau < c$ and write $g = \widehat{u}_\tau$. The inequality $g \leq u_M - M\tau$, valid for every $M > 0$, gives

$$P_\theta[g] \leq P_\theta[u_M] = \varphi.$$

For $C > 0$ put $q_C = P_\theta(g + C, 0)$. Since $g \leq 0$, the function g is a competitor, so $q_C \not\equiv -\infty$, and

$$g \leq q_C \leq P_\theta[g] \leq \varphi, \quad q_C - C \leq g \leq u_M - M\tau.$$

The affine path $q_C - Ct/M$ is admissible for the endpoints φ and $u_M - M\tau$ on $[0, M]$. Adding $-t\tau$ gives a bijection between the competitor families for the endpoints φ, u_M and $\varphi, u_M - M\tau$, by [Proposition 16.1.1](#), so the Perron segment for the latter endpoints is $u_t - t\tau$. For $0 < s \leq 1$ this yields

$$q_C - Cs \leq u_{sM} - sM\tau.$$

Taking the infimum over $M > 0$ gives $q_C - Cs \leq g$, and letting $s \downarrow 0$ gives $q_C \leq g$. Thus $q_C = g$ for every $C > 0$, and letting $C \rightarrow \infty$ in the definition of $P_\theta[g]$ proves $P_\theta[g] = g$.

Let $\psi = (\sup_{\tau < c} \widehat{u}_\tau)^*$; since $\widehat{u}_\tau = P_\theta[\widehat{u}_\tau] \leq \varphi$, we have $\psi \leq \varphi$. Because $u_t - ct$ is decreasing in t , the limit of $u_t(x)$ as $t \downarrow 0$ exists at every x , and an almost everywhere convergent sequence given by the L^1 convergence $u_t \rightarrow \varphi$ identifies it with φ almost everywhere. At these points, the endpoint identity in [Lemma 1.20.2](#) gives

$$\sup_{\tau < c} \inf_{t>0} (u_t(x) - t\tau) = \varphi(x).$$

Therefore $\psi = \varphi$ by [Lemma 1.3.3](#).

As $\tau \uparrow c$, the transforms decrease to $\widehat{u}_c$, since the infima over $t > 0$ and over $\tau < c$ commute; this is the convention for the value at the cutoff. Finally, [Lemma 1.20.2](#) recovers u_t from its inverse transforms, also at points where $t \mapsto u_t(x)$ is identically

$-\infty$, and [Lemma 1.20.3](#) recovers each test curve from its forward transform. Hence the correspondence is a bijection. $\square$

17.4 A logarithmic pole on the projective line

Let $X = \mathbb{P}^1$ and $\varphi = 0$. The envelope of a multiple of a logarithmic pole is obtained by replacing part of a convex function by a tangent line. The corresponding ray is smooth, and all its slices are bounded; the pole appears only in the behavior of the ray as $t \rightarrow \infty$. In the affine coordinate z , take

$$\theta = \text{dd}^c \log(1 + |z|^2), \quad g(z) = \log \frac{|z|^2}{1 + |z|^2}.$$

The form θ extends to the Fubini–Study form of $\mathbb{P}^1$, which has integral one. The potential g is θ -plurisubharmonic, has a logarithmic pole at zero, and extends smoothly across infinity, with value zero there.

Put $H(\lambda) = -\lambda \log \lambda - (1 - \lambda) \log(1 - \lambda)$ for $0 < \lambda < 1$, with $H(0) = H(1) = 0$. For $0 < \lambda < 1$, define

$$\Gamma_\lambda(z) = \begin{cases} \lambda \log |z|^2 - \log(1 + |z|^2) + H(\lambda), & |z|^2 \leq \lambda/(1 - \lambda), \\ 0, & |z|^2 \geq \lambda/(1 - \lambda). \end{cases} \quad (17.2)$$

Set $\Gamma_\lambda = 0$ for $\lambda \leq 0$, $\Gamma_1 = g$, and $\Gamma_\lambda = -\infty$ for $\lambda > 1$.

Proposition 17.4.1 *The family (Γ_λ) is an envelope test curve with initial potential zero and cutoff one. Its forward transform is*

$$U_t(z) = \log \frac{1 + e^t |z|^2}{1 + |z|^2}, \quad t > 0. \quad (17.3)$$

At $z = 0$ its value is zero, and at infinity its value is t .

Proof Fix $0 < \lambda < 1$. For $s = \log |z|^2$, let $q_\lambda(s) = \Gamma_\lambda(z) + \log(1 + e^s)$. In the first region of (17.2) this is the affine function $\lambda s + H(\lambda)$, which is tangent to $\log(1 + e^s)$ at $s_\lambda = \log(\lambda/(1 - \lambda))$, and in the second region it is $\log(1 + e^s)$. Its derivative is continuous at the junction and nondecreasing, so q_λ is convex. By [Corollary 1.20.1](#), Γ_λ is θ -plurisubharmonic away from zero, and it extends across its logarithmic pole by [Lemma 1.3.7](#). It vanishes near infinity and has the ordinary type of λg .

To prove $\Gamma_\lambda = P_\theta[\lambda g]$, let $v \leq 0$ be a competitor with $v \preceq \lambda g$. On the punctured disk $0 < |z|^2 < \lambda/(1 - \lambda)$, the function

$$v - \Gamma_\lambda = v + \log(1 + |z|^2) - \lambda \log |z|^2 - H(\lambda)$$

is subharmonic, since $v + \log(1 + |z|^2)$ is subharmonic and $\log |z|^2$ is harmonic there. Since $v \preceq \lambda g$, this difference is bounded above near zero, so it extends

subharmonically across zero by [Lemma 1.3.7](#). Its upper limits at the boundary circle are at most zero, since $v \leq 0$ and $\Gamma_\lambda = 0$ there. The maximum principle gives $v \leq \Gamma_\lambda$ on the disk (at zero both have the value $-\infty$), and outside the disk the same inequality follows from $\Gamma_\lambda = 0$. Thus every competitor lies below Γ_λ , which is itself a competitor, so $\Gamma_\lambda = P_\theta[\lambda g]$. Since the envelope depends only on the ordinary type, also $P_\theta[\Gamma_\lambda] = \Gamma_\lambda$. The zero potential is an envelope fixed point as well.

For a fixed $0 < |z| < \infty$, put $p = |z|^2/(1 + |z|^2)$. The function $\lambda \mapsto \Gamma_\lambda(z)$ is zero for $\lambda \leq p$. For $p < \lambda < 1$ its derivative is

$$\log |z|^2 + \log \frac{1 - \lambda}{\lambda}.$$

It vanishes at $\lambda = p$ and decreases in λ , which proves that $\lambda \mapsto \Gamma_\lambda(z)$ is concave and decreasing. At $z = 0$, the function is zero for $\lambda \leq 0$ and $-\infty$ for $\lambda > 0$; at $z = \infty$, it is zero for $\lambda \leq 1$. These functions are concave and decreasing as well. Finally, $\sup_{\lambda < 1} \Gamma_\lambda = 0$, and the limit as $\lambda \uparrow 1$ is g , so the family is an envelope test curve with cutoff one.

For finite nonzero z and $t > 0$, the supremum defining $U_t(z)$ is attained at a parameter $\lambda > p$, namely at

$$\lambda = \frac{e^t |z|^2}{1 + e^t |z|^2},$$

and substituting this value into the first line of [\(17.2\)](#) gives [\(17.3\)](#). At $z = 0$, only the parameters $\lambda \leq 0$ give finite values, and the supremum is zero; at $z = \infty$, the supremum of $t\lambda$ over $\lambda < 1$ is t . In the coordinate $w = 1/z$, the formula reads $\log((|w|^2 + e^t)/(|w|^2 + 1))$, so the ray is smooth in both charts. $\square$

Each slice of this ray is bounded and has envelope zero, whereas its inverse transforms for $0 < \lambda \leq 1$ have logarithmic poles. At $z = 0$, the parameters $\lambda \leq 0$ determine the transform: omitting them would give the wrong value $U_t(0) = -\infty$.

Fig. 17.1 The explicit test curve and its ray, at points with $\log |z|^2 = -2$ (solid), 0 (dashed), and 2 (dotted). The parameter functions on the left are concave; their transforms on the right are convex.

Chapter 18

Restriction and intrinsic trace data

Let X be a connected compact complex manifold, let $Y \subset X$ be a connected compact complex submanifold of positive dimension, and fix a quasi-plurisubharmonic function $u \in \text{QPSH}(X)$ whose generic Lelong number along Y vanishes: $\nu(u, Y) = \inf_{y \in Y} \nu(u, y) = 0$.

Even when all multiplier ideals of u are trivial, its restriction to Y can have logarithmic poles. To keep only information determined by the multiplier ideals of u on X , we restrict the ideals themselves and take their asymptotic vanishing orders on modifications of Y . These orders form the divisorial trace data. Subadditivity of multiplier ideals and analytic approximation make the trace data additive under sums of potentials.

The next question is whether a potential on Y realizes these numbers. On a curve, they form an atomic measure, whose Green potential has exactly the prescribed Lelong numbers. In higher dimension, restricted analytic envelopes converge to the largest potential satisfying the trace inequalities, but Lelong semicontinuity gives only a lower bound for its divisorial Lelong numbers. When Y is Kähler, convergence in a sufficiently large closed background gives the reverse bound; pullback from a curve gives another exact realization, also for non-Kähler Y . The product examples at the end show that exact trace data still does not determine the Monge–Ampère mass.

Choose a smooth real $(1, 1)$ -form θ with $u \in \text{PSH}(X, \theta)$ and a Hermitian form ω on X . We use the analytic approximants u_m of [Corollary 1.15.1](#): they have analytic type $(1/m, \mathcal{I}(mu))$ in the sense of [Section 1.13](#) and satisfy $\theta + \text{dd}^c u_m \geq -\epsilon_m \omega$ with $\epsilon_m \downarrow 0$. By [Corollary 1.22.1](#), their restrictions to Y are quasi-plurisubharmonic, in particular not identically $-\infty$. As in [Chapter 6](#), MA^{ext} denotes the extended non-pluripolar Monge–Ampère measure, also written MA when its total mass is finite.

18.1 Restricted ideals and trace data

The restriction of a multiplier ideal to Y records the vanishing of its local generators along Y . Its vanishing order along a divisor on a modification of Y can grow with the weight, even when the ideal is generically trivial on Y .

For $t > 0$ put

$$\mathfrak{a}_t(u; Y) = \mathcal{I}(tu)\mathcal{O}_Y.$$

Here $\mathcal{I}(tu)\mathcal{O}_Y$ denotes the image of $\mathcal{I}(tu)$ under the restriction map $\mathcal{O}_X \rightarrow \mathcal{O}_Y$. This is a coherent ideal sheaf on Y , and it is nonzero: since $v(u, Y) = 0$, there is $y \in Y$ with $v(u, y) < 1/t$, and Skoda's integrability theorem gives $\mathcal{I}(tu)_y = \mathcal{O}_{X, y}$.

In this chapter, a *divisor over Y* is a prime divisor E on a connected smooth compact modification $\pi : Z \rightarrow Y$. For a nonzero coherent ideal $\mathfrak{a}$ on Y , let $\text{ord}_E(\mathfrak{a})$ be the generic vanishing order along E of the ideal generated by its pullback to Z ; it is a nonnegative integer.

Theorem 18.1.1 *For every divisor E over Y , the limit*

$$\tau_{Y, u}(E) := \lim_{t \rightarrow \infty} \frac{\text{ord}_E \mathfrak{a}_t(u; Y)}{t} = \sup_{t > 0} \frac{\text{ord}_E \mathfrak{a}_t(u; Y)}{t} \quad (18.1)$$

exists and is finite, and it equals the limit along positive integers. These numbers depend only on the multiplier-ideal equivalence class of u on X .

Proof Fix the modification $\pi : Z \rightarrow Y$ carrying E , and write $b(t) = \text{ord}_E \mathfrak{a}_t(u; Y)$ for $t > 0$. For $s, t > 0$, the subadditivity of multiplier ideals (the second inclusion in (1.21)), followed by restriction to Y , gives

$$\mathfrak{a}_{s+t} \subseteq \mathfrak{a}_s \mathfrak{a}_t, \quad b(s+t) \geq b(s) + b(t).$$

Moreover, $b(t) \geq 0$. For fixed $s > 0$ and $t = ks + r$ with k a nonnegative integer and $0 \leq r < s$, repeated superadditivity gives $b(t) \geq kb(s)$. Hence

$$\liminf_{t \rightarrow \infty} \frac{b(t)}{t} \geq \frac{b(s)}{s}.$$

Taking the supremum over s proves the existence of the limit and the supremum formula, with the value $+\infty$ allowed at this stage. In particular, the limit along positive integers is the same.

For every sufficiently large integer m , the restriction $u_m|_Y$ has analytic type $(1/m, \mathfrak{a}_m(u; Y))$ by Section 1.13, and therefore

$$\frac{b(m)}{m} = v((u_m|_Y) \circ \pi, E).$$

These numbers are uniformly bounded by Corollary 1.22.1, so the limit along integers, and hence the supremum, is finite. Finally, the ideals $\mathfrak{a}_t(u; Y)$ are unchanged when u is replaced by a potential with the same multiplier ideals, which proves the last assertion. $\square$

We call the function $E \mapsto \tau_{Y,u}(E)$, defined on all divisors over Y , the *divisorial trace data* of u along Y .

Inclusions of ideals give monotonicity and homogeneity of the trace data directly. For sums, subadditivity of multiplier ideals gives one inequality; for the reverse inequality, an analytic approximant of the sum controls sufficiently fine approximants of both summands.

Proposition 18.1.1 *Let $v \in \text{QPSH}(X)$ also have zero generic Lelong number along Y , and recall that $u \preceq_I v$ means $\mathcal{I}(ku) \subseteq \mathcal{I}(kv)$ for every real $k > 0$ (Section 1.12). Then, as functions on divisors over Y ,*

- (1) $u \preceq_I v$ implies $\tau_{Y,u} \geq \tau_{Y,v}$;
- (2) $\tau_{Y,au} = a\tau_{Y,u}$ for every $a > 0$;
- (3) $\tau_{Y,u+v} = \tau_{Y,u} + \tau_{Y,v}$;
- (4) $\tau_{Y,\max(u,v)} \leq \min\{\tau_{Y,u}, \tau_{Y,v}\}$.

Proof The inclusions of ideals defining $\preceq_I$ persist after restriction and reverse the vanishing orders, which proves (1). Replacing t by at in (18.1) proves (2). Moreover,

$$\mathcal{I}(tu) + \mathcal{I}(tv) \subseteq \mathcal{I}(t \max(u, v)).$$

Since the order of a sum of ideals is the minimum of their orders, restriction and passage to the limit prove (4); note that $\max(u, v)$ also has zero generic Lelong number along Y . Generic Lelong numbers of sums add, so $u + v$ has zero generic Lelong number along Y as well.

For (3), subadditivity of multiplier ideals gives $\tau_{Y,u+v} \geq \tau_{Y,u} + \tau_{Y,v}$. For the reverse inequality, fix a sufficiently large integer k and the analytic approximant S_k of $u + v$ given by Theorem 1.15.1, of analytic type $(1/k, \mathcal{I}(k(u + v)))$; that theorem gives $u + v \leq S_k$. Let U_m, V_m be the corresponding approximants of u and v . Lemma 1.17.10 gives

$$U_m + V_m \leq (1 - \delta_m)S_k + O(1), \quad \delta_m \downarrow 0.$$

Here both δ_m and the bounded error may depend on the fixed k . The restrictions of U_m, V_m and S_k to Y are not identically $-\infty$ by Corollary 1.22.1. Restricting, pulling back to a fixed modification and taking the generic Lelong number along a divisor E on it, we obtain

$$\frac{\text{ord}_E \mathfrak{a}_m(u; Y)}{m} + \frac{\text{ord}_E \mathfrak{a}_m(v; Y)}{m} \geq (1 - \delta_m) \frac{\text{ord}_E \mathfrak{a}_k(u + v; Y)}{k}.$$

Letting first $m \rightarrow \infty$, with k fixed, and then $k \rightarrow \infty$, the finite limits of Theorem 18.1.1 give the reverse inequality. $\square$

18.2 Comparison with ordinary restriction

When the restriction $u|_Y$ is not identically $-\infty$, the restriction theorem for multiplier ideals bounds the trace data by its divisorial Lelong numbers. For analytic singularities, comparison with the approximants gives the reverse inequality.

Proposition 18.2.1 *If $v = u|_Y$ is not identically $-\infty$, then*

$$\tau_{Y,u}(E) \leq v(v \circ \pi, E)$$

for every divisor E over Y . If u has analytic singularities, equality holds.

Proof The restriction theorem, which is the first inclusion in (1.21), and Lemma 1.17.7, applied on Y , give for every $t > 0$

$$\text{ord}_E \mathfrak{a}_t(u; Y) \leq \text{ord}_E \mathcal{I}(tv) \leq tv(v \circ \pi, E).$$

Divide by t and use Theorem 18.1.1.

If u has analytic singularities, apply Lemma 1.17.10 to the pair $(u, 0)$, with $s = u$, $U_m = u_m$ and $V_m = 0$. It gives

$$u_m \leq (1 - \delta_m)u + O(1), \quad \delta_m \downarrow 0.$$

Restricting to Y , pulling back by π and taking the generic Lelong number along E , we obtain, since u_m has analytic type $(1/m, \mathcal{I}(mu))$,

$$\frac{1}{m} \text{ord}_E \mathfrak{a}_m(u; Y) \geq (1 - \delta_m) v((u|_Y) \circ \pi, E).$$

Letting $m \rightarrow \infty$ proves the reverse inequality, hence equality. All the restrictions involved are quasi-plurisubharmonic, because $v(u, Y) = 0$. $\square$

The inequality can be strict, as the following local example shows. On a small bidisk in $\mathbb{C}^2$ with coordinates (z, w) , write

$$u(z, w) = \max\{-\log(-\log |z|^2), \log |w|^2\}, \quad Y = \{z = 0\}.$$

The bidisk is chosen with $|z| < e^{-1}$, and the first function is extended by $-\infty$ along $z = 0$. It is plurisubharmonic, since $s \mapsto -\log(-s)$ is increasing and convex for $s < 0$, and hence so is the maximum. For every $t > 0$,

$$e^{-tu} \leq (-\log |z|^2)^t,$$

which is locally integrable. Thus all multiplier ideals of u are trivial and the trace data vanishes, whereas $u|_Y = \log |w|^2$ has Lelong number one at the origin. This example is taken from [Xia, Example 8.1.2].

18.3 Realization on a compact curve

We return to the compact setting, and until [Section 18.6](#) we assume that Y is a curve. Since every modification of a compact smooth curve is an isomorphism, the divisors over Y are its points, and the trace data prescribes an atomic curvature measure. Stokes' theorem bounds its total mass by the degree of the background on Y , and filling the remaining mass with a smooth measure gives a positive current whose potential realizes the data.

Set

$$D_u = \sum_{p \in Y} \tau_{Y,u}(p) \delta_p,$$

where the sum is understood as the supremum of its finite subsums.

Theorem 18.3.1 *Put $M = \int_Y \theta|_Y$. Then*

$$0 \leq D_u(Y) \leq M. \quad (18.2)$$

The finite atomic measure D_u determines a canonical ordinary singularity type of quasi-plurisubharmonic functions on Y : for every smooth positive form η on Y with $\int_Y \eta = 1$, this type has a representative $v \in \text{PSH}(Y, \theta|_Y)$ with

$$\theta|_Y + \text{dd}^c v = D_u + (M - D_u(Y))\eta. \quad (18.3)$$

The extended Monge–Ampère measure of v is $(M - D_u(Y))\eta$. The ordinary type does not depend on η , on the choice of the smooth form θ with $u \in \text{PSH}(X, \theta)$, or on the choice of u within its multiplier-ideal class.

Proof For integer m let

$$D_m = \frac{1}{m} \sum_{p \in Y} \text{ord}_p \mathfrak{a}_m(u; Y) \delta_p.$$

A nonzero coherent ideal on a compact smooth curve has finitely many zeros, so this sum is finite. Since $u_m|_Y$ has analytic type $(1/m, \mathfrak{a}_m(u; Y))$, the measure D_m is the atomic part of the positive current $(\theta + \epsilon_m \omega)|_Y + \text{dd}^c(u_m|_Y)$, and Stokes' theorem on the curve gives

$$D_m(Y) \leq M + \epsilon_m \int_Y \omega|_Y.$$

For any finite subset of Y , passing to the limit in the sum of the corresponding coefficients by [Theorem 18.1.1](#), and then taking the supremum over finite subsets, gives (18.2). In particular, the positive coefficients have at most countable support and define a finite measure. Write $d = D_u(Y)$.

Choose a Green kernel G for dd^c on the curve, normalized so that

$$\text{dd}_x^c G(x, p) = \delta_p - \eta, \quad G(x, p) \leq 0.$$

Such a kernel exists: the Green kernel of the scalar Laplacian on the compact Riemann surface has, in a local coordinate z , the singularity $\log |z(x) - z(p)|^2$, it is uniformly bounded above, and $\sup_p \int_Y |G(x, p)| \eta(x) < \infty$; subtracting a constant gives the sign condition. By Fubini's theorem,

$$w(x) = \int_Y G(x, p) dD_u(p)$$

is integrable, and it is quasi-subharmonic with $dd^c w = D_u - d\eta$. Its Lelong number at every point p is the mass of D_u at p , namely $\tau_{Y,u}(p)$.

Since $M\eta - \theta|_Y$ is smooth with integral zero, the Poisson equation gives a smooth s with $dd^c s = M\eta - \theta|_Y$. Then $v = w + s$ satisfies (18.3), and the right-hand side is positive because $M \geq d$. At every atom of D_u , the positive Lelong number forces $v = -\infty$. The extended measure of v is the restriction of the current in (18.3) to the set where $v > -\infty$; this set contains no atom of D_u , and its complement is polar and therefore not charged by η . Hence the extended measure is $(M - d)\eta$.

If another smooth form η or another smooth background θ is used, the two constructed representatives have the same atomic curvature, and all other terms in their equations are smooth. Their difference therefore has smooth dd^c , so it is smooth by elliptic regularity, and in particular bounded. This proves independence of these choices at the level of ordinary types. Independence of the choice of u within its multiplier-ideal class holds because the numbers defining D_u depend only on that class. $\square$

We denote this ordinary type by $\text{Tr}_Y^{\text{at}}(u)$ and call it the *atomic trace* of u on the curve Y ; the same symbol also denotes any of its representatives. All potentials on a curve with these Lelong numbers have the same multiplier ideals, but they need not have the same ordinary type; the construction selects the type whose curvature, apart from the atoms, is a smooth measure. Additivity of the trace data (Proposition 18.1.1) and linearity of the Green operator give

$$\text{Tr}_Y^{\text{at}}(u + v) \sim \text{Tr}_Y^{\text{at}}(u) + \text{Tr}_Y^{\text{at}}(v), \quad \text{Tr}_Y^{\text{at}}(au) \sim a \text{Tr}_Y^{\text{at}}(u) \quad (a > 0).$$

Here $v \in \text{QPSH}(X)$ is any function that also has zero generic Lelong number along Y .

Keep D_m , G and w from the proof, and put $w_m = \int_Y G(\cdot, p) dD_m(p)$.

Proposition 18.3.1 *The measures D_m satisfy $D_m \leq D_u$ and converge to D_u in total variation, and they increase along dyadic indices. For a fixed nonpositive Green kernel, the potentials w_{2^j} decrease to w , and $w_m \rightarrow w$ in $L^1(Y)$. Each w_m has the ordinary singularity type of $u_m|_Y$.*

If the restriction $u|_Y$ is not identically $-\infty$, it is at least as singular as the atomic trace:

$$u|_Y \preceq \text{Tr}_Y^{\text{at}}(u).$$

If u has analytic singularities, the two are ordinarily equivalent.

Proof The supremum formula in (18.1) gives $D_m \leq D_u$ coefficient by coefficient. Since the coefficients converge and are dominated by those of the finite measure D_u , dominated convergence gives $D_m(Y) \rightarrow D_u(Y)$, and hence convergence in total variation. Superadditivity with $s = t = m$ gives $D_{2m} \geq D_m$, and since $G \leq 0$ the potentials w_{2j} decrease. Monotone convergence for $-G$ identifies their pointwise limit with w , including at poles. The uniform L^1 bound for the kernel also gives

$$\|w_m - w\|_{L^1(\eta)} \leq C\|D_m - D_u\|_{\text{TV}} \rightarrow 0.$$

Each D_m is finitely supported, and locally both w_m and $u_m|_Y$ are the sum of the logarithmic singularities prescribed by D_m and a bounded function. Thus their ordinary types agree.

If $a = u|_Y$ is not identically $-\infty$, Proposition 18.2.1 gives $v(a, p) \geq \tau_{Y,u}(p)$ at every point. Since $\text{dd}^c w = D_u - D_u(Y)\eta$, Lemma 1.17.4 implies $a \preceq w$. If u has analytic singularities, Proposition 18.2.1 identifies the finitely many logarithmic coefficients of $u|_Y$ with those of D_u , and the bounded local remainders give ordinary equivalence. $\square$

18.4 The Poisson equation in the atomic trace type

Write $d = D_u(Y)$, and let w be the Green representative above. For every $\theta|_Y$ -plurisubharmonic potential in the ordinary type of w , the part of its curvature measure carried by polar sets is D_u , and its extended measure is the remaining part, of total mass $M - d$. Prescribing the extended measure therefore amounts to solving a Poisson equation for the bounded difference from w .

Theorem 18.4.1 *Let dV be a smooth positive volume form on Y , and let $0 \leq f \in L^p(dV)$, $p > 1$, with $\int_Y f dV > 0$. There is a solution v in the atomic trace type of*

$$\text{MA}_{\theta|_Y}^{\text{ext}}(v) = cf dV, \quad c > 0,$$

if and only if $M > d$. In that case

$$c = \frac{M - d}{\int_Y f dV},$$

and v is unique up to an additive constant. If $M = d$, there is instead a potential in this type with extended measure zero, unique up to an additive constant.

Proof Assume that $M > d$, take the value of c given above, and solve

$$\text{dd}^c s = d\eta + cf dV - \theta|_Y.$$

The right-hand side has integral zero, so the elliptic L^p theory gives a solution $s \in W^{2,p}(Y)$, unique up to constants. In real dimension two, the Sobolev embedding

for $p > 1$ makes s continuous and bounded. The potential $v = w + s$ has the atomic trace type and satisfies

$$\theta|_Y + \text{dd}^c v = D_u + c f dV \geq 0.$$

Its extended measure is $c f dV$, since this absolutely continuous measure does not charge the polar set of poles, while the atoms lie in it. For $M = d$, the same construction with $c = 0$ has a smooth right-hand side and gives the asserted potential with zero extended measure.

To prove necessity and uniqueness, let a be any $\theta|_Y$ -plurisubharmonic potential in the ordinary type of w , and put $\mu = \theta|_Y + \text{dd}^c a$. By [Corollary 1.6.1](#), ordinary equivalence with w makes the polar part of μ equal to D_u . Consequently

$$\text{MA}_{\theta|_Y}^{\text{ext}}(a) = \mu - D_u, \quad \int_Y \text{MA}_{\theta|_Y}^{\text{ext}}(a) = M - d.$$

Integrating the equation therefore forces the stated value of c , so a positive c requires $M > d$. If two potentials solve the equation with the same density and constant, their curvature currents both equal $D_u + c f dV$; their difference has zero dd^c and is therefore constant on the compact connected curve. The same argument proves uniqueness in the case of zero extended measure. $\square$

18.5 Singularity distance on a curve

On the curve Y , the singularity pseudometric d_S of [\[Xia, Definition 6.2.1\]](#) measures the difference of the masses of two ordered potentials. For the Green representatives w and w_m , it is half the atomic mass missing from D_m . When X is Kähler, this identifies the atomic trace with the Kähler trace of [\[Xia, Section 8.1\]](#), up to P -equivalence, that is, up to potentials with the same singularity envelope; the distance calculation itself uses only the geometry of the curve.

Proposition 18.5.1 *Choose a smooth positive form η of integral one on Y and choose $A > D_u(Y)$ so large that every restricted approximant $u_m|_Y$ is $A\eta$ -plurisubharmonic. Define w and w_m as above, with a fixed nonpositive Green kernel. Then*

$$d_{S,A\eta}(w, u_m|_Y) = d_{S,A\eta}(w, w_m) = \frac{1}{2}(D_u(Y) - D_m(Y)) \longrightarrow 0. \quad (18.4)$$

In particular, the atomic trace has $\mathcal{I}$ -good singularities on the curve, in the sense recalled in [Chapter 15](#). If X is Kähler, the atomic trace represents the P -equivalence class of the Kähler trace.

Proof The curvature bounds of [Corollary 1.15.1](#), restricted to Y , are dominated by a single form $A\eta$ once A is large. Since $D_m \leq D_u$ and $G \leq 0$, we have $w \leq w_m$. Also

$$A\eta + \text{dd}^c w = D_u + (A - D_u(Y))\eta, \quad A\eta + \text{dd}^c w_m = D_m + (A - D_m(Y))\eta.$$

Hence their extended masses are $A - D_u(Y)$ and $A - D_m(Y)$, both positive. For $a, b \in \text{PSH}(Y, A\eta)$ with $a \leq b$, the formula for the distance of ordered potentials [Xia, Lemma 6.2.2] reads

$$d_{S, A\eta}(a, b) = \frac{1}{2} \left(\int_Y \text{MA}_{A\eta}(b) - \int_Y \text{MA}_{A\eta}(a) \right).$$

Substituting $a = w$ and $b = w_m$ proves the second equality in (18.4). Since $u_m|_Y$ and w_m are ordinarily equivalent, their distance vanishes, which proves the first equality. The convergence of D_m in total variation proves the limit.

Each w_m has finitely many logarithmic poles with rational coefficients, hence analytic singularities. The characterization in [Xia, Theorem 7.1.1], applied on the compact Kähler curve Y , shows that their d_S -limit w is $\mathcal{I}$ -good.

Finally, suppose that X is Kähler. The Kähler trace is defined in [Xia, Definition 8.1.1 and Proposition 8.1.2] through a quasi-equisingular approximation of u with analytic types $(2^{-j}, \mathcal{I}(2^j u))$, whose restriction to Y has the ordinary type of w_{2^j} . The same distance calculation shows that these restrictions converge to w for $d_{S, A\eta}$, so w represents the Kähler trace up to P -equivalence. $\square$

18.5.1 Total variation of the atomic data

The distance calculation extends to all multiplier-ideal envelopes $P_\beta[\cdot]_{\mathcal{I}}$ of Definition 15.2.1 on the curve Y . Such an envelope is determined by its atomic curvature, and the maximum of two of them has as atomic curvature the common part of the two atomic measures. The formula for the distance of ordered potentials can therefore compare envelopes whose poles are unrelated. Throughout this subsection, fix a smooth positive form β on Y , put $A = \int_Y \beta$, and choose a nonpositive Green kernel G for $\eta = \beta/A$. All atomic measures below have countable support and finite total mass.

For a positive atomic measure D with $D(Y) \leq A$, set

$$w_D(x) = \int_Y G(x, p) dD(p), \quad q_D = P_\beta[w_D]_{\mathcal{I}}.$$

As in the proof of Theorem 18.3.1, w_D is a quasi-plurisubharmonic function, not identically $-\infty$, with $\text{dd}^c w_D = D - D(Y)\eta$.

Lemma 18.5.1 *The function w_D is β -plurisubharmonic, and*

$$q_D \sim w_D, \quad \int_Y \text{MA}_\beta(q_D) = \int_Y \text{MA}_\beta(w_D) = A - D(Y).$$

The map $D \mapsto q_D$ is a bijection from the positive atomic measures of mass at most A onto the set of all envelopes $P_\beta[a]_{\mathcal{I}}$, $a \in \text{PSH}(Y, \beta)$, and q_D has positive mass exactly when $D(Y) < A$. The measure D is the atomic part of $\beta + \text{dd}^c q_D$.

Proof One has

$$\beta + \text{dd}^c w_D = D + (A - D(Y))\eta \geq 0.$$

Every atom of D is a pole of w_D , and the smooth measure η charges no polar set, including any additional poles caused by accumulation of the atoms. Hence $\text{MA}_\beta(w_D) = (A - D(Y))\eta$.

Put $q = q_D$. By [Theorem 15.2.1](#), q has the same multiplier ideals, and hence the same Lelong numbers at points, as w_D . Applied to $\text{dd}^c w_D = D - D(Y)\eta$, [Lemma 1.17.4](#) gives $q \preceq w_D$, and the envelope inequality $q \geq w_D - \sup_Y w_D$ proves $q \sim w_D$. By [Corollary 1.6.1](#), the polar part of $\beta + \text{dd}^c q$ is therefore also D , and Stokes' theorem gives the non-pluripolar mass $A - D(Y)$.

For any $a \in \text{PSH}(Y, \beta)$, its Lelong numbers at points give an atomic measure D_a of mass at most A . On a smooth curve these numbers determine all multiplier ideals, by [Theorem 1.16.1](#). Thus $a \sim_I w_{D_a}$, so $P_\beta[a]_I = q_{D_a}$. If $D_a(Y) = A$, the atoms exhaust the whole curvature measure, and the non-pluripolar mass is zero. This proves surjectivity and the description of the potentials of positive mass. Distinct atomic measures give distinct Lelong numbers, which proves injectivity. $\square$

Theorem 18.5.1 *For positive atomic measures D, E with masses less than A ,*

$$\frac{1}{96} \|D - E\|_{\text{TV}} \leq d_{S, \beta}(q_D, q_E) \leq \frac{1}{2} \|D - E\|_{\text{TV}}.$$

Thus the singularity distance is a metric on these ideal envelopes, and convergence for it is exactly convergence of the atomic measures in total variation.

Proof Write $d_S = d_{S, \beta}$ and $a \vee b = \max(a, b)$. For potentials $u, v \in \text{PSH}(Y, \beta)$ of positive mass, besides the formula for ordered potentials we use the inequality [[Xia](#), Lemma 6.2.1]

$$d_S(u, v) \leq d_S(u, u \vee v) + d_S(v, u \vee v) \leq 48 d_S(u, v)$$

on a curve; here $48 = 3(1 + 1)2^{1+2}$ is the constant of that lemma in dimension one.

Put $z = \max(w_D, w_E)$. By [Lemma 18.5.1](#), the polar parts of the curvature measures of w_D and w_E are D and E . By [\(1.8\)](#), the polar part of the curvature measure of z is $D \wedge E$, the atomic measure with the smaller coefficient at each point. Stokes' theorem therefore gives

$$\text{MA}_\beta(z)(Y) = A - (D \wedge E)(Y).$$

The formula for ordered potentials yields

$$\begin{aligned} d_S(w_D, z) + d_S(w_E, z) &= \frac{1}{2} (D(Y) + E(Y) - 2(D \wedge E)(Y)) \\ &= \frac{1}{2} \|D - E\|_{\text{TV}}. \end{aligned}$$

Combining this equality with the two inequalities above proves both bounds, since replacing w_D, w_E by the ordinarily equivalent q_D, q_E does not change the singularity

distance. The lower bound and the injectivity in [Lemma 18.5.1](#) make the pseudometric a metric on these envelopes. $\square$

Corollary 18.5.1 *For $0 < \varepsilon < A$, the normalized ideal envelopes satisfying $\text{MA}_\beta(q)(Y) \geq \varepsilon$ form a complete space for $d_{S,\beta}$. Analytic ideal envelopes are dense in this space. The space is not totally bounded.*

Proof By [Lemma 18.5.1](#), the space corresponds to the positive atomic measures of mass at most $A - \varepsilon$. This set is complete for total variation. Indeed, a Cauchy sequence has as limit a positive finite measure with the same mass bound. The union of the countable supports of the sequence is countable, and total-variation convergence shows that the limit gives zero mass to the complement of that union, so the limit is again atomic. The two metric estimates of [Theorem 18.5.1](#) transfer completeness to the ideal envelopes.

Finite truncation, followed by rational approximation of each coefficient from below, preserves the mass bound and converges in total variation. The resulting Green potentials have finitely many logarithmic poles with rational coefficients, and their ideal envelopes have the same ordinary types by [Lemma 18.5.1](#). These envelopes therefore have analytic singularities, and the upper metric estimate proves density.

Finally, fix $0 < a < A - \varepsilon$. The measures $a\delta_p$, for distinct $p \in Y$, have pairwise total-variation distance $2a$, so their ideal envelopes have pairwise d_S distance at least $a/48$. This infinite separated family rules out total boundedness. $\square$

This topology differs from the one given by the L^1 metric on ideal envelopes of [Proposition 15.4.1](#), since that metric is totally bounded. The sequence in [Proposition 15.4.2](#) makes the difference quantitative: it converges for that L^1 metric while remaining at a fixed positive d_S distance from its limit.

18.6 The trace envelope
